Abstract. We measured sub-surface heat fluxes and calculated the energy budget of the coarse blocky active layer (AL) of Murtèl rock glacier, a seasonally snow-covered permafrost landform located in the eastern Swiss Alps. In the highly permeable AL, conductive/diffusive heat transfer, including thermal radiation, non-conductive heat transfer by air circulation (convection), and heat storage changes from seasonal build-up and melting of ground ice, shapes the ground thermal regime. Individual heat fluxes are quantified based on a novel in situ sensor array in the AL (operational from 2020-2023) and direct observations of the ground ice melt (in thaw seasons 2022–2024). The AL energy budget yields the first field-data-based quantitative estimate of the climate sensitivity of rock glaciers. The total Murtèl AL heat uptake during the thaw season has been increasing by 4- 10 MJ m^{-2} per decade (4 %–11 % of the 2022 heat uptake of 94 MJ m⁻²), driven by earlier snow melt-out in June and increasingly hot and dry July-September periods. Two thaw-season processes render Murtèl rock glacier comparatively climate-robust. First, the AL intercepts $\sim 70\%$ (55–85 MJ m⁻²) of the thaw-season ground heat flux by melting ground ice that runs off as meltwater, $\sim 20\%$ (10–20 MJ m⁻²) is spent on heating the blocks, and only $\sim 10\%$ (7–13 MJ m⁻²) is transferred into the permafrost body beneath and causes slow permafrost degradation. Second, the effective thermal conductivity in the ventilated AL increases from $1.2 \text{ W m}^{-1} \text{ K}^{-1}$ under strongly stable temperature gradients (weak warming) to episodically over $10 \,\mathrm{Wm^{-1}K^{-1}}$ under unstable temperature gradients (strong cooling), favouring convective cooling by buoyancy-driven Rayleigh ventilation (thermal semiconductor effect). In winter, radiatively cooled air infiltrating through a discontinuous, semi-closed snow cover leads to strong AL cooling. The two characteristic parameters (effective thermal conductivity and intrinsic permeability) are sensitive to debris texture; hence the two undercooling processes are specific to highly permeable coarse blocky material.

1 Introduction

The deglaciating high mountains under climate change are now entering a transient phase characterised by strong disequilibria between cryospheric landscape components of differing climate sensitivity and adjustment timescales (Haeberli et al., 2017). Declining seasonal snowpacks (Gottlieb and Mankin, 2024) and vanishing glaciers (Hugonnet et al., 2021) react sensitively and rapidly to the ongoing climatic changes, while shifting vegetation patterns (Körner and Hiltbrunner, 2024) and permafrost warming and degradation (Biskaborn et al., 2019) lag behind. Emerging hazard chains and an altered high-mountain water cycle put ecosystems and communities in mountain areas and downstream lowlands under pressure to adapt (and perhaps to mitigate) (Hock et al., 2022; Hayashi, 2020). In the mountain cryosphere, icerich permafrost landforms overlain by a thick, coarse blocky debris layer stand out as the least sensitive, i.e. most robust, landforms, appearing as rock glaciers (Haeberli et al., 2006) and frozen talus slopes (Delaloye and Lambiel, 2005) that have been responding slowly to climate change. Note that we use the term "robust" in the sense of "climate-insensitive" (Schaffer and MacDonell, 2022) or "resistant to changes", which is one aspect of resilience (Walker et al., 2004; Jorgenson et al., 2010).

Coarse blocky landforms benefit from specific processes that occur in the clast-supported coarse debris (decimetresized blocks, sparse fine material), collectively known as undercooling processes (Wakonigg, 1996; Rist et al., 2003). Undercooling locally creates a stable ground thermal regime (microclimate) that is typically 1-5 °C colder than the surrounding fine-grained or bedrock terrain (Gorbunov et al., 2004; Harris et al., 1998) and can preserve permafrost conditions under otherwise unfavourable topo-climatic conditions (azonal permafrost) (Morard et al., 2010; Wicky and Hauck, 2020; Wicky et al., 2024). The effect of undercooling has been known for a long time from field investigations (Bächler, 1930; Wakonigg, 1996; Harris and Pedersen, 1998; Kneisel et al., 2000; Gorbunov et al., 2004; Delaloye and Lambiel, 2005; Sawada et al., 2003; Delaloye and Lambiel, 2005; Herz, 2006; Millar et al., 2014; Popescu et al., 2017b; Wagner et al., 2019) and arises from an interplay of several heat transfer and storage processes in a permeable buffer layer between the ground and atmosphere or seasonal snow cover (Johansen, 1975; Wakonigg, 1996). Exact processes have long remained elusive. Undercooling is specific to coarse blocky landforms that exhibit a high permeability, pointing at the key role of non-conductive heat transfer by airflow and ice build-up. Climate change has brought these "cold spots", once known as local curiosities (Balch, 1900; Bächler, 1930; Trüssel, 2013), to the attention of scientists (e.g. hydrologists (Schaffer et al., 2019; Schaffer and MacDonell, 2022; Navarro et al., 2023) and ecologists (Růžička et al., 2012)) and engineers (e.g. artificial passive ground cooling, Guodong, 2005). By storing frozen and liquid water at seasonal timescales (Jones et al., 2019; Wagner et al., 2021), the hydrological buffer capacity of undercooled permafrost landforms will increasingly contribute to reliable baseflow during droughts, sustaining "icy seeps" (Tronstad et al., 2016) and wet meadows (Reato et al., 2021), which are refugia for cold-adapted species (Millar et al., 2015; Brighenti et al., 2021). Nonetheless, despite the cold microclimate within their active layer (AL), even these robust undercooled permafrost landforms are not exempt from slow degradation, as exemplarily shown by the Alpine-wide warming (Noetzli and Pellet, 2023), ice loss (Morard et al., 2024), synchronous acceleration (Delaloye et al., 2010; Kellerer-Pirklbauer and Kaufmann, 2012), and in some cases destabilisation (Roer et al., 2008; Marcer et al., 2021; Hartl et al., 2023) of rock glaciers. As our mountains enter uncharted territory, site-specific empirical relations might become invalid. We need quantitative process understanding to anticipate the changes.

On Murtèl rock glacier (Engadine, south-eastern Swiss Alps), undercooling heat transfer processes have been investigated for decades. Large seasonal deviations of the estimated surface energy balance (SEB) were attributed to unmeasured and insufficiently represented non-conductive subsurface heat transfer processes in the AL (Hoelzle et al., 1999, 2001; Mittaz et al., 2000). The first field studies dedicated to the sub-surface (AL) heat transfer processes have been published by Hanson and Hoelzle (2004, 2005) based on their temperature measurements in the uppermost 90 cm of the AL and previous works (Oswald, 2004; Naguel, 1998). Important insights into the near-surface AL heat transfer processes and interaction with the snow cover have been gained, but the quantitative understanding was insufficient to reliably estimate heat fluxes. The thermal characterisation of the coarse blocky material with geophysical methods (electrical resistivity tomography, refraction seismic tomography) has been another important step towards AL heat transfer modelling (Schneider et al., 2012, 2013) and has been carried out by Scherler et al. (2014). Air circulation and convective heat transfer, long suspected to be the primary heat transfer process to shape the thermal regime in highly permeable coarse blocky debris, have been investigated in the field by Oswald (2004), Panz (2008), and Schneider (2014) and studied numerically by Wicky and Hauck (2017, 2020). In parallel, another important field study on the micro-climate of coarse blocky scree has been carried out by Herz et al. (2003a, b) and Herz (2006) in the Matter Valley (western Swiss Alps). They have described the heat transfer processes in detail and estimated heat fluxes and the thermal diffusivity but due to the lack of appropriate measurements could not verify them. One of the few comprehensive data sets beyond ground temperatures in mountain permafrost has been gathered by Rist and Phillips (2005) and Rist (2007). They deployed a heat flux plate, ultrasound probes, conductometers, vapour traps, and reflectometer probes to characterise the ground hydro-thermal regime of a steep, permafrostunderlain scree slope. To summarise, several heat transfer processes have been successfully simulated separately, for example buoyancy-driven air circulation (Wicky and Hauck, 2017, 2020), purely conductive processes from the interplay between a low-conductivity ground and snow cover (Gruber and Hoelzle, 2008), or the interplay between sensible and latent heat storage (Renette et al., 2023). However, few microclimatological studies have attempted to simultaneously parametrise all heat fluxes (Mittaz et al., 2000; Hoelzle et al., 2001, 2003; Stocker-Mittaz et al., 2002; Hoelzle and Gruber, 2008; Scherler et al., 2014), and few comprehensive subsurface hydro-thermal measurements beyond ground temperatures exist in blocky mountain permafrost (Rist et al., 2003; Rist and Phillips, 2005). Also, AL properties like the thermal conductivity are poorly investigated for such coarse blocky material as that on Murtèl, where individual blocks have volumes of $\sim 0.1 \text{ m}^3$ (up to $1-10 \text{ m}^3$). Lacking better knowledge, empirical engineering relations developed for sand or gravel have often been extrapolated to such large blocks. Without in situ data, it is unclear whether such extrapolations are valid.

This work, a follow-up study of Amschwand et al. (2024), where we estimated the SEB, contributes to the quantitative process understanding of heat transfer in the AL of an undercooled, ventilated coarse blocky permafrost landform by presenting a unique data set gained from in situ measurements on Murtèl rock glacier. Our virtually unparalleled sub-surface measurements (except Rist and Phillips, 2005, to our knowledge) in the natural openings between the coarse blocks go beyond common ground temperature recordings and include humidity, airflow speed, thermal radiation, direct heat flux measurements, and stake measurements of the seasonally falling and rising ground ice table in the coarse blocky AL. We quantitatively describe the two main processes that give rise to the undercooling effect of permeable coarse blocky landforms, namely (i) seasonal build-up and melt of ground ice (seasonal ice turnover) and (ii) convective heat transfer (thermal semiconductor effect; Guodong et al., 2007). We constrain heat fluxes and heat transfer parameters (effective thermal conductivity) that can be carried into numerical permafrost models. Hence, this work provides insights into the capability and limits of the undercooling effect and the climate robustness of coarse blocky landforms.

2 Study site

The studied Murtèl rock glacier (WGS 84: $46^{\circ}25'47''$ N, $9^{\circ}49'15''$ E; CH1903+/LV95: 2783 080, 1144 820; 2620–2700 m a.s.l.; Fig. 1) is located in a north-facing periglacial area of Piz Corvatsch in the upper Engadine, a continental, rain-shadowed high valley in the eastern Swiss Alps. The mean annual air temperature (MAAT) is $-1.7 \,^{\circ}$ C, and the mean annual precipitation is $\sim 900 \,$ mm (Scherler et al., 2014). The tongue-shaped, single-unit (monomorphic sensu;

Figure 1. Location of Murtèl rock glacier in the upper Engadine, a high valley in the eastern Swiss Alps (projection: LV95 Swiss coordinate system). Inset map: location and extent (black rectangle) of regional map within Switzerland (source: Swiss Federal Office of Topography swisstopo). Red northing and latitude lines correspond to the main and inset map, respectively.

Frauenfelder and Kääb, 2000), active rock glacier is surrounded by steep rock faces and is in direct connection with a talus slope (2700–2850 m a.s.l.) that is \sim 250 m long and \sim 150 m wide and advances slowly onto a permafrost-free, vegetated forefield thinly covered by glacial sediments (till veneer, few large boulders) (Schneider et al., 2013). Murtèl is located at the lower permafrost margin. Crescent-shaped furrows (\sim 3–5 m deep) and ridges with steep, in places near-vertical slopes dissect the overall gently north-northwestward-dipping surface ($\sim 10-12^\circ$, $< 15^\circ$; Guodong et al., 2007) and create a pronounced furrow-and-ridge microtopography in the lowermost part of the rock glacier (Kääb et al., 1998). The snow cover is thicker and lasts longer in furrows than on ridges, influencing the ground thermal regime on a small scale (Bernhard et al., 1998; Keller and Gubler, 1993; Hoelzle et al., 2003). In the colder furrows, the otherwise 3-5 m thick, coarse-grained and clast-supported debris mantle is only ~ 2 m thick. The ground ice table is accessible in a few places.

The stratigraphy to a depth of 60 m is known from several boreholes (Vonder Mühll and Haeberli, 1990; Vonder Mühll, 1996; Arenson et al., 2002, 2010). The coarse blocky AL is 3 m thick on average (2–5 m) and consists of large blocks typically with edge lengths of 0.1 to 2 m (Scherler et al., 2014). A few boulders reach dimensions of $\sim 3-5$ m. Fine material (\leq sand) is sparse near the surface, but its volume fraction varies laterally and increases with depth (inverse grading; Haeberli et al., 2006). The AL has a poor water retention capacity. Supra-permafrost water drains within hours to days at the AL base (Tenthorey and Gerber, 1991) and is not considered to significantly modify the ground thermal properties. The vast, connected pores create a high intrinsic permeability

(Wicky and Hauck, 2020). Beneath the coarse blocky debris mantle, roughly coinciding with the thermally defined AL, lies the perennially frozen ice-supersaturated rock glacier core. Drill cores have revealed sand- and silt-bearing massive ice (3–28 m depth, ice content over 90 % vol.), although boreholes drilled within \sim 30 m distance suggest some lateral small-scale heterogeneity (Vonder Mühll and Haeberli, 1990; Arenson et al., 2010).

3 Measurements and data processing

3.1 Field observations and instrumentation

We use measurements from the PERMA-XT sensor cluster presented in Amschwand et al. (2024), where the abovesurface sensors are described. Most of the below-surface sensors were installed in one natural cavity of the coarse blocky AL that was large enough for a human to enter and deep enough to come close to the AL base (Figs. 2, 3). This instrumented main cavity was completely destroyed by rockfall on 20 September 2023. A narrow passage covered by a large block ("lid") leads into a spacious "main chamber", with its "floor" at 2m depth. A narrow extension reached a depth of 3m. Its base was covered by wet, fine material (gravel, sand). The cavity in the clast-supported coarse blocky AL was enclosed by large blocks with voids in between, allowing air circulation. In August 2020, this comparatively large cavity (dimensions $\sim 2 \times 1.5 \times 3$ m) was instrumented with sensors to measure the temperature, humidity, thermal radiation, heat flux, and AL airflow speed at several depths down to 3 m. Detailed sensor specifications of the sub-surface sensors are given in Table 1, and the locations are shown in Fig. 3 and Table 2. One thermistor string was suspended in air (TK1), and another one (TK6) had its five thermistors drilled 5cm into the blocks at depths corresponding to the TK1 thermistors. Relative humidity was measured at two levels, 0.7 (HV5/1) and 2.0 m (HV5/2) beneath the surface. Three thermo-anemometers recorded wind speed at three levels: close to the surface (WS/3 at -0.35 m), mid-cavity (WS/2 at -1.5 m), and in a narrow extension at depth (WS/1 at -2.1 m). A back-to-back pair of pyrgeometers mounted at mid-cavity level (CGR3 at -1.55 m) measured the upward and downward thermal radiation in the cavity. Two heat flux plates were cemented onto the rock surface, one at the underside of a near-surface block (HFP/2 at -1.1 m), another one on the cavity "floor" (HFP/1 at -2.0 m). Since accurate distances are required for the calculation of vertical gradients and fluxes, we triangulated the relative height of the sensors in the instrumented cavity with a Leica DISTO X310 laser distance meter and goniometer.

Additional thermistor strings and thermo-anemometers were installed in the vicinity at different micro-topographical locations to reveal the spatial pattern of temperature and airflow. One additional thermo-anemometer was installed in a similar cavity 20m away (WS/4), together with another airsuspended thermistor string (TK5), one near the surface beneath a wind-swept large block on a ridge (WS/5, "wind hole") and one near the surface in a nearby rock glacier furrow (WS/6). The sub-surface sensor array is completed by 10 autonomous miniature temperature loggers (UTL; Table 1) distributed on the rock glacier to determine the variability in the near-surface ground temperature.

We measured the seasonal ice turnover directly with stake measurements inside the coarse blocky AL. The ground ice is accessible at a few spots at shallow depths of 1-2 m b.g.l. (below ground level), all located in furrows where the AL is thinner. In one spot, a plastic tube was drilled ca. 120 cm into the ice in August 2009 but subsequently abandoned (Christin Hilbich, personal communication, 2022). We made serendipitous use of it as an "ablation stake", manually measuring the height of the ground ice table at each field visit in summer 2022. One nearby autonomous miniature temperature logger (UTL no. 2735; Fig. 2) measures a near-surface ground temperature $\sim 0.5 \text{ m b.g.l.}$

Additionally, we use borehole temperature data provided by the Swiss Permafrost Monitoring Network (PERMOS) for basal conductive heat flux from the rock glacier core and point-wise surface radiation data from the PERMOS automatic weather station (Noetzli et al., 2019).

3.2 Data processing

We analyse the data of 2 years, from 1 September 2020 to 30 September 2022. The above-surface sensors and the corresponding data processing (air temperature, relative humidity, precipitation, snow height) are described in Amschwand et al. (2024). The (measurement or meteorological) variables, parameters, and constants used are tabulated in Table G1.

3.2.1 Sub-surface thermal radiation

The net radiative flux in the AL Q_{CGR3}^{rad} is calculated from the thermal (long-wave/thermal infrared) radiation of a back-toback pyrgeometer pair installed in the instrumented cavity (Amschwand et al., 2024),

$$Q_{\text{CGR3}}^{\text{rad}} = (L_{\text{al}}^{\downarrow} - L_{\text{al}}^{\uparrow}) \tag{1}$$

as the difference between the upwards L_{al}^{\uparrow} and downwards L_{al}^{\downarrow} thermal radiation components. The raw outputs $L_{raw}^{\uparrow/\downarrow}$ of the two pyrgeometers in the instrumented cavity are corrected by accounting for the thermal radiation emitted by the instruments themselves (Kipp & Zonen CGR3 manual, 2014) as in Amschwand et al. (2024):

$$L_{\rm al}^{\uparrow/\downarrow} = L_{\rm raw}^{\uparrow/\downarrow} + \sigma T_{\rm CGR3}^4, \tag{2}$$

with the pyrgeometers' housing temperature T_{CGR3} . Large (> 0.5 °C) or rapid changes in the housing temperature differences between the back-to-back-mounted pyrgeometers

Figure 2. Oblique aerial view of the Murtèl rock glacier (foreground) and location of the above-surface sensors and the ground ice observations in the rock glacier furrow.

hint at dust or water deposition on the upward-facing pyrgeometer window. Such disturbed measurements showed up in the high-resolution (10 min) data but did not significantly affect the daily thermal net radiation balance in the sheltered cavity.

3.2.2 Sub-surface airflow speed

We refer to the sub-surface "wind" in the permeable AL as "airflow" to differentiate it from the atmospheric wind. Mea-

surements of an airflow speed proxy in the AL pore space were performed with six Hukseflux TP01 sensors (formerly WS01; Table 1) consisting of a heated foil that measures the cooling rate, expressed as a heat transfer coefficient $h_{\rm WS}$ [W m⁻² K⁻¹]. One measurement cycle takes 1 min and consists of three measurements to detect any offset: one initial measurement before heating, one at 30 s, and a final one after cool-down at 60 s. The heat transfer coefficient $h_{\rm WS}$ is related to airflow speed via $u_{\rm WS} = (h_{\rm WS} - 5)/4$. This empirical linearised relation is valid with reasonable accuracy for airflow speeds in the range of $0.1-2 \text{ m s}^{-1}$ (Hukseflux WS01 manual, 2006). The TP01 sensor does not resolve the direction of the airflow. The deviation of the linearised relation from the common engineering relation $\text{Nu} := hL/k_a = 0.6 \text{ Re}^{0.5}$ (Schuepp, 1993) is within $0.2 \,\mathrm{m \, s^{-1}}$ for $u_{\rm WS} < 0.6 \,\mathrm{m \, s^{-1}}$. Hence, the measurements are qualitative rather than absolute. Although the foils were oriented parallel to the dominant airflow direction that can be expected from the local cavity geometry, any airflow perpendicular to the foil creates turbulence that affects the heat transfer efficiency. At very low wind speeds or if the sensor is much warmer than the surrounding air, buoyancy effects become important relative to forced convection and disturb the airflow speed measurement (increases h_{WS}). Also, deposition and evaporation of liquid water can disturb the measurements (increases $h_{\rm WS}$), as was revealed by wrapping the heated foils in moist tissues. WS measurements during precipitation events at shallow levels, where water may infiltrate, are discarded. Repeated zeropoint checks were performed throughout the snow-free season by enclosing the heated foil in small and dry plastic bags for a few hours, ensuring stagnant conditions with zero airflow speed. Neither a drift nor a temperature dependency beyond the measurement uncertainty was detected.

3.2.3 Heat flux plates

Unlike the CGR3 that measures only thermal radiation, the HFP measures the heat flux across the disc-shaped sensor without discriminating between different heat transfer processes. A limitation is that the small-scale local HFP measurements (sensing area of $8 \times 10^{-4} \text{ m}^2$) might not be as representative of the average vertical AL fluxes as the CGR3 measurements that hemispherically integrate over the inner cavity surface ("REV uncertainty"). Furthermore, the heat flux plate (HFP) itself adds additional resistance to the heat flow from the rock slab interior to the cavity ("resistance error", Hukseflux HFP manual, 2016), which is within 20% and sufficient in our context, given the field conditions and the REV uncertainty. The heat flux plates are cemented onto the block surface to avoid air gaps and to minimise the contact resistance. We assess the resistance error by conceptualising the heat flow through the block and the HFP into the open cavity as resistances in series. The total resistance R_{tot} is the sum of the conductive resistance in the rock slab within a "zone of influence" of the HFP given by the sensor diameter $d_{\rm HFP}$, $R_{\rm r} = d_{\rm HFP}/k_{\rm r} \approx 80 \times 10^{-3} \,{\rm m}/2.5 \,{\rm W}\,{\rm m}^{-1}\,{\rm K}^{-1}$; the HFP resistance $R_{\rm HFP} = 71 \times 10^{-4} \,\rm K \,m^2 \,W^{-1}$; and the interfacial radiative-convective resistance R_s between the rock surface and the cavity, i.e. $R_{tot} = R_r + R_{HFP} + R_s$. An upper bound for R_s is the stagnant (no convection), radiationonly inverse heat transfer coefficient $1/h_{\rm rad} = (4\varepsilon\sigma\overline{T}^3)^{-1} \approx$ $1/5 \,\mathrm{K} \,\mathrm{m}^2 \,\mathrm{W}^{-1}$ ($\varepsilon \approx 1$). Hence, the HFP is the least resistive link of the heat transfer chain.

4 Parameterisations and heat flux modelling

4.1 Heat transfer and air circulation

Heat is transferred by three basic modes - convection/advection by moving fluid parcels (air/water), the emission/absorption of electromagnetic (thermal infrared) radiation, and thermal conduction by molecular interaction - whose dominance in unfrozen (excluding latent heat effects) porous materials such as soils under field conditions is controlled by debris texture (characteristic particle size) and water content (degree of saturation) (Johansen, 1975). These heat transfer modes combined result in the ground heat flux $Q_{\rm G}$ (Eq. 4). In coarse debris far from water saturation, the most important heat transfer modes are air convection, heat carried by air circulation, and thermal radiation (Q_r) , radiative heat transfer between blocks of different temperatures by electromagnetic waves that travel across the pore space (Fillion et al., 2011). Heat advection by intercepted rainfall that percolates to the ground ice table results in a small rain heat flux Q_{Pr} (part of $Q_{\rm G}$ in Eq. 4). Heat conduction alone compared to radiation is considered negligible in the coarse blocky AL because the contact areas between the blocks are too small in the clastsupported debris (see Esence et al., 2017) but transfers the heat within the blocks and also in the permafrost body beneath the AL, Q_{PF} (Scherler et al., 2014; Schneider, 2014). Hence, we conceptualise conductive heat transfer within the blocks and radiative heat transfer between the blocks as a heat transfer chain in series and denote it as conductiveradiative. We outline a simple heat transfer model in terms of a thermal resistance circuit in Appendix A.

Furthermore, it is useful to differentiate two types/modes of air convection according to the driving force: (i) buoyancy-driven and (ii) forced convection (Nield and Bejan, 2017). Buoyancy-driven convection refers to air set in motion by air density instabilities within the coarse blocky AL, i.e. when denser (~colder, drier) air is on top of lighter (~warmer, more moist) air and is driven by gravity. The entire unstable air column is set in motion. It exerts a cooling effect: comparatively colder air sinks into the coarse blocky AL, displaces the warmer air, and subsequently impedes the penetration of warmer air. Warmer air is evacuated rapidly (Balch effect or thermal semiconductor effect). The vigour of buoyancy-driven convection in a porous medium is a function of the Rayleigh–Darcy number Ra defined as (Nield and Bejan, 2017; Johansen, 1975; Kane et al., 2001; Herz, 2006; Côté et al., 2011; Wicky and Hauck, 2020)

$$Ra := \frac{\rho_{\rm a}C_{\rm p}}{k_{\rm eff}^0} \frac{g\beta_{\rm a}Kh_{\rm al}\Delta T_{\rm a}}{(\mu_{\rm a}/\rho_{\rm a})},\tag{3}$$

where ρ_a is the air density [kg m⁻³], C_p the isobaric specific heat capacity [Jkg⁻¹K⁻¹], k_{eff}^0 the stagnant (absence of convection) bulk thermal conductivity of the AL [Wm⁻¹K⁻¹], $\beta_a \approx 1/T_0$ the thermal expansion coefficient (273 K)⁻¹, *K* the intrinsic AL permeability estimated with the Kozeny– Carman equation $(2 \times 10^{-5} \text{ m}^2; \text{Eq. D1}; \text{Herz, } 2006; \text{Côté et}$ al., 2011; Wicky and Hauck, 2020), hal the AL layer thickness [m], ΔT the temperature difference across the AL [K or °C], μ_a the air dynamic viscosity [Pas], and g the gravitational acceleration (9.81 m s⁻²). Buoyancy-driven convection can be expected when Ra exceeds a threshold value (critical Rayleigh number Ra_c), commonly given as 27 in open voids or 40 beneath a snow cover. Wind-forced convection or continuous air exchange with the atmosphere (Humlum, 1997; Harris and Pedersen, 1998; Kane et al., 2001; Juliussen and Humlum, 2008) refers to air set in motion by external wind, i.e. at the ground surface. Wind gusts propagating into the permeable AL (shear flow, momentum diffusion by rough surface) lead to forced mechanical mixing. It can rapidly cool or warm the ground, depending on the air temperature relative to the ground temperature. Mixing is strongest near the surface and decreases with depth as a function of permeability and AL air density gradient. Low permeability and stable air density gradients oppose forced mixing, limiting its reach to a near-surface sub-layer of the AL. In contrast, high permeability and a labile, (near-)isothermal air column favour mixing to greater AL depths (Evatt et al., 2015). A labile, (near-)isothermal air column is most easily mixed.

4.2 Energy budget of the Murtèl coarse blocky active layer (AL)

The ground heat flux Q_G and the rain heat flux Q_{Pr} [W m⁻²] from the ground surface downwards into the coarse blocky AL are spent on warming the debris ΔH_{al}^{θ} (sensible heat storage changes), melting ground ice in the AL Q_m (latent heat storage changes), and conducted into the permafrost body beneath Q_{PF} ("permafrost heat flux") (see Hayashi et al., 2007; Woo and Xia, 1996),

$$(Q_{\rm G} + Q_{\rm Pr}) - (\Delta H_{\rm al}^{\theta} + Q_{\rm m} + Q_{\rm PF}) = 0 \, [{\rm W} \, {\rm m}^{-2}].$$
(4)

The fluxes are counted as positive if they provide energy to the reference volume, the AL. We use different approaches to independently estimate each term in Eq. (4) (Sect. 4.3) and compare with direct measurements (Sect. 3.2.1, 3.2.3).

4.3 Heat flux estimations

4.3.1 Ground surface heat flux $Q_{\rm G}$

The ground heat flux at the surface, Q_G , is estimated using the measured thermal net radiation Q_{CGR3}^{rad} extrapolated to the surface by the transient heat storage in the layer between the surface and pyrgeometers' depth. Details are in Amschwand et al. (2024).

4.3.2 Rain heat flux QPr

The flux of infiltrating rainwater $r \, [m^3 m^{-2} s^{-1}]$ is the intercepted rainwater (from the rain gauge data) that rapidly

percolates to the ground ice table and is cooled from the initial precipitation temperature T_{Pr} to 0 °C (at the most) (Sakai et al., 2004; Hayashi et al., 2007). It releases a sensible heat flux

$$Q_{\rm Pr} = C_{\rm w} r (T_{\rm Pr} - 0^{\circ} {\rm C}), \text{ if } h_{\rm S} = 0, \ T_{\rm wb} \ge 2^{\circ} C,$$
 (5)

with the volumetric heat capacity $C_w = \rho_w c_w [10^3 \text{ kg m}^{-3} \times 4.2 \text{ kJ kg}^{-1} \text{ K}^{-1}]$ and snow height h_S [m]. As a conservative estimate, the rainwater is assumed to be cooled from surface temperature $T_{\text{Pr}} := T_s$ to the freezing point. Precipitation data are taken from the on-site rain gauge, assuming that precipitation is liquid based on a threshold air temperature of $T_{wb} = 2 \text{ °C}$ (Amschwand et al., 2024). Upslope-flowing water contributions to the rock glacier and liquid precipitation falling into the snowpack are not accounted for (no reliable precipitation measurements from snow-covered rain gauge).

4.3.3 Sensible heat storage changes ΔH_{al}^{θ}

The sensible heat ΔH_{al}^{θ} stored/released by temperature changes in the blocks are estimated using the calorimetric method based on AL temperatures via (Amschwand et al., 2024)

$$\Delta H_{\rm al}^{\theta} = \int_{-h_{\rm al}}^{0} \frac{\mathrm{d}}{\mathrm{d}t} \{ (1 - \phi_{\rm al}) \rho_{\rm r} c_{\rm r} T_{\rm r}(z) \} \,\mathrm{d}z \approx (1 - \phi_{\rm al})$$
$$\frac{\langle \rho_{\rm r} c_{\rm r} \rangle}{\Delta t_{\rm r}} \sum_{i} \{ \langle \overline{T}_{\rm a}(z_{i}, t + \Delta t_{\rm r}) \rangle - \langle \overline{T}_{a}(z_{i}, t) \rangle \} \Delta z_{i}, \tag{6}$$

with $h_{\rm al} = 3 \,\mathrm{m}$ the AL thickness; $\rho_{\rm r}$ the rock density $(2690 \text{ kg m}^{-3}; \text{ Corvatsch granodiorite, Schneider, 2014}); c_r$ the specific heat capacity $(790 \, \text{Jkg}^{-1} \, \text{K}^{-1})$; AL porosity $\phi_{al} = 0.4$ (Scherler et al., 2014); and $T_r(z)$ and $T_a(z)$ the vertical rock and in-cavity air temperature profile [°C], respectively. In practice, we use the AL temperature T_{al} [°C] as measured by the thermistor string TK1 hanging in air (Tables 1 and 2) and integrate over timescales where local thermal equilibrium (LTE) holds (discussed in Appendix A). In the discretised formulation, the temperatures $\langle T(z_i) \rangle$ are layer-wise averages in the *i*th layer with thickness Δz_i (denoted by $\langle \cdot \rangle$), derived from the thermistor string TK1/1 and the radiometric surface temperature T_s . Since AL water contents are always low enough not to significantly influence the heat capacity, $C_v = (1 - \phi_{al})\rho_r c_r$ is a time-invariant, fixed AL thermal property (Scherler et al., 2014).

4.3.4 Ground ice melt heat flux dev_{al} , Q_m

The latent heat consumed by melting ground ice is estimated from the deviation of the AL budget (Eq. 4), i.e. the residual $dev_{al} := Q_G + Q_{Pr} - |Q_{PF}|$, as well as using the stake measurements (denoted as Q_m) via

$$Q_{\rm m} = f_i L_{\rm m} \rho_{\rm i} \frac{\mathrm{d}\zeta}{\mathrm{d}t},\tag{7}$$

where ζ is the observed depth of the ground ice table [m]; f_i [-], L_m (3.34 × 10⁵ Jkg⁻¹), and ρ_i [kg m⁻³] are the volumetric ice content, latent heat of melting, and ice density, respectively.

4.3.5 AL base flux through permafrost body $Q_{\rm PF}$

The heat flux across the permafrost table Q_{PF} is estimated with the gradient method from PERMOS borehole temperature data via Fourier's heat conduction equation:

$$Q_{\rm PF} = -k_{\rm PF} \frac{\mathrm{d}T}{\mathrm{d}z} \approx -k_{\rm PF} \frac{\Delta T_{\rm PF}}{\Delta z},\tag{8}$$

where the borehole temperatures are measured at 4 and 5 m depth in the permafrost body beneath the AL. We take a constant thermal conductivity k_{PF} value of 2.5 W m⁻¹ K⁻¹ (Vonder Mühll and Haeberli, 1990; Scherler et al., 2014).

4.4 Stefan parameterisation of ground ice melt

If the ground heat flux is mostly spent on melting ground ice (discussed in Sect. 6.1), the rate of lowering the thaw front/ground ice table $d\zeta/dt \ [m s^{-1}]$ can be approximated with a linearised heat conduction equation (Hayashi et al., 2007),

$$\rho_{\rm i} f_i L_{\rm m} \frac{\mathrm{d}\zeta}{\mathrm{d}t} = k_{\rm eff} \frac{T_{\rm s} - 0\,^{\circ}\mathrm{C}}{\zeta},\tag{9}$$

whose solution is the Stefan equation of the form (Hayashi et al., 2007)

$$\zeta(t) = \sqrt{\frac{2k_{\rm eff}I(t)}{\rho_{\rm i}f_i L_{\rm m}}},\tag{10}$$

where $k_{\rm eff}$ is the effective thermal conductivity of the (unfrozen) AL above the thaw front/ground ice table $[Wm^{-1}K^{-1}]$ located at depth ζ [m] beneath the ground surface (Fig. 4) and I(t) the surface that index [°C ×d] (defined below). Two modifications are necessary to account for the AL stratigraphy on Murtèl (Fig. 4). First, the seasonal lowering of the ground ice table (assumed to coincide with the thaw front) is modelled with a modified Stefan equation for a two-layered AL (Nixon and McRoberts, 1973; Kurylyk, 2015). In Eq. (10), the frozen ground is initially (at the onset of thaw season) uniform. However, on Murtèl, the ice does not fill the AL pore space up to the ground surface. Rather, a layer (with thickness h_1) on top of the ice-saturated AL remains nearly ice-free year-round. This ice-poor overburden dampens ground ice melt rates/thaw rates from the onset of the thaw season. Apart from the different ground ice content, the two layers share the same properties (porosity). The second modification is a correction factor λ_5 for sensible heat storage changes in the thawed AL. λ_5 is derived from the Stefan number Ste, $\lambda_5 = 1 - 0.16$ Ste + 0.038 Ste² (Kurylyk and Hayashi, 2016). The depth-averaged dimensionless Stefan number Ste is proportional to the ratio of sensible heat to latent heat absorbed during thawing (Kurylyk and Hayashi, 2016),

Ste :=
$$\frac{C_{\rm v}\overline{T}_{\rm s}}{L_{\rm m}\langle f \rangle \rho_{\rm i}},$$
 (11)

with the bulk volumetric heat capacity $C_v = (1 - \phi_{al})\rho_r c_r$ [J m⁻³ K⁻¹] of the (unfrozen, ice-free) AL (identical for both layers), the average surface temperature \overline{T}_s for the time *t* elapsed since onset of the thaw season, and the latent heat consumed by the melting of the ground ice $L_m \langle f \rangle \rho_i$ (different in each layer, with the depth-averaged value denoted by $\langle \cdot \rangle$; details in Kurylyk and Hayashi, 2016). In other words, the Murtèl AL stratigraphy calls for a multi-layer Stefan equation accounting for sensible heat storage. We use the extension of Eq. (10) developed by Kurylyk (2015) and Aldrich and Paynter (1953) to predict the thaw depth ζ , which for our purpose reduces to (because of $k_1 = k_2 := k_{\text{eff}}$ in Eq. 23 in Kurylyk, 2015)

$$\zeta(t) = \begin{cases} \sqrt{\frac{2k_{\text{eff}}I_{t}(t)}{L_{\text{m}}f_{1}\rho_{\text{i}}}}, \\ \text{if } I_{t}(t) \leq I_{1} \text{ (ice-poor overburden)} \\ \sqrt{h_{1}^{2}\left(1 - \frac{f_{1}}{f_{2}}\right) + \frac{2k_{\text{eff}}I_{t}(t)}{L_{\text{m}}f_{2}\rho_{\text{i}}}}, \\ \text{if } I_{t}(t) > I_{1} \text{ (ice-rich layer)}, \end{cases}$$
(12)

with the effective thermal conductivity k_{eff} [W m⁻¹ K⁻¹] of the (thawed/unfrozen) AL above the thaw front/ground ice table, the volumetric pore ice content f of each layer (maximum at saturation, $f \le \phi_{\text{al}}$), and the pore ice density ρ_{i} (900 kg m⁻³). The total surface thaw index $I_t(t)$ [°C × d] is defined as

$$I_t(t) := \int_0^t \lambda_5^2 T_s(t') \, \mathrm{d}t', \tag{13}$$

and the thaw index of the ice-poor AL overburden I_1 is defined as

$$I_1 := \frac{h_1^2 L_{\rm m} f_1 \rho_{\rm i}}{2k_{\rm eff}}.$$
 (14)

Equation (12) can be reduced if we assume that the icepoor overburden has a negligible ice content, $f_1 \ll f_2$, and approximates the thaw depth late in the thaw season when $I_t(t) \gg I_1$. Then, Eq. (12) reduces to

$$\zeta(t) = \sqrt{h_1^2 + \frac{2k_{\text{eff}}I_t(t)}{L_m\rho_i(f_2 - f_1)}}$$

$$\stackrel{f_2 \gg f_1}{\approx} \sqrt{h_1^2 + \frac{2k_{\text{eff}}I_t(t)}{L_m\rho_i f_2}} \text{ for } I_t(t) > I_1.$$
(15)

Figure 4. Ground ice thaw and the Stefan equation. (a) Initial stratigraphy at the onset of the thaw season with ice-poor overburden and ice-saturated layer. (b) Seasonal thaw front penetration.

Equation (15) is a useful approximation when the overburden is thick and ice poor; i.e. the effect of f_1 is small compared to the effect of h_1 . Without the damping effect of the overburden ($h_1 \rightarrow 0$), Eq. (15) reduces further to the "classic" Stefan solution (Eq. 10).

In discretised form with daily average surface temperatures, $I_t(t_i) = 86400\sum_i (\overline{\lambda}_5^2 \overline{T}_s)[t_i]$, summed over the *i*th day since onset of the thaw season (Hayashi et al., 2007). Equation (12) is premised on the assumption of (i) initial uniform temperature at the freezing point throughout the AL and uniform temperature beneath the thaw front (zero heat flux from the permafrost body beneath; Sect. 6.1), (ii) layer-wise homogeneous and time-invariant thermal properties and ground ice content, and (iii) quasi-steady-state conditions (Kurylyk and Hayashi, 2016).

4.5 Estimation of AL heat transfer parameters (k_{eff} , κ_a)

We derive the heat transfer parameters of the AL, the effective thermal conductivity k_{eff} , and the apparent thermal diffusivity κ_a from in situ measurements using two different approaches based on different measurements; k_{eff} and κ_a are related via the volumetric heat capacity C_v (Vonder Mühll and Haeberli, 1990),

$$\kappa_{\rm a} = \frac{k_{\rm eff}}{C_{\rm v}} = \frac{k_{\rm eff}}{(1 - \phi_{\rm al})\rho_{\rm r}c_{\rm r}}.$$
(16)

Values for the porosity ϕ_{al} , rock density ρ_r , and the heat capacity c_r given in Sect. 4.3.3 yield $C_v = 1.275 \text{ MJ m}^{-3} \text{ K}^{-1}$.

4.5.1 Effective thermal conductivity k_{eff} estimation

The effective thermal conductivity k_{eff} [Wm⁻¹K⁻¹] is derived from the measured AL thermal radiation $Q_{\text{CGR3}}^{\text{rad}}$ and vertical AL temperature gradient $\frac{dT_{\text{al}}}{dz} := \nabla_z T_{\text{al}}$ using a diffusive flux-gradient relation of the form

$$Q_{\rm CGR3}^{\rm rad} = -k_{\rm eff} \frac{\mathrm{d}T_{\rm al}}{\mathrm{d}z}.$$
 (17)

This approach yields a thaw-season-averaged effective thermal conductivity k_{eff} [W m⁻¹ K⁻¹], which we denote by \bar{k}_{eff}^{rad} for precision. It might seem odd to use Eq. (17), a diffusion equation formally identical to Fourier's heat conduction equation (see Eq. 8) since heat conduction is considered insignificant in the coarse blocky AL (Sect. 4.1; discussed in Sect. 6.3.2). However, radiative heat transfer in a porous medium with opaque particles (rock) and transparent fluid (air) can be expressed as diffusive (Fillion et al., 2011; Lebeau and Konrad, 2016); \bar{k}_{eff}^{rad} is an effective thermal conductivity that lumps conductive/radiative and non-conductive (convective) heat transfer in the highly permeable blocky material (Herz, 2006).

4.5.2 Apparent thermal diffusivity κ_a estimation

The apparent thermal diffusivity $\kappa_a \, [m^2 \, s^{-1}]$ is derived from measured AL temperatures T_{al} using the derivative method based on the one-dimensional transient thermal diffusion equation (Biot–Fourier equation) (Hinkel et al., 1990; Conway and Rasmussen, 2000),

$$\frac{\mathrm{d}T_{\mathrm{al}}}{\mathrm{d}t} = \kappa_{\mathrm{a}} \frac{\mathrm{d}^2 T_{\mathrm{al}}}{\mathrm{d}z^2},\tag{18}$$

where *t* [s] is the time, and *z* is the AL depth [m]. Analogous to $\overline{k}_{\text{eff}}^{\text{rad}}$, κ_a is an apparent thermal diffusivity that lumps conductive/radiative and non-conductive (convective) heat transfer. Only the latent effects of freezing/thawing are minimised by using values from the unfrozen AL ($T_{\text{al}} > 0.5 \,^{\circ}\text{C}$). Dayto-day temperature change dT_{al}/dt and the second derivative d^2T_{al}/dz^2 are calculated using the Petersen et al. (2022) algorithm from daily average AL temperature data (TK1/2– 4). To avoid spurious κ_a values, no κ_a is calculated for near-isothermal conditions (unstable numerics; Hinkel et al., 1990).

5 Measurement results

5.1 Meteorological conditions

The weather in each season differed markedly in the 2 years 2020–2022, which is reflected by air temperature and snow at the surface (Fig. 5) and the AL temperatures at depth (Fig. 6a). Winter 2020–2021 was colder (-6.2 °C November–April average) and more snow-rich (120 cm February peak measured on a windswept ridge) and lasted longer than the unusually snow-poor (two 80 cm peaks in December and April), short winter 2021–2022, with snow disappearance in May–June, 1 month earlier than the usual melt-out in July. AL temperatures fluctuated more and attained lower values ($T_{al} < -8$ °C) in the less cold (-5.3 °C) winter 2021–2022. Summer 2021 was cool and wet compared to the hot and dry summer 2022; temperatures were lower (July–August average: 6.9 °C vs. 9.3 °C), with a frequent passage of weather fronts, often bringing cold air (\leq

No.	Condition	Temperature profile Rayleigh number	Heat flux (daily average)	Air circulation mode
Proce	esses on seasonal times	cale (over weeks to months)		
1	Thaw season	Mostly ^a near-linear profile (daily timescale), positive gradient (stable)	$Q_{\rm HFP} \propto Q_{\rm CGR3}^{\rm rad} \propto \nabla_z T_{\rm al},$ 5–15 W m ⁻² downwards, $Q_{\rm CGR3}^{\rm rad} \propto T_{\rm s}$	Wind-forced convection radiative–conductive heat transfer
2	Winter stagnant/ closed snow cover	Near-linear profile, isothermal or weakly unstable gradient, slowly evolving	$Q_{ m HFP} \approx Q_{ m CGR3}^{ m rad}, < 2 { m W} { m m}^{-2}$ upwards	Calm/stagnant, no convective AL–atmosphere coupling
3	Winter semi-closed snow cover	"Bulged" and fluctuating profile	$Q_{\rm HFP} > Q_{\rm CGR3}^{\rm rad}$, often anti-correlated, $2-10 {\rm W}{\rm m}^{-2}$ upwards	Cold-air infiltration through semi-closed snow cover (snow funnels)
Shor	t-lived events (hours to	days)		
4	Convective overturning	Unstable ($Ra > Ra_c$), rapidly changing (transient)	$Q_{\rm HFP} \gg Q_{\rm CGR3}^{\rm rad}$, large: 20–30 W m ⁻² upwards	Rayleigh ventilation (dominant heat transfer mode)
5	Storm-wind mixing	Strongest if (near-)isothermal	Small (minor impact ^{b})	Wind-forced convection
6	Water refreezing	Rapid temperature rise towards 0 °C at all AL depths beneath ripe ("warm") snowpack	$Q_{\rm HFP} > Q_{\rm CGR3}^{\rm rad},$ 4–8 W m ⁻² downwards	Typically calm (minor impact)

Table 3. Typical temperature profiles, heat fluxes and airflow patterns during different seasons, characteristic weather patterns, and snowpack conditions on Murtèl rock glacier (ciphers I-@ are referred to in the text and figures).

^a Exceptions are dry-hot weather spells (Fig. 7a) or during the passage of weather fronts (Rayleigh ventilation). ^b In wind-sheltered Murtèl cirque.

3 °C; minimum daily average temperature: 0.7 °C vs. 5.6 °C) and mixed precipitation (sleet). A few snow patches survived in the Murtèl catchment, which has rarely occurred in the last ~ 15 years (Martin Hoelzle and Christian Hauck, personal communication, 2021). In contrast, summer 2022 was marked by heat waves ($T_{al} > 10$ °C in June and July) cooccurring with dry spells. The surface meteorological conditions are described in more detail in Amschwand et al. (2024).

5.2 Ground thermal and moisture regime

We characterise the ground thermal regime in terms of the Rayleigh–Darcy number Ra (Eq. 3). Ra numbers indicate the stability of the AL air column in a shallow sub-layer (0.5–1.1 m; Fig. 6b1) and the entire AL (0.5–3 m; Fig. 6b2). Onset of buoyancy-driven convection is potentially at $Ra \ge Ra_c$ of 27 under snow-free and 40 under snow-covered conditions. Autumn 2020 starts at the end of September with rapid cooling at high, super-critical Rayleigh numbers. Cooling continues more slowly throughout November, until a thick, "closed" snow cover stalled winter cooling in December 2020, when the snow height exceeded a threshold (60 cm on a rock glacier ridge; Fig. 5b). The AL remained

near-isothermal and near-isohume at sub-critical Ra numbers until May 2022. Summer 2022 was characterised by frequent shallow instabilities, i.e. super-critical Ra numbers in the uppermost 1 m of the AL. The deep AL remained stably stratified. The instabilities became more frequent and encompassed the entire AL in October 2021. In the snow-poor winter 2021–2022, the snow cover remained "open" as the snow height only rarely exceeded the threshold. The AL temperature kept fluctuating at occasionally sub-critical Ra numbers. In summer 2022, shallow instabilities occurred less frequently than in summer 2021 (Fig. 6b1).

The temperature profiles are specific to certain conditions that we mark with circled numbers (1-4) and use throughout this work. An overview is given in Table 3, which shows how the heat transfer processes are reflected by the belowground temperature and airflow measurements. The thawseason temperature profiles (Fig. 7a, number (1)) are nearlinear down to the daily timescale, but not on sub-diurnal timescales or on days with rapid cooling (Rayleigh ventilation, Fig. 7a, number (4), e.g. during the passage of cold fronts). The thaw-season-average temperature gradients are 2.0 Km^{-1} for 2021 ($R^2 = 0.995$) and 2.8 Km^{-1} for 2022 ($R^2 = 0.998$). The near-surface AL is often warmer and

Figure 5. Meteorological conditions. (a) Air temperature (daily mean) and precipitation (daily sum). (b) Snow height and snow water equivalent (SWE). Rain and sleet (mixed precipitation) separated based on a wet-bulb temperature threshold of $2 \degree C$ (Amschwand et al., 2024). A snow height of $h_S = 60 \degree m$ (measured on a windswept ridge) discriminates between a semi-closed and a closed/insulating snowpack (see Fig. 8). Precipitation data at the *Piz Corvatsch* station from MeteoSuisse.

Figure 6. (a) AL temperatures T_{al} in the instrumented main cavity (contour plot from TK1 data). Selected isotherms shown as contour lines. (b) Rayleigh numbers Ra indicate the air column stability in the near-surface AL (b1) and entire AL (b2) (Eq. 3, 10 min resolution). Coloured periods are those shown in Fig. 7. The circled number ④ refers to Table 3.

therefore unstable with respect to the atmosphere despite stable air stratification inside the AL (nonlocal static stability sensu; Stull, 1991). The winter averages (December–April) are near-isothermal in winter 2020–2021 (Fig. 7a, number ②). In winter 2021–2022, occasional temperature minima at roughly 2 m depth ("bulges") hint at lateral cold airflow (Sect. 6.4, Fig. 7a, number ③). The locally (near-)stable AL air is nonlocally unstable compared to the radiatively cooled snow surface with average surface temperature $T_{\rm s}$ of -10 °C (but can go as low as -30 °C). Note the striking asymmetry between near-isothermal winter and steep (2.0–

 $2.8 \,\mathrm{K}\,\mathrm{m}^{-1}$) thaw-season temperature profiles (asymmetric envelopes).

The temperature amplitude ΔT is attenuated exponentially with depth z (Fig. 7b) proportional to exp{-1.083z}. Looking at sub-daily resolution, the AL temperature showed a daily course without a time lag down to -2.9 m, only with attenuated amplitudes (Fig. B1a–b). Specific humidity gradients (Fig. 7d) averaged over days to weeks were parallel to the temperature gradients because the AL is most often close to saturation (Fig. 7c). Exceptions were the summer 2022 dry spells that dried out the AL.

Figure 7. Characteristic temperature and humidity profiles. (a) Vertical temperature profiles ("trumpet curves") during selected periods (the circled numbers (1-4) refer to Table 3): (1) summer/thaw season, (2) stagnant winter conditions (December 2020–April 2021), (3) wintertime cold-air infiltration (winter average December 2021–April 2022, infiltration period 26 February–2 March), (4) convective overturning by Rayleigh ventilation (event of 26–28 September 2020). (b) Amplitude of daily temperature variation (max–min). On a timescale of 1 d or longer, the thaw-season temperature profiles are near-linear, and daily amplitude decays exponentially with depth, even in the comparatively large instrumented cavity. (c, d) Vertical relative humidity (rH) and specific q_{al} humidity profiles.

5.3 Heat flux plate and pyrgeometer measurements

The direct heat flux plate $Q_{\rm HFP}$ and pyrgeometer $Q_{\rm CGR3}^{\rm rad}$ (thermal infrared radiation) measurements give an overview of flux magnitudes and seasonality (Fig. 8). For clarity, we describe the heat fluxes at seasonal down to daily resolution. Sub-daily (hourly) resolution data provide additional insights discussed in Appendix B. The measured heat fluxes vary seasonally primarily according to the snow conditions and the AL temperature gradient $\nabla_z T_{\rm al}$ (characteristic temperature profiles are shown in Fig. 7). The circled numbers (1)-(6)refer to the characteristic weather conditions introduced in Fig. 7 and are marked in Figs. 6b, 8, and 11 (Table 3).

During the thaw season ($T_{al} > 0 \,^{\circ}$ C), when temperature gradients are most often stable ($\nabla_z T_{al} > 0 \,\mathrm{Km^{-1}}$), measured daily average heat fluxes Q_{HFP} and $Q_{\mathrm{CGR3}}^{\mathrm{rad}}$ are 5– 20 W m⁻² downwards ①). The downward ($Q_{\mathrm{HFP}} > 0$) flux into the block on which the HFP/1 is placed (warming, positive sign) is strongly correlated ($R^2 = 0.9$) with the net downward radiation in the instrumented cavity ($Q_{\mathrm{CGR3}}^{\mathrm{rad}} > 0$) (Fig. 8, number ①), with $Q_{\mathrm{HFP}} = 0.7 \, Q_{\mathrm{CGR3}}^{\mathrm{rad}} + 0.7 \,\mathrm{W m^{-2}}$ (Fig. A1). In other words, $Q_{\mathrm{HFP}} > 0$ is congruent with $0.7 \, Q_{\mathrm{CGR3}}^{\mathrm{rad}}$ (histogram in Fig. 8b). The remaining deviation defined as $Q_{\mathrm{HFP}} - 0.7 \, Q_{\mathrm{CGR3}}^{\mathrm{rad}}$ is generally insignificant (within $\pm 2 \,\mathrm{Wm^{-2}}$) during the thaw season, suggesting that radiative–conductive heat transfer dominates: $Q_{\mathrm{CGR3}}^{\mathrm{rad}}$ explains the total heat transfer Q_{HFP} measured by the heat flux plate, $Q_{\mathrm{CGR3}}^{\mathrm{rad}} \sim Q_{\mathrm{HFP}}$. The different scaling of the Q_{HFP} and $Q_{\mathrm{CGR3}}^{\mathrm{rad}}$ measurements can be explained by (i) the instrumental uncertainty (notably the Q_{HFP} resistance error of up to 20 %) and (ii) the REV uncertainty: the HFP/1 measures the heat flux locally, whereas each pyrgeometer integrates hemispherically (with a cosine response) over the cavity surface.

In contrast, non-radiative heat fluxes dominate the upward $Q_{\rm HFP} < 0 \,{\rm W}\,{\rm m}^{-2}$ fluxes (cooling) in autumn and winter. $Q_{\rm HFP} < 0$ is congruent with the deviation (histogram in Fig. 8b) but is unrelated to Q_{CGR3}^{rad} , Q_{CGR3}^{rad} not ~ Q_{HFP} . Un-like Q_{CGR3}^{rad} , upward Q_{HFP} fluxes rapidly increase with unstable (negative) AL air temperature gradients (shown by the colours in Fig. A1a), pointing to air convection as the dominant heat transfer process. Additionally, the snowpack modulates the wintertime heat transfer: in winter 2021-2022, heat fluxes were small ($\leq 2 W m^{-2}$; ②) beneath a closed snow cover when the snow height $h_{\rm S}$ exceeded 60 cm (measured on a windswept rock glacier ridge). In the snow-poor winter 2021–2022, $Q_{\rm HFP}$ and $Q_{\rm CGR3}^{\rm rad}$ were episodically anticorrelated; i.e. the downward net radiation increased with rapid cooling (December 2021–February 2022; ③). Strong cooling occurred in summer and in autumn (September-October 2020, October 2021, September 2022; (4)) during the passage of cold weather fronts.

In spring (before the onset of the zero curtain) and occasionally also during winter (e.g. November 2020), brief events of heat input lead to rapid AL warming towards (but not exceeding) 0 °C. These "warming spikes" (5) often occur during winter/spring "heat waves" ($T_a > 0$ °C), pointing to AL warming by the refreezing of snowmelt via the released latent heat. The attribution is most reliable in the event of a closed/insulating snow cover (e.g. in June 2021), when (storm) wind pumping (5) can be excluded.

Figure 8. (a) Heat flux measured by the heat flux plate HFP/1 at the cavity floor Q_{HFP} , AL thermal net radiation measured by the pyrgeometer pair $Q_{\text{CGR3}}^{\text{rad}}$, and the deviation $Q_{\text{HFP}} - 0.7 Q_{\text{CGR3}}^{\text{rad}}$ (daily averages). Positive flux is downwards into the rock slab. The circled numbers ①–6 refer to Table 3 and are detailed in the text. The snow cover is classified as "semi-closed" (convective exchange through snow funnels) or "closed" (no convective AL–atmosphere exchange; Fig. 5b) (Amschwand et al., 2024, Fig. 4 therein). (b) Normalised histogram of the daily average fluxes. Downward fluxes (positive) are mainly conductive/radiative ($Q_{\text{HFP}} > 0$ is congruent with $0.7 Q_{\text{CGR3}}^{\text{rad}}$; Fig. A1a), upward fluxes (negative) are mainly non-conductive/convective ($Q_{\text{HFP}} < 0$ is congruent with the deviation). (c) Air and AL temperatures and snow cover status (closed/semi-closed). Coloured periods are those shown in Fig. 7.

5.4 AL heat transfer parameters (k_{eff} , κ_a)

5.4.1 Thaw-season-average $k_{\rm eff}$

During the thaw seasons, daily average thermal net radiation Q_{CGR3}^{rad} is strongly correlated with the vertical AL air temperature gradient $\nabla_z T_{al}$ in the cavity, although the cavity is small enough that the air in the cavity is transparent to thermal radiation and does not participate in the radiative heat transfer (discussed in Appendix A). Linear regressions of daily average values of Q_{CGR3}^{rad} and $\nabla_z T_{al}$ yield $Q_{CGR3}^{rad} = 3.0 \nabla_z T_{al} + 0.26 \text{ W m}^{-2}$ ($R^2 = 0.957$) for summer 2021 and $Q_{CGR3}^{rad} = 3.8 \nabla_z T_{al} - 0.45 \text{ W m}^{-2}$ ($R^2 = 0.965$) for summer 2022 (Fig. 9), suggesting $\overline{k}_{eff}^{rad} = 3.0 \,\mathrm{W m^{-1} K^{-1}}$ (for 2021) and 3.8 W m⁻¹ K⁻¹ (for 2022). These \overline{k}_{eff}^{rad} values refer to the timescale of an entire thaw season (hence the overbar -rad in \overline{k}_{eff}^{rad}). At that timescale, radiative–conductive heat transfer dominates, but it does not exclude convective heat transfer altogether. In fact, convection does occur and appears in the measurements when zooming in to sub-daily resolution. Plotting hourly values of a clear summer day (15 July 2022, as an example in Fig. 9) reveals clockwise "loops" caused by diurnal cycles of $Q_{\text{CGR3}}^{\text{rad}}$ out of phase with $\nabla_z T_{\text{al}}$ (black points, midnight value marked by the red cross). AL air temperature leads, and thermal net radiation follows (discussed in Appendix A). Convection that contributes to the total heat transfer to a different extent likely explains the slightly different $Q_{CGR3}^{rad} - \nabla_z T_{al}$ relation for the two thaw seasons 2021 and 2022. The independently calculated κ_a shows the influence of convection on the AL heat transfer parameter more clearly (Sect. 5.4.2).

5.4.2 Daily apparent thermal diffusivity κ_a

The apparent thermal diffusivity κ_a (calculated from daily AL temperatures as outlined in Sect. 4.5.2, Eq. 18) during the 2021 and 2022 thaw seasons varies over 2 orders of magnitude between 2×10^{-5} and 2×10^{-7} m² s⁻¹ and includes negative values (Fig. 10); κ_a systematically varies primarily with the AL temperature gradient $\nabla_z T_{al}$ and secondarily with the atmospheric wind speed u. On daily timescale, the impact of convective heat transfer on the heat transfer parameters appears; κ_a is largest at unstable or near-isothermal air stratification $(1.9 \times 10^{-5} \text{ m}^2 \text{ s}^{-1} \text{ at } \nabla_z T_{al} < 0.5 \text{ K m}^{-1})$, has the largest scatter under weakly to moderately stable conditions (0.5 K m⁻¹ < $\nabla_z T_{al}$ < 4 K m⁻¹), and approaches $\kappa_a^0 = 9.6 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ at strongly stable air stratification ($\nabla_z T_{al} > 4 \text{ K m}^{-1}$), where turbulence is suppressed, and convective heat transfer is minimal. The thaw-season log-mean $\overline{\kappa}_{a}$ is $2.3 \times 10^{-6} \text{ m}^{2} \text{ s}^{-1}$, which, converted to k_{eff} via Eq. (16), yields $2.9 \text{ Wm}^{-1} \text{ K}^{-1}$, in agreement with the independently estimated \bar{k}_{eff}^{rad} . Importantly, the simple explanation of an "insulating" AL in the literal sense of a low thermal conductiv-ity falls short on Murtèl rock glacier: \overline{k}_{eff}^{rad} is that of the local

Figure 9. Thermal net radiation Q_{CGR3}^{rad} vs. vertical AL air temperature gradient $\nabla_z T_{al}$. Daily averages are highly correlated (Eq. 17). Hourly values show a diurnal loop.

Figure 10. Apparent thermal diffusivity κ_a during the two thaw seasons 2021 and 2022 ($T_{al} > 1$ °C) calculated from daily average AL temperatures in the instrumented cavity (TK1/3 at 1.6 m depth; Eq. 18).

bedrock (Schneider et al., 2012) or the underlying permafrost body (Weber and Cicoira, 2024) and roughly 10 times higher than that of the snowpack (Amschwand et al., 2024).

5.5 Sub-surface airflow

The same three variables that control κ_a (Fig. 10) – the snow cover, AL temperature gradient $\nabla_z T_{al}$, and atmospheric wind speed u – also control the below-ground airflow speeds.

Airflow speeds increase with negative $\nabla_z T_{al}$ and increasing u (Fig. E2a), as does κ_a (Fig. 10). Hence, the independent airflow speed measurements attest to the importance of convection. Airflow speeds (Fig. E1) differ seasonally in terms of (i) vertical airflow speed profile (depth of maximum speed) and (ii) temporal pattern (timing of diurnal oscillations). Figure 11 shows a data illustration of three characteristic air circulation modes that occurred on the days around the transition from thaw season to autumn 2020: (i) wind-forced shallow ventilation of the stably stratified AL air column; (ii) buoyancy-driven Rayleigh ventilation; and (iii) wind-forced mixing of the isothermal, labilised air column ("storm-wind mixing"). First, during the snow-free thaw season with unresisted AL-atmosphere connectivity, belowground airflow follows a strong, regular diurnal cycle with an afternoon speed peak and calm nights (Fig. 11b), in phase with insolation, the surface temperature T_s , and the thermally driven (anabatic) local slope winds (Amschwand et al., 2024) (Fig. B1). This diurnal pattern is shared by all wind speed sensors. Airflow speeds are always highest near the surface (up to $20 \,\mathrm{cm}\,\mathrm{s}^{-1}$) and decrease with depth (see Evatt et al., 2015), except in the deeper parts of the instrumented main cavity. There, the lowermost WS/1 mounted in a narrow constriction (Fig. 3, Table 2) showed higher wind speeds and responded more sensitively than the WS/2 in the more spacious mid-cavity. However, this is due to the Venturi effect and does not detract from the general observation that windforced ventilation under stable temperature gradients decays with depth. At typical depths of the ground ice table (3-5 m), airflow speeds were low (close to the resolution limit of a few centimetres per second) but tended to be higher under strong atmospheric winds. Hence, the effect of wind-forced convection under stable AL temperature gradients is weak but detectable down to 3 m depth in the spacious instrumented cavity (Fig. E2a). Second, wind most efficiently mixes an isothermal, labilised AL air column like that, for example, in October 2020 (Fig. 11). This storm-wind mixing had little impact on Murtèl's ground thermal regime because the AL is rarely isothermal under snow-free conditions. Third, typically in autumn, Rayleigh ventilation under unstable temperature gradients sets the entire air column in motion and leads to rapid cooling of the entire AL within hours to days, for example in late September 2020 (Figs. 6b, 11).

In winter (Fig. E1; not shown in Fig. 11), the amount of snow controls the strength of the air circulation and possibly also the pathways. The thicker the snow cover and the stronger the decoupling between AL and atmosphere (AL–atmosphere coupling in Amschwand et al., 2024), the more important density contrasts become to drive the air circulation (buoyancy-driven ventilation), however at overall lower airflow speeds (Fig. E2b–c). Under a thick snow cover in winter 2020–2021, AL airflow is weak and beneath the level of detection at all sensors and depths. For example, the wind hole instrumented with the WS/5 was completely snowed up and closed. In the snow-poor winter 2021–2022, AL circu-

Figure 11. Close-up of the autumnal cooling in 2020 that illustrates the different air circulation modes in the coarse blocky AL. Above-surface meteorological conditions (insolation and surface temperature, wind speed) and the ground thermal regime (vertical temperature gradient) interact to produce characteristic air circulation modes. (a) Atmospheric wind speed. (b) Strong diurnal surface heating with shallow *wind-forced ventilation* (WS/3) is characteristic of clear summer days ①. Stable air stratification allows only weak circulation in the deep cavity (WS/1) despite occasionally strong winds. Rapid surface cooling destabilises the air column and produces buoyancy-driven circulation (Rayleigh ventilation (4)). Vigorous mechanical mixing of the isothermal, labile air column by strong winds rarely occurs because it requires an isothermal air column under snow-free conditions. (c) Temperatures. (The circled numbers ① and (4) refer to Table 3).

lation resumed in December 2021, 1 month after the onset of the snow cover. Measured air circulation is most vigorous and persistent in a rock glacier furrow, a topographic depression (WS/6 in Fig. E1), and tends to increase with depth. The airflow follows a regular diurnal cycle with nocturnal speed peaks and calm days, in phase with thermally driven (katabatic) local slope winds (Amschwand et al., 2024). The timing and vertical speed profile of wintertime diurnal oscillation are opposite to the "summer mode", however much weaker and not as regular as in summer.

5.6 Seasonal AL ice turnover

5.6.1 Stake measurements

The ground ice is rarely accessible in coarse blocky landforms. Here, we present one of few (to our knowledge) in situ measurements of the seasonal turnover of superimposed AL ice in rock glaciers and periglacial landforms like block fields (Sawada et al., 2003; Marchenko et al., 2012, 2024). The ground ice table as measured at the stake in a rock glacier furrow deepened by 60 cm during the thaw season June-September 2022 rose by (at least) 40 cm in winter 2022-2023, deepened again by 40 cm in July-September 2023, and rose by 60cm in winter 2023–2024 (Fig. 12a–c). The stake measurements show no local AL thickening for the years 2022–2024. At least locally in the rock glacier furrow, the ground ice that melted during each thaw season was regenerated by trapping in-blown snow and refreezing snowmelt in the following winter and spring, resulting in a substantial turnover (build-up and melt) of $\Delta \zeta \approx 0$ cm within the coarse blocky AL (equivalent to $\Delta \zeta \phi_{al} \rho_i = 220 \,\text{mm}$ water equivalent, w.e.). Note that the lowering of the ground ice table is observed within the blocky AL, i.e. needs to be multiplied by the AL porosity ϕ_{al} and ice density ρ_i to obtain an ablation in the glaciological sense (in water equivalent).

The amount of ice lost due to melt is equivalent to a heat flux $\overline{Q}_{\rm m}$ of ~ 10 W m⁻² on average during the 2022 thaw season (porosity $f_i = \phi_{\rm al} = 0.4$ in Eq. 7; Fig. 12d), in good agreement with $Q_{\rm CGR3}^{\rm rad}$ (Fig. 8). The melt/thaw rates accelerate and decelerate, with a peak in mid-July, proportional to the ground surface temperature $d\zeta/dt := \dot{\zeta} \propto T_{\rm s}$ (within their uncertainty) throughout the thaw season (Fig. 12d). Measured melt rates are independent of the time elapsed since onset of the thaw season. This justifies the two-layer Stefan equation (Eq. 12) because the one-layer Stefan equation (Eq. 10) predicts $\dot{\zeta} \propto \sqrt{t}$, with thaw rates rapidly slowing down as the thaw front recedes away from the surface.

5.6.2 Stefan parameterisation

With $k_{\text{eff}} = 3.0 \pm 0.3 \text{ W m}^{-1} \text{ K}^{-1}$ a priori derived from our measurements (Sect. 5.4) and $f_2 = \phi_{\text{al}} = 0.4$ (saturation), the best-fit parameters for Eq. 12 are $\hat{f}_1 = 0.01$ and $\hat{h}_1 = 3.0 \pm 0.25 \text{ m}$ (Fig. 12a). This relation based on 2022 data predicts the 2023 ablation rates well (Fig. 12b). The estimated \hat{h}_1 is 50% thicker than the actual distance to the initial ground ice table (~ 2 m), but still plausible given the rough terrain and input data uncertainties: the "excess" overburden/insulation might compensate for the likely too-high

Figure 12. Observed vertical changes in the ground ice table in that season (a)–(c) 2022–2024 with seasonal build-up and melt. Measurement uncertainty $\sim 5 \text{ cm}$. Melt is simulated with the Stefan model (Eq. 12, Fig. 4). (d) The ground ice melt rates are correlated with the ground surface temperature T_s .

forcing thaw index $I_t(T_s)$ in the shaded furrow, as $I_t(T_s)$ is derived from the PERMOS outgoing long-wave radiation on a sun-exposed plateau.

6 Discussion

- 6.1 AL energy budget: thaw-season heat uptake and partitioning
- 6.1.1 Heat uptake driven by earlier snow melt-out and hot and dry summer weather

During the thaw season, the AL is a net heat sink. Figure 14 shows the cumulative heat uptake during the two thaw seasons 2021 and 2022. At the onset of the thaw season, which coincides with the disappearance of the snow cover, the AL exits the zero-curtain-phase isothermal at 0 °C (Fig. 7a). This is the thermodynamic zero level $0MJm^{-2}$ in Fig. 14. The sensible heat content $H_{\rm al}^{\theta}$ is zero at the onset and end of the thaw season. During the thaw season, the AL is a heat sink that absorbs roughly 10 % of the surface net radiation Q^* (not to be confused with the below-ground long-wave/thermal net radiation $Q_{\text{CGR3}}^{\text{rad}}$; Fig. 14), hence $Q_{\text{G}} \approx Q^*/10$ (Amschwand et al., 2024), in both thaw seasons until the middle/end of August. Roughly 90% of Q^* is exported back into the atmosphere via sensible and latent turbulent fluxes (Fig. 13 in Amschwand et al., 2024), but the rock glacier is vulnerable to hot and dry weather spells.

The total heat uptake during the thaw season is first controlled by the date of the thaw-season onset, that is, the snow melt-out date, in turn controlled by winter precipitation and spring weather. A warm autumn also extends the thaw season, and September heat waves can bring in heat almost at August rates (August–September 2023; Table 4), but the impact is presumably less severe than an earlier onset in spring because solar radiation is less intense then. After the snow-poor winter 2021-2022, the thaw season 2022 started 1 month earlier than in 2021 and received almost twice the amount of heat, 93.7 MJ m⁻² instead of 52.1 MJ m⁻², although the thaw season lasted only 15 d longer (Table 5). A 1-month-earlier snow melt-out at the beginning of June instead of the beginning of July caused a heat uptake of $\sim 40 \,\mathrm{MJ}\,\mathrm{m}^{-2}$, amounting to $\sim 40\%$ of the entire 2022 heat uptake. A snow-free June alone brings in over 70% of the entire 2021 heat uptake. Weather conditions during the thaw season also matter: hot and dry weather spells deplete the water and ice stores in the AL, decrease its latent buffer capacity (Sect. 6.2), and enhance the downward heat transfer (heat uptake ratio by Q_{CGR3}^{rad} ; Fig. 14b2) (Amschwand et al., 2024). Based on Q_{CGR3}^{rad} , the 1 July–15 September heat uptake (a period common to both thaw seasons) in 2022 was $16.8 \,\mathrm{MJ}\,\mathrm{m}^{-2}$ higher than in the 2.3 °C cooler summer 2021 (Table 4), an increase of 33 %, roughly corresponding to 10 d worth of heat uptake in June. Importantly, proportionally more heat from the surface net radiation Q^* was also transferred to deeper AL levels, 8.9% (of 748 MJ m⁻²) in 2022 compared to 7.5% $(of 664 MJ m^{-2})$ in 2021. Thaw season 2023 was overall similar to 2022, except for a warmer September.

Period-averaged radiometric GST \overline{T}_{s} [°C]

Hence, two forcings mainly control the total heat uptake of the AL during the thaw season, (i) its date of onset and (ii) weather conditions. With our quantitative data, we can attempt to estimate how strongly each of these forcings impacts Murtèl by unravelling how much heat is taken up by the AL in response to (i) the trend towards earlier meltout and (ii) the warming trend (Table 4). First, the June heat uptake scales with 0.9 times the number of snow-free June days (Fig. 13b), i.e. has a sensitivity of 1.1 MJ m⁻² per snow-free June day. Second, the 1 July–15 September heat uptake scales with 6.6 times the air temperature increase with respect to the 2021 average \overline{T}_a (Fig. 13c), i.e. a sensitivity of 6.6 MJ m⁻² per degree Celsius of summer warm-

ing. Translating these sensitivities to trends should be interpreted with utmost caution because the snowmelt (Matiu et al., 2021) and warming trends have a spatio-temporal variability and have accelerated in the recent decades, and the climate sensitivity is itself sensitive to the evolving AL properties (e.g. negative feedback by AL thickening (Haeberli et al., 2024), altered SEB). First, Hoelzle et al. (2022) (for Murtèl 1997-2018; Fig. 13a), Klein et al. (2016), and Matiu et al. (2021) report trends of earlier snowmelt of 1-5 d per decade $\times 1.1 \text{ MJ m}^{-2} \text{ d}^{-1} = 1.1 - 5.5 \text{ MJ m}^{-2}$ per decade. Second, a warming trend (Hoelzle et al., 2022) of 0.4-0.7 °C per decade $\times 6.6 \text{ MJ m}^{-2} (^{\circ}\text{C})^{-1} = 2.6-4.6 \text{ MJ m}^{-2}$ per decade. The total AL heat uptake has likely been increasing by 4- 10 MJ m^{-2} per decade (4 %–11 % of the 2022 heat uptake of 94 MJ m^{-2}). This calculation is (to our knowledge) the first quantitative attempt to express the climate sensitivity of a rock glacier in numbers based on in situ heat flux measurements instead of modelling.

The above calculation refers only to the thaw-season heat uptake. However, to fully assess the impact of climate change on Murtèl rock glacier (Scherler et al., 2013), the winter cooling needs to be accounted for as well, for both the AL and the permafrost body beneath. In a coarse blocky AL, only the amount of cold content that is converted to ground ice contributes to offsetting the heat uptake during the thaw season. No sensible cold content ($T_{al} < 0 \,^{\circ}C$) can be retained in the highly permeable AL flushed by snowmelt and warmed to 0 °C in spring (isothermal entering the zero curtain; Fig. 7). AL ice build-up is discussed in Sect. 6.2. The second process is building cold content of the permafrost body (rock glacier core) beneath by (preferentially convective) heat export through the AL and the snowpack (Luetschg et al., 2008). We discuss wintertime heat transfer in Sect. 6.4, while the year-round energy budget of the entire rock glacier (AL and permafrost body) is beyond the scope of this study.

6.1.2 Heat partitioning

The available heat from the surface ground heat flux $Q_{\rm G}$ is partitioned into sensible heat storage changes ΔH_{al}^{θ} and latent heat storage changes (ice melt) $Q_{\rm m}$ and conducted into the permafrost body beneath the AL $Q_{\rm PF}$ (Eq. 4, Table 5). On thaw-season average, $Q_{\rm G}$ is largely (~ 70 %) spent on melting ground ice. Hence, latent heat effects contribute substantially to the thermal buffering. This is one process that renders rock glaciers climate-robust, as long as seasonal build-up of superimposed ice compensates for its melt (discussed in Sect. 6.2). Roughly $\sim 20\%$ of $Q_{\rm G}$ is absorbed by the coarse blocky AL as sensible heat storage H_{al}^{θ} . The heat conducted into the permafrost body beneath the AL $Q_{\rm PF}$ amounts to ~10 MJ m⁻² (~10 % of $Q_{\rm G}$), about 1 % of the available net radiation Q^* at the surface $(Q_{\rm PF}/Q^*$ in Table 5). The cumulative rain heat flux $Q_{\rm Pr}$ (Eq. 5) is $11 \,\mathrm{MJ}\,\mathrm{m}^{-2}$ in the cool and wet summer 2021. Q_{Pr} is a small flux compared to $Q_{\rm G}$ in 2022 (5%-10% considering the rainfall undercatch), but not in 2021 (20%), and is in any case similar to $Q_{\rm PF}$. Hence, the rain heat flux $Q_{\rm Pr}$ has a weak cooling effect near the surface ($Q_{Pr} < Q_m, Q_G$), but potentially an important warming effect at depth ($Q_{Pr} \approx Q_{PF}$).

The thaw season is divided into two phases, an AL heating and a ground ice melting phase (Fig. 14a2, b2). Initially, the ice-poor shallow AL is heated from the surface downwards. During the first phase, the uptake of sensible heat takes 2– 3 weeks to saturate at an average H_{al}^{θ} , after which the sensible heat storage changes little (and even slowly loses heat in late summer), and the heat goes mainly into ice melt. Due to the shallow AL and steep temperature gradients shortly after the thaw-season onset, Q_{CGR3}^{rad} is relatively large compared to ΔH_{al}^{θ} (Fig. 14a2, b2). In the second phase, the near-surface AL does still warm and cool in response to the atmospheric forcing, but the sensible heat storage changes ΔH_{al}^{θ} are small compared to the cumulative heat uptake.

Figure 13. (a) Melt-out trend at Murtèl (data from Hoelzle et al., 2022). The trend of $-0.1 \, d \, yr^{-1}$ is not statistically significant because the time series is short compared to the inter-annual variability but is likely to continue with ongoing climate change. (a–b) The 2021–2023 sensitivity of the AL heat uptake: (b) the more snow-free days in June and (c) the warmer the July–September period, the larger the heat uptake.

Figure 14. Heat uptake and partitioning during the (a) 2021 and (b) 2022 thaw seasons. Most of the heat supplied to the AL is intercepted by melting ground ice. SEB refers to the Amschwand et al. (2024) surface energy balance. (a2, b2) Sensible heat storage H_{al}^{θ} and thermal net radiation Q_{CGR3}^{rad} are correlated. Phases 1 and 2 are explained in the text. The marked 2022 heat waves are also shown in Fig. 5.

6.2 The seasonal ice turnover in the AL: ice protects the underlying permafrost

The 2022 stake measurements (Fig. 12a–c) in the rock glacier furrow (interpolated and converted to $Q_{\rm m}$ using Eqs. 12 and 7, respectively) agree within 10 MJ m⁻² with the melt dev_{al} calculated from the AL energy budget in the nearby instrumented cavity (Eq. 4, Fig. 14b, Table 5). The AL budget, es-

timated in a broad ridge with thicker AL, predicted more sensible storage H_{al}^{θ} gains and less ice melt dev_{al} than the stake measurements Q_m show for the narrow rock glacier furrow (see Fig. 2). The discrepancy relative to the total heat uptake decreases during the thaw season; end-of-thaw-season estimates match. Although our plot-scale observations do point to some differential melt beneath furrows and ridges

^a Q_r is the pyrgeometer measurement Q_{CGR3}^{rad} . ^b is the AL energy budget deviation dev_{al} := $Q_G + Q_{Pr} - H_{al}^{\theta} - Q_{PF}$. ^c Ablation parameterised via Eq. (12) and converted to Q_m via Eq. (7). The 2021 ablation where no observations are available is estimated with the 2022 parameters and the 2021 forcing T_s .

(a micro-topographic variability mentioned by Kääb et al., 1998, and Halla et al., 2021), the agreement suggests that our estimates of end-of-thaw-season ice storage changes are fairly representative over the landform within an uncertainty that we estimate as $\pm 30\%$. No systematic stake measurements were taken in 2021; $Q_{\rm m}$ is estimated with the 2022 parameters forced by the 2021 $T_{\rm s}$ (Fig. 14a). Differential heat storage effects are smaller in the cooler thaw season 2021.

The AL ice was fully regenerated, and no net ice loss occurred between September 2020-September 2024, at least locally in the furrow. While this is not exactly true for the entire Murtèl rock glacier, where slow permafrost degradation and AL have been measured (Noetzli and Pellet, 2023), Murtèl's slow response attests to the important latent buffer effect of the AL ice (Sect. 6.1), a feature common to icerich permafrost landforms (Scherler et al., 2013). The regeneration of ground ice in the AL partly explains the climate robustness of coarse blocky landforms (Scherler et al., 2013). If the lost ground ice is not regenerated, the permafrost landform is preconditioned towards AL thickening and irreversible degradation (Hilbich et al., 2008; Hauck and Hilbich, 2024). Moreover, the modelling study by Renette et al. (2023) suggests that dry cooling in early winter and ice build-up in spring, a timing specific to permeable and well-drained (sloped) permafrost landforms, are themselves an undercooling process, in addition to convective undercooling (Sect. 6.3.1). This dry undercooling effect is most pronounced in deeply snow-covered landforms where the autumn-early winter "window of opportunity" for cooling before the onset of an insulating snow cover is shorter. The intricate relations between hydraulic and ground thermal regimes in coarse blocky permafrost landforms and the AL ice as a meltwater "source" in hot and dry summer periods are discussed further in Amschwand et al. (2025).

6.3 Thaw-season heat transfer

6.3.1 The thermal semi-conductor effect: air convection selectively enhances the apparent thermal diffusivity during cooling events

The sensitivity of the apparent thermal diffusivity κ_a to AL temperature gradients reflects how efficient convective heat transfer operates compared to radiation-conduction in the coarse blocky AL; κ_a is primarily controlled by the AL air column stability (vertical temperature gradient $\nabla_z T_{al}$) that induces buoyancy-driven convection and secondarily by the atmospheric wind speed u that induces wind-forced convection (Fig. 10) (Herz, 2006). Hence, the convection-enhanced apparent κ_a is as much determined by the time-variable meteorological conditions as by the debris texture and is thus variable in time. Note that in such permeable material, water content does not affect heat transfer properties; κ_a is higher for cooling (upwards heat transfer) at unstable temperature gradients than for warming (downwards heat transfer) at stable temperature gradients. This feedback between AL temperature gradient and thermal diffusivity profoundly impacts the ground thermal regime of permeable, ventilated landforms: frequent, but less efficient radiativeconductive warming (suppressed convection) is countered by only occasionally occurring, but highly efficient convective cooling (enhanced convection; Figs. 8, 10). Ventilation leads to locally lower ground temperatures in coarse blocky, permeable terrain, an observation known as undercooling (Wakonigg, 1996), and is another process that renders rock glaciers climate-robust. This effect has long been qualitatively known as "Balch ventilation" (Balch, 1900) or the "thermal semi-conductor effect" (Guodong et al., 2007) (see Johansen, 1975; Herz, 2006). Our study is the first one (to our knowledge) that quantifies the effect based on field data and calculates a convection-enhanced apparent thermal diffusivity κ_a . Table 3 provides an overview on how the seasonally varying dominant heat transfer processes are shown by our data. The impact of air convection is visible in the temperature, airflow speed, and heat flux plate measurements at sub-diurnal resolution (Appendix B).

Our κ_a values agree with published values for ventilated coarse blocky material but are generally 2 – 6 times higher than for finer material of supra-glacial debris (Rowan et al., 2021) or cryic regosol (Table F1). The important contribution of forced air convection to the total heat transfer even at stable air stratification is characteristic of highly permeable and dry materials, i.e. is specific to coarse blocky landforms, and most pronounced in the strongly ventilated, wind-exposed

near-surface layer (Yoshikawa et al., 2023). With smaller grain size or increasing fine-material content that clogs the pore space (typically near the AL base), convective and radiative heat transfer (Sect. 6.3.2) becomes less important in favour of conductive heat transfer. We estimate the key parameter intrinsic permeability K using the Kozeny–Carman relation in Appendix D.

6.3.2 Radiative heat transfer and stagnant effective thermal diffusivity κ_a^0

Above a temperature gradient of 4 K m^{-1} , turbulence is suppressed to the point where the effective thermal diffusivity κ_a becomes independent of $\nabla_z T_{al}$ (Fig. 10). The thermal stratification inside the AL becomes too stable to be mixed by the wind, and wind-forced convection is "switched off" at a temperature gradient threshold, slowing down an "overheating" of the AL. This "non-linear heating of the AL with air temperature" has been reported by Hanson and Hoelzle (2004) and Herz (2006). Our threshold temperature of 8–10 °C (ca. 2 m above the AL base at 0 °C) is higher than the 6 °C threshold reported by Hanson and Hoelzle (2004) for a less coarse blocky measurement spot on Murtèl. Perhaps the higher permeability around our instrumented cavity imposed less resistance to wind-forced mixing for a given temperature gradient.

Moreover, this κ_a under strongly stable air stratification is our best-available field estimate of the stagnant effective thermal diffusivity $\kappa_a^0 = 9.6 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ ($k_{\text{eff}}^0 \approx 1.2 \text{ Wm}^{-1} \text{ K}^{-1}$), i.e. a radiative–conductive thermal diffusivity without convection. This k_{eff}^0 is ~ 3 times higher than what would be expected from the geometric mean or empirical engineering parameterisations that ignore radiation, for example the $k_{dry} = 0.039 \phi^{-2.2} \pm 25\%$ of Johansen (1975) for dry crushed rock (Côté and Konrad, 2005). A relatively large κ_a uncertainty of ~ 30 % (mainly due to variable block sizes) does not detract from this finding. Hence, an important insight for modellers is that the stagnant thermal diffusivity κ_a^0 of coarse blocky material is underestimated if radiative heat transfer is ignored. Our measurements confirm previous investigations on Murtèl in that respect (Scherler et al., 2014; Schneider, 2014) and are further supported by the cold-region engineering study by Fillion et al. (2011). The radiative thermal diffusivity κ_a^0 increases linearly with block/pore size (actually: the effective length for radiation in the air-filled gaps between particles) and mean temperature cubed (Lebeau and Konrad, 2016); i.e. it tends to counteract undercooling (quantitative details in Appendix D). Laboratory tests using crushed rock beds showed that radiative heat transfer begins to dominate over conduction at effective particle sizes (d_{10} diameter) exceeding 9 cm (cobbles) (Fillion et al., 2011; Rieksts et al., 2019), corroborating an earlier work by Johansen (1975).

6.4 Autumn and wintertime heat transfer

The early winter snow cover determines the ground thermal regime in winter and spring by controlling the magnitude of the heat fluxes and convective air exchange across the snow cover via snow funnels. In terms of qualitative process understanding, this is established knowledge (Haeberli et al., 2006; Wagner et al., 2019) and is shown on Murtèl by the permafrost temperature time series since 1987 (Noetzli and Pellet, 2023): strong ground cooling during snow-poor winters can offset the warming of the preceding years in the permafrost body to more than 20 m depth. The degree of snow cover insulation is shown in our data by the two contrasting winters 2020-2021 (average snow conditions, weak air circulation beneath a closed snow cover) and 2021-2022 (snowpoor winter, strong air circulation beneath a semi-closed snow cover). Although the air column in the somewhat insulated AL and in a thin, strongly cooled layer above the snow surface was typically nonlocally unstable (i.e. near-surface $T_{\rm a} \approx T_{\rm s} < \max\{T_{\rm al}\}$; Fig. 7a) and the potential for buoyancydriven convection was available, different air circulation patterns emerged depending on snow height: (i) Rayleigh ventilation (Marchenko, 2001; Millar et al., 2014) prevailed in unresisted circulation, (ii) cold-air infiltration (Herz, 2006) occurred beneath a moderately thick/semi-closed snow cover, and (iii) stagnant-conductive conditions without air circulation occurred beneath a thick/closed snow cover. The circulation patterns differ in terms of persistence in time, heat flux magnitude, vertical temperature profile, and Rayleigh numbers (local instability). Hence in addition to the temperature profile, the AL-atmosphere connectivity through the snow cover ("effective aeraulic resistance") co-controlled which type of air circulation occurred and ultimately how strong the winter cooling was.

6.4.1 Rayleigh circulation under snow-free conditions or beneath a thin/open snow cover

Rayleigh ventilation events typically occurred in autumn before the onset of a thick snow cover, for example in October 2020 (Fig. 6b, Table 3, number ④). With unresisted AL– atmosphere exchange, it is an efficient (20–30 W m⁻²; Fig. 8) top-down cooling process associated with the characteristic negative AL temperature gradients (locally unstable air stratification; Fig. 7a, Table 3, number ④) and is diagnosed by super-critical Rayleigh numbers ($Ra > Ra_c$). Rayleigh ventilation events as a response to rapid atmospheric cooling are a short-lived, but efficient heat transfer process. Thermal equilibrium was reached rapidly within hours to days, for example in September 2020 or 2022. It contributed to the rapid end of the 2022 thaw season, where the entire AL was cooled from 5 to 0 °C within 1 d.

6.4.2 Cold-air infiltration beneath a semi-closed snow cover

During extended cold-air infiltration phases with a semiclosed (patchy) snow cover ($h_{\rm S} < 60\,{\rm cm}$; Fig. 5b; Amschwand et al., 2024), the AL cooled slowly from the bottom up and persistently over longer periods (days to weeks) at moderate fluxes ($\leq 10 \,\mathrm{W}\,\mathrm{m}^{-2}$, $Q_{\mathrm{CGR3}}^{\mathrm{rad}}$ not $\propto Q_{\mathrm{HFP}}$; Fig. 8, Table 3, number (3). Cold-air infiltration shaped the ground thermal regime in November 2020 and throughout the snowpoor winter 2021-2022. It caused 5 °C lower AL temperature minima compared to winter 2020-2021, although winter 2021–2022 was 0.4°C warmer (November–March average). Convective exchange with the atmosphere is shown by fluctuating AL temperatures and characteristic concave temperature profiles with a minimum at mid-cavity level ("bulges"; Fig. 7a-b, Table 3, number (3); Herz et al., 2003b) whose depth coincides with increased daily temperature amplitudes (Fig. 7b). Cooling at depth stabilised the AL air column, shown as sub-critical Rayleigh numbers ($Ra < Ra_c$), and led to a net downward radiative transfer $Q_{CGR3}^{rad} > 0$ like during the thaw season (although much smaller), opposite to the measured HFP/1 heat flux $Q_{\rm HFP}$ (Fig. 8). Modelling convective heat exchange with the Rayleigh number alone would miss this type of air circulation. The bottom-up cooling was accompanied by a bottom-up drying, since ventilation brought in "fresh", dry outside air into the otherwise saturated AL (Fig. 15, Fig. 7c-d, number (3)), opposite to the summertime evaporative top-down drying. In-phase diurnal oscillations of AL relative humidity, temperature differences between AL and surface temperatures $(T_s - \min\{T_{al}\})$, and strong nighttime ventilation recorded in the rock glacier furrow (WS/6 in a topographic depression; Fig. E1) suggest that cold-air infiltration occurred on clear-sky nights. Radiatively cooled air on the snow surface, produced by the nocturnal negative radiation balance (Amschwand et al., 2024), infiltrated into the coarse blocky AL (Herz, 2006). Cold-air infiltration is an effect of nonlocal static instability (Stull, 1991) that arises from interactions between AL and a semi-closed snow cover. The process is analogous to the summertime nocturnal near-surface air circulation that switches on when the near-surface atmosphere cools below the near-surface AL (nocturnal Balch ventilation; Amschwand et al., 2024). Although our isolated point-wise measurements could not reveal the lateral extent and connectivity of the airflow, and we did not perform gas tracer tests (Popescu et al., 2017a), the cold-air infiltration likely corresponds to the landform-scale cold-air drainage described in the literature (Wakonigg, 1996; Delaloye and Lambiel, 2005; Millar et al., 2014), where the infiltrating cold air flows laterally downslope in the permeable AL beneath the snow cover (convection-advection), analogous to the katabatic drainage flows on the snow cover (Amschwand et al., 2024).

Figure 15. Nocturnal cold-air infiltration episodes in March 2022 as indicated by airflow speed measurement (WS/6) and a simultaneous drop in AL relative humidity (HV5/1–2) and temperature (TK1/3) due to the ventilation with fresh, dry–cold outside air. As soon as the ventilation stops, the AL air approaches saturation within hours. Higher WS/6 airflow speeds always coincide with negative (T_s – min{ T_{al} }). Using air temperature T_a instead of snow surface temperature T_s would underestimate the occurrence of coldair infiltration episodes. Note the WS/6 data gaps due to power shortage.

6.4.3 Stagnant conduction beneath a thick/closed snow cover

In the more snow-rich winter 2020–2021, after closing of the snow cover in December ($h_{\rm S} > 60 \, {\rm cm}$; Fig. 5b), heat fluxes were small ($< 2 \, {\rm W} \, {\rm m}^{-2}$) and upwards (Fig. 8, Table 3, number ②; "closed/insulating snow cover" sensu; Amschwand et al., 2024). Heat transfer on a daily timescale appeared diffusive ($Q_{\rm CGR3}^{\rm rad} \propto Q_{\rm HFP}$). The AL heat flux was not larger than the conductive heat flux $Q_{\rm S}$ across the snow cover as calculated in Amschwand et al. (2024). The AL air column was near-isothermal (Fig. 7a, Table 3, number ③) and weakly unstable (sub-critical Rayleigh numbers in Fig. 6b). The measurements of heat fluxes and airflow speed were close to their instrumental accuracy.

6.5 Scope and transferability of Murtèl findings

The findings of this detailed single-site case study are transferable to other sites to varying degrees, which is a key consideration for upscaling. Caution is necessary because convective and radiative heat transfer and the ice build-up are specific to a high permeability, large pore dimensions, and dry conditions, which are in turn characteristic of a coarse blocky debris texture. First, the SEB and the AL energy budget (i.e. the *total* heat uptake) that more strongly reflect topo-climatic and snow conditions are most transferable in the sense that they are the least sensitive to the debris texture (Amschwand et al., 2024). The effects of earlier spring melt-out and warmer summers, exacerbated by dry periods, strongly impact the AL energy budget primarily via the surface net radiation and sensible turbulent fluxes (Amschwand et al., 2024). However, moisture storage, transfer, and evaporation (latent turbulent fluxes) are more sensitive to debris texture. Second, the two undercooling processes heat interception by the AL ice turnover and convective thermal semi-conductor effect - are characteristic features of all coarse blocky permafrost landforms and shape the ground thermal regime in different debris permafrost landforms, including rock glaciers, frozen talus slopes, and block fields, as long as their AL is permeable and dry. Hence, the detailed process understanding gained on Murtèl qualitatively applies to widespread mountain permafrost landforms located in various topo-climatic conditions and gives a processoriented, field-data-based explanation for the climate robustness of undercooled "cold rocky landforms" (Brighenti et al., 2021). Only the spatial pattern of air circulation differs in sloped landforms such as talus slopes (Caltagirone and Bories, 1985; Guodong et al., 2007): convective heat transfer

is then no longer dominantly vertical as on Murtèl. Surfaceparallel (lateral) advective heat transfer leads to an undercooled foot and an "overwarmed" top of the slope ("chimney effect") (Delaloye and Lambiel, 2005; Morard et al., 2010; Růžička et al., 2012; Wicky, 2022; Zegers et al., 2024). Third, the least transferable are the exact values of the heat transfer parameters (k_{eff} , κ_a), which are so sensitive to the debris texture that they typically vary even on the landform itself (Appendix D). The numbers are only valid for landforms similar to Murtèl in terms of debris texture.

7 Conclusions

We investigated heat transfer and storage processes in the ventilated coarse blocky active layer (AL) of the seasonally snow-covered Murtèl rock glacier situated in a cirque in the upper Engadine (eastern Swiss Alps). In the highly permeable AL, conductive/diffusive heat transfer, including thermal radiation, non-conductive heat transfer by air circulation, and heat storage changes from seasonal build-up and melting of ground ice, create a cool and stable ground thermal regime known as undercooling, rendering these permafrost landforms comparatively robust against climate change. While the undercooling effects have long been known qualitatively, this study resolves different processes quantitatively, providing insights into the capability and limits of the undercooling effect and the climate robustness of coarse blocky landforms. We provided estimates of sub-surface heat flux and storage changes for the 2-year period 2020-2022 based on a novel in situ sensor array in the AL and stake measurements of the seasonal progression of the ground ice table, i.e. ground ice build-up and melt. The measurements included thermistor strings, hygrometers, heat flux plates, and thermal radiation sensors. Airflow speed sensors (thermo-anemometers) distributed in the AL revealed air circulation patterns. We parameterised the seasonal ground ice melt using a modified Stefan equation, whose key parameter, the effective thermal conductivity, was derived from the in situ measurements.

This study unravels the two thaw-season processes that render Murtèl rock glacier climate-robust, the seasonal ground ice turnover and convective cooling. First, the coarse blocky AL intercepts $\sim 90\%$ of the thaw-season ground heat flux of $\sim 5-15$ W m⁻² by melting ground ice (~ 70 %, latent storage change that leaves the system as meltwater) and by heating the rock mass (~ 20 %, sensible storage change). A smaller fraction ($\sim 10\%$) is transferred into the permafrost body beneath and causes slow permafrost degradation. The cumulative heat uptake of \sim 50–90 MJ m⁻² during the thaw season is primarily controlled by the date of its onset, i.e. the date of snow melt-out, and secondarily by the weather throughout the thaw season. Second, convective heat transfer selectively enhances cooling over warming (thermal semiconductor effect), as shown by time-varying effective thermal conductivity that increases from $1.2 \,\mathrm{Wm^{-1} K^{-1}}$ under strongly stable AL temperature gradients (weak warming) to episodically over 10Wm⁻¹K⁻¹ under unstable AL temperature gradients (strong cooling). The snow cover controls whether and which type of buoyancy-driven cooling convection takes place: first, Rayleigh ventilation typically occurs in autumn, when the atmosphere cools faster than the AL, and air density instabilities induce convective overturning. It is the most efficient cooling process, with episodically large, but short-lived upward fluxes up to $\sim 20 \,\mathrm{W}\,\mathrm{m}^{-2}$ under snowfree or snow-poor conditions. Second, beneath a semi-closed snow cover perforated by snow funnels, radiatively cooled air infiltrates into the AL. Cold-air infiltration/drainage leads to moderate, but persistent fluxes of $\sim 2-5$ W m⁻² that result in strong convective winter cooling in snow-poor winters. This cooling process is not diagnosed by Rayleigh numbers as the cold, dense air pools near the AL base but should not be overlooked in future heat transfer modelling. Third, no convection occurred beneath a closed/insulating snow cover; small heat fluxes (within 2 W m^{-2}) prevent a strong winter cooling.

Our field-based heat flux measurement and estimates of effective thermal conductivity $k_{\rm eff}$ are valuable for thermal numerical modelling. A thaw-season $k_{\rm eff}^0 = 1.2 \,{\rm W}\,{\rm m}^{-1}\,{\rm K}^{-1}$ under stagnant (no convection) conditions indicates that radiative heat exchange is an important heat transfer process in coarse blocky material. This finding, which agrees with geotechnical laboratory experiments with crushed-rock beds, has often been overlooked in the geomorphological literature, although it tends to counteract undercooling. In the strongly ventilated near-surface AL, atmospheric wind and penetrating warm air tend to enhance mechanical turbulence and increase $k_{\rm eff}$ (*wind-forced convection*), leading to a thaw-season-averaged $\overline{k}_{\rm eff} = 3 \,{\rm W}\,{\rm m}^{-1}\,{\rm K}^{-1}$. A Stefan parametrisation with this field-measured $k_{\rm eff}$ successfully simulated

the seasonal ground ice melt as measured in a nearby rock glacier furrow. Our measurement experience could guide future quantitative research, and our derived values could calibrate or validate numerical modelling studies like Renette et al. (2023) or Zegers et al. (2024). Mountain permafrost is entering uncharted territory where empirical relations based on past experience might no longer apply. Our study is a step towards process-based numerical modelling of coarse blocky landforms needed to anticipate their response to climate change.

Appendix A: Electrical heat transfer analogy and local thermal (non-)equilibrium (LTE, LTNE)

A question that arose (Fig. 9) is why the Q_{CGR3}^{rad} heat flux is correlated with daily average AL air temperature gradients, even though the thermal radiation is emitted by the rock surfaces, not by the air, and why the correlation deteriorates when taking hourly or 10 min data (Fig. A1a) or when taking near-surface HFP/2 data (Fig. A1b). After all, even moist air is virtually transparent to thermal radiation at length scales encountered in the AL pore space. The question is of practical relevance because AL temperatures are more conveniently measured in the pore space rather than inside the blocks. This perhaps puzzling observation can be explained by a thermal resistance circuit (an electrical analogue to the heat transfer) and local thermal (non-)equilibrium (LTE/LTNE), which is important to understand the measurements in porous media consisting of constituents with diverging thermal inertia, here rock particles and air.

In the unfrozen coarse blocky AL, the total heat transfer is composed of two "chains", air convection (turbulent fluxes $Q_h + Q_{le}$) in the pore space *parallel* to the heat transfer by the blocky matrix (Fig. A2). Heat transfer in the blocky matrix is composed of the heat conduction within the blocks $Q_{\rm c}$ and radiative heat transfer Q_r between blocks across the airfilled pore space (air is transparent to thermal radiation on the pore length scale). Since the blocks barely touch (clastsupported/open-framework), particle-to-particle conduction is negligible, and thermal radiation is the only heat transfer that links the blocks. Conduction and radiation operate *in series* (implying that $Q_{\rm r} = Q_{\rm c}$). Over timescales where a local thermal equilibrium (LTE) between air and blocks is reached ($\sim 1 d$) and in periods where convection does not dominate the heat transfer, locally uniform temperatures in the blocks and the air can be assumed. The different phases are no longer distinguished, and the entire coarse blocky AL is treated as an effective medium with a single temperature profile represented by the below-ground air temperature $T_{\rm al}$, which is more conveniently measured in the pore space (TK1) than inside the blocks (TK6). The overall heat transfer is treated as diffusive, which is true for conduction and applicable for thermal radiation in porous media (Fillion et al., 2011) but questionable for convection and described by the effective thermal conductivity $k_{\rm eff}$, which lumps together all three conductive, radiative, and convective processes in both "chains". Hence, such a k_{eff} is only meaningful at LTE timescales. As indicated by the relation between $Q_{\rm HFP} \approx Q_{\rm G}, Q_{\rm CGR3} \approx Q_{\rm r}$, and $\nabla_z T_{\rm al}$ that is valid for daily average values (minimum LTE timescale), the total heat flux

Figure A1. The heat flux plate measurements of HFP/1 (Q_{HFP}) and HFP/2 (not discussed in main text) are correlated with the thermal net radiation $Q_{\text{CGR3}}^{\text{rad}}$, but only for stable temperature gradients $\nabla_z T_{\text{al}}$ ($Q_{\text{HFP}} \propto Q_{\text{CGR3}}^{\text{rad}}$). Diurnal loops are stronger in the (**b**) HFP/2 data closer to the surface (at -1.1 m) because transient effects of the daily solar cycle are more intense than at (**a**) HFP/1 depth (at -2.0 m). At HFP/2, hourly heat fluxes shift direction, with heat moving upwards from the cavity into the block during warm afternoons in the thaw season, opposite to the downward daily average heat fluxes (black dots). Sign convention: positive means into the block (downward for HFP/1, upwards for HFP/2; Fig. 3). Note the different *y* axis. HFP/2 measurement available only after 26 July 2022.

 $Q_{\rm G}$ during most of the thaw season is represented by radiation Q_r and the measured Q_{CGR3} , $Q_r \approx Q_G$. At subdaily timescales or during strong convection events, LTE is no longer a valid assumption. This is shown by diverging AL air (TK1) and rock (TK6) temperatures and the different hourly pattern of the $Q_{\rm HFP}$ and $Q_{\rm CGR3}$ measurements $(Q_{\rm HFP} \not\approx Q_{\rm CGR3};$ Appendix B). Due to the thermal inertia of the blocks, rock temperatures and radiative heat transfer $Q_{\rm CGR3}$ lag behind AL air temperature and heat flux $Q_{\rm HFP}$. The total heat transfer is then adequately described by the local thermal non-equilibrium (LTNE) approach with phasespecific energy equations that account for the air-rock interface heat transfer (Marchenko, 2001; Zegers et al., 2024). The closer we look at the measurements gathered in the pore space of the AL, the more convective LTNE processes appear in the data.

Figure A2. Schematic heat transfer in a dry, unfrozen, coarse, blocky AL conceptualised as a resistance circuit. (a) Heat transfer modes (Sect. 4.1). (b, c) The total heat transfer Q_G arises from convection $Q_h + Q_{le}$ (in the pore space) in parallel with radiation-conduction, $Q_G = Q_h Q_{le} + Q_r$. Radiation-conduction is radiation Q_r in pore space and conduction Q_c in blocks in series. Figure inspired by Schneider (2014).

Appendix B: Sub-daily measurements reveal wind-forced convection

In the large and highly permeable instrumented main cavity, wind-forced convection transfers some heat to large AL depths $\sim 2 \,\mathrm{m}$ even under stable air stratification and increases the heat transfer rate compared to radiation-conduction alone (Sect. 6.3.1). Sub-daily data show the processes (Fig. B1) and show the link between above- and below-ground conditions: driven by the anabatic atmospheric wind (a thermal upslope wind that develops in the wind-sheltered cirque), AL airflow speeds are highest in the afternoon (Fig. B1b), precisely when the near-surface AL is most strongly heated, and temperature gradients are largest (Fig. B1a). The (comparatively) strong afternoon winds counteract the stabilising positive temperature gradients. Warm air masses penetrate the permeable coarse blocky AL (shown by the afternoon HFP/2 measurements that indicate a heat flux upwards into the block; Fig. A1b). Forced convection transfers the heat downwards in the late morning-afternoon parallel (electrical analogue in Appendix A) to the radiative-conductive "background flux" (as shown by the TK1 and HFP/1 Q_{HFP} data; Fig. B1a, d), to which AL rock temperatures and the AL thermal net radiation Q_{CGR3}^{rad} respond with some time lag (TK6/2 and Q_{CGR3}^{rad} peak in the evening; Fig. B1a, d). This pattern of atmospheric wind speed, AL airflow speed, and AL air temperature gradients that co-vary in phase is in turn an effect of the low-albedo debris surface (micro-topography) in the sheltered cirque (macro-topography) that gives rise to insolationdriven diurnal cycles. Such daily oscillations of the AL air and rock temperatures without time lag down to 2.9 m that indicate non-conductive heat transfer were also observed by Herz (2006) in the Ritigraben block slope.

Figure B1. Evidence for wind-forced convection from sub-daily data: August 2022 hourly averages of (a) temperatures (T_s , T_a , AL air TK1, AL blocks TK6), (b) temperature fluctuations $T' := T - \overline{T}$ (24 h running mean subtracted) and gradient $\Delta T_{al}/\Delta z$, (c) AL airflow and wind speeds, and (d) measured AL heat fluxes. (a, b) AL air temperatures (TK1, solid lines) and (c) AL airflow speeds down to 2.9 m (WS/1) show a daily course without time lag, only attenuated in amplitude. Rock temperatures (TK6, dash-dotted lines) lag behind AL air temperatures. (d) Q_{HFP} HFP/1 is in phase with airflow speed and AL air temperature gradient, whereas Q_{CGR3}^{rad} is in phase with the lagging rock temperatures TK6/2.

Appendix C: Simple relations for modellers

We found simple relations between the below-ground radiative heat transfer and ice melt rates during the thaw season and the (remotely measurable) ground surface temperature. The numbers are site-specific, slightly differ between the thaw seasons 2021 and 2022, and are far from exact. The relations should be used with caution and are certainly not valid on timescales shorter than a few days. We nonetheless report them here because they suffice for rough order-of-magnitude estimates and potentially lead to simple tools useful for remote sensing and modelling applications.

First, the radiative–conductive downwards heat transfer can be related to the surface temperature T_s on snow-free ground. Daily average in-cavity thermal net radiation Q_{CGR3}^{rad} is correlated with the 2 m air T_a ($R^2 = 0.738$ and 0.614 for 2021 and 2022, respectively; plot not shown) and the radiometric ground surface temperature T_s (derived from the PERMOS outgoing long-wave radiation; Amschwand et al., 2024) as long as T_s is above the freezing point (Fig. C1). The correlation slightly improves for T_s of the *previous day* rather than T_s of the same day (2022 R^2 increases from 0.723 to 0.786). Like \overline{k}_{eff}^{rad} , the Q_{CGR3}^{rad} – T_s relation also differs for the two thaw seasons 2021 and 2022, possibly due to the differing impact of convection that affects T_s and $\nabla_z T_{al}$ (note that the Q_{HFP} – Q_{CGR3}^{rad} –relation is identical for both thaw seasons; Fig. A1a). Below 0 °C and beneath snow-covered ground, the Q_{CGR3}^{rad} – T_s relation breaks down, and radiative fluxes remain small, within $\pm 2 \text{ Wm}^{-2}$, with Q_{CGR3}^{rad} magnitude and direction independent of the outside air or surface temperatures.

Second, a parameter used for modelling sub-debris melt rates on debris-covered glaciers is the thermal resistance. Assuming steady-state conditions, an effective thermal resistance $R_{\rm eff}$ [Km²W⁻¹] of the AL can be derived from the observed linear temperature profile (Fig. 9) and the linear $Q_{\rm CGR3}^{\rm rad}$ - $T_{\rm s}$ relation (Fig. C1; e.g. Nakawo and Young, 1981, 1982; Kayastha et al., 2000; Mihalcea et al., 2006; Fujita and Sakai, 2014; Rounce and McKinney, 2014),

$$R_{\rm eff} := \frac{h_{\rm al}}{\overline{k}_{\rm eff}^{\rm rad}} = \frac{T_{\rm s} - 0^{\circ} \rm C}{\mathcal{Q}_{\rm CGR3}^{\rm rad}},\tag{C1}$$

where $h_{\rm al}$ is the AL thickness (~4m, extrapolated from the linear temperature profiles). The inverse thermal resistance corresponds to thermal conductivity normalised by AL thickness. Both formulations yield similar values of $R_{\rm eff} \approx$ $1.0 \pm 0.2 \,\mathrm{K} \,\mathrm{m}^2 \,\mathrm{W}^{-1}$.

Third, the linear regression of the stake measurements (converted to melt heat flux $Q_{\rm m}$ using Eq. 7) with the ground surface temperature $T_{\rm s}$ also yields $Q_{\rm m} = -0.1 + (0.7 \pm 0.2)T_{\rm s}$ [W m⁻²] (Fig. 12d), which is consistent with the above $R_{\rm eff}$ derived from the radiation measurements (Eq. C1, taking $Q_{\rm m} = Q_{\rm r}$).

Figure C1. Thermal net radiation and ground surface temperature of the previous day are correlated beneath snow-free ground.

Appendix D: Notes on upscaling: variability in intrinsic permeability K and radiative thermal conductivity k^{r}

The contribution of non-conductive heat transfer by air convection and thermal radiation is conditioned by the intrinsic permeability *K* that generally increases with block/pore size. Here, we give quantitative formulae for how the two related key parameters, the intrinsic permeability *K* and the radiative thermal conductivity k^r , increase with effective particle size. The strong sensitivity of *K* and $k_{eff}^0 := k^r$ to debris texture at the landform scale needs be kept in mind when attempting to upscale from plot-scale measurements.

D1 Intrinsic permeability $K_{\rm KC}$

The intrinsic permeability K, an indication of the ability for fluids to pass through the porous medium, is commonly estimated via the Kozeny–Carman relation (Wicky and Hauck, 2020)

$$K_{\rm KC} = \frac{1}{4.25} \frac{\phi_{\rm al}^3}{5(6/d_{10})^2 (1 - \phi_{\rm al})^2},\tag{D1}$$

where $\phi_{al} = 0.4$ is the porosity, d_{10} a characteristic grain diameter such that 10% of the particles are smaller than d_{10} , and 1/4.25 is the empirical Côté et al. (2011) correction factor for coarse material. For a characteristic block diameter $d_{10} = 0.3$ m, Eq. (D1) predicts ~ 4.7 × 10⁻⁶ m², reasonably agreeing with the estimated 3×10^{-6} m² by Wicky and Hauck (2020) inferred from thermal numerical modelling. Although the Kozeny–Carman relation has not been rigorously tested for Murtèl-sized debris composed of non-spherical blocks, estimates from different studies are consistent (Herz, 2006; Wicky and Hauck, 2020; Côté et al., 2011), and the Kozeny– Carman relation has proven useful even in turbulent airflow regimes far from Darcian. The Kozeny–Carman relation implies that the permeability K scales with d_{10}^2 , suggesting lateral and vertical variability even on the same landform, as fine material is typically more abundant near the AL base.

D2 Radiative thermal conductivity k^{r}

Radiative thermal conductivity increases with block/pore size (actually the effective length for radiation between particles) and mean temperature cubed, $k_{\text{eff}}^0 = k^r \sim (d_{10}, \sigma \overline{T}^3)$. The larger the pores and the distance between particles, the larger the surface temperature differences across the pore space and the radiative thermal conductivity k^r since the resulting radiative flux

$$Q_{\rm r} = E\sigma (T_2^4 - T_1^4) \tag{D2}$$

is independent of the inter-particle distance (Fillion et al., 2011; Lebeau and Konrad, 2016). Radiative heat transfer bridges the pore space by bypassing the high conductive contact resistance between the blocks, whereas conduction transfers the heat within the blocks (Vortmeyer, 1979). Radiative heat transfer in porous media with opaque particles is effectively diffusive and along the temperature gradient, analogous to heat conduction. Hence, a radiative thermal conductivity k^r analogous to a (conductive) thermal conductivity can be defined. The radiative conductivity is obtained from linearisation of Eq. (D2) to recast it as a flux–gradient relation (diffusion equation) of the form $Q_r := k^r (\nabla_z T_{al})$ (using $(T_2^4 - T_1^4) \approx 4\overline{T}^3(T_2 - T_1)$; approximation valid for $(T_2 - T_1)/T \ll 1$) (Kaviany, 1995; Lebeau and Konrad, 2016; Esence et al., 2017; Rieksts et al., 2019),

$$k^{\rm r} = 4Ed_{10}\sigma \overline{T}^3. \tag{D3}$$

E is a semi-empirical exchange factor (that absorbs the surface emissivity ε and the rock thermal conductivity k_r and accounts for the particle arrangement), d_{10} the effective particle diameter (10% of the whole material mass has particles smaller than d_{10} ; Fillion et al., 2011), σ the Stefan–Boltzmann constant, and $\overline{T} := (T_1 + T_2)/2$ a characteristic mean temperature. Note that radiative heat transfer counteracts undercooling because k^r increases with temperature; i.e. at higher temperatures (during the thaw season), more heat is transferred under the same absolute temperature gradient (Fillion et al., 2011). This "radiative asymmetry" is opposite to the convective thermal semi-conductor effect. Using the semi-empirical Eq. (D3) (Eq. 11 in Fillion et al., 2011) yields $1.0 \le k_{\text{eff}}^0 \le 2.6 \,\text{Wm}^{-1} \,\text{K}^{-1}$ for $0.3 \le d_{10} \le 0.8 \,\text{m} \,(E := \varepsilon/(2 - \varepsilon), \varepsilon = 0.8, \overline{T} = 5 \,^{\circ}\text{C}, \sigma = 5.67 \,\times$

 10^{-8} W m⁻² K⁻⁴). As for K_{KC} , beware of extrapolation: due to the increasing thermal resistance, k^{r} no longer scales linearly for large blocks ("particle non-isothermality effect"; Singh and Kaviany, 1994; Ryan et al., 2020).

Appendix E: Seasonal patterns and drivers of air circulation

The seasonal airflow speed pattern controlled by the snow cover is shown in Fig. E1. At large AL depth (deepest WS/1 at -2.1 m; Fig. E2a), airflow speed was highest either with unstable air density stratification (Rayleigh ventilation) or with an isothermal cavity at high outside wind speeds (windforced convection). Atmospheric wind set the labilised air column down to the cavity base in motion. At stable AL air temperature gradients, airflow speed was overall low, but even then, airflow speeds tended to be higher under high atmospheric wind speed. The effect of wind-forced convection was weak, but detectable in the wide instrumented cavity down to 2m depth. Note the striking similarity with Fig. A1a. Near the surface (WS/6 in Fig. E2b-c), airflow speed was overall higher under snow-free conditions, increased with atmospheric wind speed (wind-forced ventilation), and was insensitive to the (at least mostly stable) vertical temperature gradient. The thicker the snow cover and the stronger the decoupling between the AL and atmosphere (AL-atmosphere coupling in Amschwand et al., 2024), the more important density contrasts became to drive the air circulation (buoyancy-driven ventilation), however at overall lower airflow speeds (Fig. E2b).

Figure E1. (b) Sub-surface airflow speed (WS) measurements with (a) wind speed and snow for context.

Figure E2. Drivers of ventilation. (a) Ventilation at depth (WS/1) is primarily buoyancy-driven (④). At stable stratification (positive temperature gradients), airflow speeds are low but enhanced by the atmospheric wind ①. (**b**, **c**) The near-surface ventilation (WS/6) transitions from mainly wind-driven (①) to buoyancy-driven circulation with increasing snow height (②, ③). The circled numbers ①–④ refer to Table 3.

Appendix F: Literature values for apparent thermal diffusivity κ_a

Literature values for the apparent thermal diffusivity κ_a in periglacial landforms, supraglacial debris, and cryic regosol are listed in Table F1.

Table F1. Literature values for the apparent thermal diffusivity κ_a .

Value $\kappa_a [m^2 s^{-1}]$	Landform/context	Reference
$ \sim 2.3 \times 10^{-6} 9.6 \times 10^{-7} \sim 10^{-2} - 10^{-5} 2.7 \times 10^{-6} (1.3 - 1.6) \times 10^{-6} 1.6 \times 10^{-6} \sim 10^{-3} - 10^{-4} 2 \times 10^{-7} (0.5 - 2.0) \times 10^{-5} 7 = 10^{-5} $	Murtèl rock glacier (ventilated) Murtèl rock glacier (stagnant) Murtèl–Chastelets periglacial area Chastelets AL Chastelets PF Murtèl bedrock Ritigraben block slope Juvvasshøe block field (AL) Openwork block field (stagnant)	This study This study Hanson and Hoelzle (2005) Schneider et al. (2012) Schneider et al. (2012) Schneider et al. (2012) Herz (2006) Isaksen et al. (2003) Juliussen and Humlum (2008)
$\begin{array}{c} (6.0-9.0)\times 10^{-7} \\ (9.50\pm 0.09)\times 10^{-7} \\ (6.41\pm 2.21)\times 10^{-7} \\ (1.6-2.0)\times 10^{-7} \end{array}$	Khumbu debris-covered glacier Ngozumpa debris-covered glacier Lirung debris-covered glacier Cryic regosol	Conway and Rasmussen (2000) Nicholson and Benn (2013) Steiner et al. (2021) Mendoza López et al. (2023)

AL: active layer; PF: permafrost body. See k_{eff} for supraglacial debris tabulated in Rowan et al. (2021).

Appendix G: Nomenclature

Variables, parameters, and constants used in this study are tabulated in Table G1.

Table G1. Nomenclature: measurement variables, parameters, dimensionless numbers, and constants.

Symbol	Unit	Name
Cp	$J kg^{-1} K^{-1}$	Isobaric specific heat capacity of moist air
$C_{\rm v}$	$Jm^{-3}K^{-1}$	AL volumetric heat capacity
$C_{\rm W}, C_{\rm f}$	$J kg^{-1} K^{-1}$	Specific heat capacity of water, rock
d_{10}	m	Effective particle diameter
E	1	Semi-empirical radiation exchange factor
$f_i(f_1, f_2)$	$m^{3}m^{-3}$	(Layer-wise) volumetric ice content
$H^{\theta}_{1}, \Delta H^{\theta}_{1}$	Jm^{-2} , Wm^{-2}	² Sensible heat storage (change)
h_{a1} , h_{s}	m	Thickness of coarse blocky AL, snow cover
hws	$W m^{-2} K^{-1}$	WS01 heat transfer coefficient
It	$^{\circ}C \times d$	Surface thaw index
K Kvc	m ²	Intrinsic AL permeability (estimated with the Kozeny–Carman equation Eq. D1)
kde	$Wm^{-1}K^{-1}$	Thermal conductivity of permafrost body
$k_{\rm FF} k^0$	$Wm^{-1}K^{-1}$	AL (stagnant) effective thermal conductivity
$\frac{\pi}{\tau}$ rad	$\mathbf{w} = \mathbf{w} = \mathbf{w}$	Description in the internal conductivity
^k eff	$W m^{-1} K^{-1}$	Pyrgeometer-derived average $k_{\rm eff}$
<i>k'</i>	$W m^{-1} K^{-1}$	Radiative thermal conductivity
$k_{\rm r}$	$W m^{-1} K^{-1}$	Rock thermal conductivity
$L_{\rm al}^{\rm V}, L_{\rm al}^{\rm T}$	Wm^{-2}	Down-/upwards thermal radiation
$Q_{\rm G}$	Wm^{-2}	Ground heat flux
$Q_{\rm h}, Q_{\rm le}$	$W m^{-2}$	Sensible and latent turbulent flux within AL
$Q_{\rm m}$	$\mathrm{W}\mathrm{m}^{-2}$	Ground ice melt heat flux
$Q_{\rm r}$ or L	$\mathrm{W}\mathrm{m}^{-2}$	Radiative heat flux (thermal radiation)
Q_{CGP3}^{rad}	$\mathrm{W}\mathrm{m}^{-2}$	Pyrgeometer net measurement
$Q_{\rm HFP}$	$ m Wm^{-2}$	Heat flux plate measurement
$\tilde{O}_{\rm PF}$	$\mathrm{W}\mathrm{m}^{-2}$	Permafrost heat flux
a, a^*	gg^{-1}	Specific humidity (at saturation)
1) 1 (1 ₂	gg^{-1}	Air specific humidity (2 m above ground)
<i>q</i> _{a1}	gg^{-1}	AL specific humidity
Raff	$K m^2 W^{-1}$	Effective thermal resistance (Eq. C1)
r	$m^3 m^{-2} s^{-1}$	Rainfall rate
, rH	m m 3 %	Relative humidity
SWE	kgm^{-2}	Snow water equivalent
	K°C	Surface temperature (coarse blocky AL snow surface)
Ta. Twb	K. °C	Air temperature (dry bulb, wet bulb)
T_{a1}	K, °C	AL temperature
$T_{\rm Pr}^{a_1}$	K, °C	Rainwater temperature
T_r	K, °C	Temperature in blocks
T_{CGR3}	°Ċ	Pyrgeometer housing temperature
$\frac{\mathrm{d}T_{\mathrm{al}}}{\mathrm{d}T_{\mathrm{al}}} := \nabla_{\tau} T_{\mathrm{al}}$	51 Km ⁻¹	Vertical AL temperature gradient
$dz \cdot \cdot z^{1}$	s. h. d	Time
u	ms^{-1}	Wind or airflow speed
 Uwe	ms^{-1}	WS01 airflow speed
" WS 7	m	Vertical coordinate
$\tilde{\beta}_{\rm e} \approx 1/T_{\rm c}$	$(273 \text{ K})^{-1}$	Air thermal expansion coefficient
$\rho_a \sim 1/10$	(275 K) 1	Surface emissivity (snow blocky surface)
د ۲	ı m	Depth of ground ice table
5 K. <u>K</u> .	$m^{2}s^{-1}$	Apparent thermal diffusivity (thaw-season log-mean average)
к а, к а	III S Dac	Air dynamic viscosity
μ_a	kam ⁻³	An uynanne viscosny Depsity of air roak ice
ρ_a, ρ_r, ρ_i	к <u>д</u> ш 1	Perovity of any total, total AI
Ψal	1	r drosny or coalse blocky AL
Dimensionle	ess numbers	
Ra	1	Rayleigh number (Eq. 3)
Constants (v	alue)	
g	m s ⁻²	Gravitational acceleration (9.81)
$L_{\rm m}$	Jkg ⁻¹	Latent heat of melting (3.34×10^5)
σ	$W m^{-2} K^{-4}$	Stefan–Boltzmann constant (5.670×10^{-8})
		· /

Data availability. The PERMOS data can be obtained from the PERMOS network (https://doi.org/10.13093/ 2021) and the permos-meteo-2021-01, Hoelzle et al., PERMA-XT measurement data from https://www.permos. ch/doi/permos-spec-2023-1 8 April 2025; (last access: https://doi.org/10.13093/permos-spec-2023-01, Amschwand et al., 2023).

Author contributions. DA performed the fieldwork, model development, and analyses for the study and wrote the manuscript. MS, MH, and BK supervised the study, provided financial and field support, and contributed to the manuscript preparation. AH and CK provided logistical support and editorial suggestions for the manuscript. HG designed the novel sensor array, regularly checked data quality, contributed to the analyses, and provided editorial suggestions for the manuscript.

Competing interests. The contact author has declared that none of the authors has any competing interests.
