Abstract

Results are presented from a pilot study of shoreface sediment dynamics on a steep, poorly sorted, coarse-grained, mega-tidal beach at the head of the Bay of Fundy, Nova Scotia, Canada. The experiment involved the first field deployment of a prototype wide-band, pulse-coherent, bistatic acoustic Doppler profiling system. Measurements of the vertical structure of flow and turbulence above a sloping bed, as well as bed material velocity, demonstrate the capabilities of this instrument vis-a-vis studies of nearshore sediment dynamics at the field scale. The second focus of the paper is the surprising observation that the surficial sediment median diameter, across the lower two-thirds of the intertidal zone, underwent a pronounced *decrease* when wave forcing was *more* energetic, compared to values observed during calmer conditions. The explanation for this result appears to involve the formation – in wave-dominated conditions – of O(1 m)-wavelength, 20 cm high ripples on the rising tide, which are then planed flat by the swash and/or the shorebreak on the subsequent ebb.

1 Introduction

During the past several years we have been developing a prototype wide-band acoustic Doppler profiler, the MFDop, for nearshore sediment and fluid dynamics studies in which the wave bottom boundary layer (WBBL) plays a significant role in the governing dynamics. The instrument, and results from laboratory investigations of turbulent oscillatory flow above fixed-roughness and mobile beds, are described in Hay et al. (2012) and the related articles cited therein. The laboratory experiments served as a proof-of-concept in preparation for deployment of the instrument in the field. This paper summarizes results from the first field deployment of the MFDop, in April–May 2012.

The experiment was carried out at Advocate Beach, located at the head of the Bay of Fundy. This site was chosen for several reasons. (a) The 10 to 12 m tidal range allowed the instrument platform to be set up at mid-tide level on the beach face at low

Interactive Discussion

5 tide, and similarly, the instrument platform could be accessed at low tide to service the instrumentation if required, without the need for diver support. (b) The beach is exposed to the > 500 km fetch of the Bay of Fundy and Gulf of Maine. (c) The beach is steep (1 : 10 slope), and measurements of sediment and wave dynamics on steeply sloping beaches are of interest in their own right (Rivero and Arcilla, 1995; Zou et al., 2006).

10 The beach itself is 5 km long, and the shoreline is nearly linear. The beach face sediments range in size from medium sand to 20 cm diameter cobbles. At low tide when the beach is fully exposed, the beach face is observed to be uniformly planar, with the exception of remnant cusps at the high and low water marks. The planar section of the exposed profile typically extends from immediately below the berm to the low water line, and can be as much as 100 m in horizontal extent in spring tides. In surveys conducted over the past 30 yr, the beach has remained planar and the 6 to 7° beach slope has persisted essentially unchanged (Fig. 1). This uniformly planar appearance at low tide is deceptive, however, as we shall demonstrate.

15 According to the classification scheme introduced by Jennings and Shulmeister (2002), the sand-to-cobble sediment size range and the 1 : 10 beach slope correspond to a mixed sand and gravel (MSG) beach. The 10 to 12 m tidal range indicates that Advocate can be classed as a megatidal rather than macrotidal beach (Levoy et al., 2000). The reader is referred to the informative reviews by Mason and Coates (2001) of MSG beach dynamics, and by Buscombe and Masselink (2006) of steep and coarse-grained – but pure gravel as opposed to MSG – beaches. Both reviews emphasize the point that there have been far fewer field investigations of flow and sediment dynamics on gravel and MSG beaches than on sand beaches.

25 Investigating the morphodynamic behaviour of MSG beaches is important for a variety of scientific and coastal management reasons, as outlined in the above reviews. Among the scientific reasons, one worth emphasizing here is the opportunity afforded by the poorly-sorted nature of the beach face sediments to study processes leading

to size-segregation, a topic of increasing interest across a wide range of space-time scales and sedimentary settings.

During the last decade, results from studies of sediment dynamics on MSG beaches have been reported by Allan et al. (2006); Ivamy and Kench (2006); Ciavola and Castiglione (2009); Curtiss et al. (2009); Dickson et al. (2011); Miller et al. (2011); Bertoni et al. (2012); Miller and Warrick (2012) and Bertoni et al. (2013). Of these only Ivamy and Kench (2006) and Curtiss et al. (2009) deployed instruments in the intertidal zone – i.e. where sensors would be subjected to the energetic conditions associated with the shorebreak. In the remaining studies, sediment movement in the intertidal zone was investigated using tracers alone – either radio-frequency identification tags (Allan et al., 2006; Dickson et al., 2011; Miller et al., 2011; Bertoni et al., 2012, 2013; Miller and Warrick, 2012) or fluorescent paint (Ciavola and Castiglione, 2009) – and information on the wave forcing was obtained from offshore buoys (Allan et al. (2006); Bertoni et al. (2012); Dickson et al. (2011), a pressure sensor in the nearshore either at or beyond the lower low tide level (Miller et al., 2011; Bertoni et al., 2012; Miller and Warrick, 2012; Bertoni et al., 2013), or estimated visually (Ciavola and Castiglione, 2009). Curtiss et al. (2009) deployed acoustic Doppler velocimeters (ADV) on bottom-mounted tripods in the intertidal, but reported only the peak near-bed velocity registered by these sensors. As far as we have been able to determine, the only study previous to the present work in which sensors have been deployed to measure flow and sediment dynamics in the intertidal zone of an MSG beach is that by Ivamy and Kench (2006, IK06), who deployed an ADV at the breakpoint. As will be seen, the results from the IK06 experiment are particularly relevant here. However, the sediment dynamics observations in IK06 were limited to active layer thickness measurements with depth-of-disturbance rods, supplemented by pre- and post-experiment bathymetric surveys.

The present paper is concerned with processes operating on storm, tidal and shorter – i.e. intra-wave and turbulence – time scales. As such, as far as we have been able to determine from the available literature at least, it is the first comprehensive investigation

of flow and sediment dynamics over this range of time scales in the intertidal zone – i.e. the zone affected by the shorebreak – on an MSG beach.

2 The Advocate Beach experiment

The central element of the experiment was the instrument platform shown in Fig. 2. This platform was installed in the beach face at mid-tide level (Fig. 1, solid black line), and supported the suite of instruments indicated in Fig. 3: (a) rotary sonars to measure the planform geometry and the cross-shore relief of features on the bed; (b) a Nortek Vector ADV to measure wave-current motions outside the WBBL; and (c) the MFDop. The instruments operated on a 15 min repeat cycle. The ADV sample rate was 4 Hz with a 18 mm sample volume. The MFDop acquired 10-ping ensemble-averaged profiles with 1.2 cm range resolution at 52 Hz. The MFDop and ADV record lengths were 4.5 and 4.8 min respectively. The rotary sonars acquired two full rotations with a 0.225° step size in azimuth and ca. 1 cm resolution in range. The MFDop and ADV ran simultaneously, and were followed by each rotary sonar in turn, thereby avoiding acoustic interference. (The operating acoustic frequencies for the instruments are: the MFDop, 1.2 to 2.3 MHz; the ADV, 6 MHz; the rotary sonars, 2.25 MHz).

Beach profile surveys and sediment sampling transects were carried out on a regular basis at low tide. Surficial sediment grain size distributions were determined from discrete 0.4 to 2.3 kg sediment samples by dry sieving, and from photographs of the beach face using a tripod-mounted camera fixed to a plywood base. Size distributions were determined from the photographs using the autocorrelation method developed by Rubin (2004). The relatively small volume of the discrete samples, and the small (20 cm × 40 cm) area of the photographs were such that reliable estimates of the cobble size fraction were not obtained. Further details on the sediment sampling and size analysis methodologies used in the 2012 experiment are given in Stark et al. (2014).

The 10 to 12 m tidal range, and the mid-tide location of the instrument platform, meant that the support structure for the platform would be subjected to non-negligible

Interactive Discussion

forces during significant wave forcing events. These forces were especially severe when the shorebreak passed the platform location on the rising or falling tide, as illustrated by the photograph in Fig. 4. It was also important that the frame legs be as thin as possible so as to minimize their effect on the local sediment dynamics. Consequently, the frame was constructed from 3.4 cm diameter steel pipe, and each of the four legs was bolted to a 100 kg foot buried about 1 m below the sediment–water interface (Fig. 3). The pressure housing for the data acquisition (DAQ) system was also buried, to minimize the total surface area of the exposed part of the platform. Power and communications – Ethernet and serial – to the DAQ were provided via buried cables.

3 Results

3.1 Forcing conditions

Time series' of the primary forcing parameters as registered by the ADV are plotted in Fig. 5: (a) water depth, h ; (b) significant wave height, $H_{1/3} = 4\sigma_p$, where σ_p is the RMS pressure, in m, in the wind wave band (Thornton and Guza, 1983); (c) significant wave orbital velocity amplitude similarly defined as $V_{1/3} = 2\sigma_v$, where σ_v is the square-root of the sum of the variances of two horizontal velocity components in the wave band; and (d) the wave angle of incidence, α , determined from the correlation between along- and cross-shore wave-band velocities. Typical peak periods were short – between 5 and 7 s – so the wind wave band was defined to be 0.05 to 0.7 Hz, the latter higher than the usual 0.3 Hz because of the high frequency content of the (fetch-limited) wave spectrum at Advocate. Mean currents (not shown) were weak: less than 0.25 ms^{-1} alongshore, and 0.07 ms^{-1} cross-shore. Noteworthy in relation to the results for bed roughness response presented later, the alongshore current maxima coincided with high tide, and alongshore currents were less than 0.08 ms^{-1} immediately after the shorebreak passed the instrument location on the rising tide.

Interactive Discussion

Conditions were relatively calm until YD130, when a wave forcing event lasting 4 days occurred (Fig. 5b and c). Significant wave heights and wave orbital velocities reached 1 m and 1 ms^{-1} respectively, with the highest values typically occurring on the rising tide in each case. The wave angle of incidence was near zero at these times: i.e. near normal incidence.

A data gap is apparent in the time series in Fig. 5: there are no data for the first tide on YD133. A major difficulty in making measurements in the intertidal zone on a steep beach with coarse-grained sediments is the risk of damage to the instrumentation from impacts with quite massive particles – i.e. gravel and possibly even cobbles – moving at m s^{-1} velocities. At Advocate Beach this difficulty is compounded by the prevalence of floating debris, including lumber from undermined shoreline structures, but the most serious risk was from logs up to 5 m or more in length, and up to 30 cm or more in diameter. The top of the dune, which is occasionally overtopped during severe winter storms, is littered with this material. During the experiment, a daily activity was to walk the length of the beach at low tide to remove logs and wood debris. However, at the height of the storm on YD132 with the tide rising, several large logs floating nearby and nightfall descending, we elected to remove the MFDop from the frame. In making the necessary changes to the data acquisition protocol the next tide (i.e. the first on YD133) was missed.

3.2 Bed roughness response

The time series of RMS bed roughness, σ_η – determined via the bed profiles extracted from the rotary pencilbeam sonar imagery (see Hay, 2011 and references therein for data processing details) – at the instrument frame location is presented in Fig. 6. Prior to the onset on YD130 of the four-day wave event, σ_η was small, with values ranging from 0.5 to 1 cm, the variations being largely due to the presence/absence of cobbles – see Fig. 2 – along the 4 m long cross-shore sweep of the sonar beam. As Fig. 6 demonstrates, a pronounced increase in the values of σ_η – by as much as an order of magnitude – occurred during the wave event. Notably, the highest RMS roughness

Interactive Discussion

values occurred on the rising tide. After the wave forcing died out at mid-day on YD134 (Fig. 5b and c), σ_η returned to pre-event levels.

The increased RMS roughness during the wave forcing event was due to the formation of up to 1.5 m wavelength, up to 20 cm height ripples, as demonstrated by the pencilbeam bed profiles in Fig. 7 and the fanbeam image in Fig. 8. There is a pronounced difference between ripple crest and trough in the texture of the fanbeam image, indicating that surficial sediments in the crests were composed of much finer sediment than that in the troughs, which included gravel and cobble-sized material up to 20 cm in diameter. The inference is that the coarse material in the troughs is a lag deposit, created by the gathering – via wave action – of the finer-grained and thus more mobile sand-sized material into the ripple crests (see Sect. 4).

As indicated by the roughness time series in Fig. 6, ripple formation occurred on the rising tide. The actual formation process was not captured in this data set, either because the rotary sonar transducers were not yet immersed in water – being about 0.5 to 1 m above the bed surface (Fig. 3) – or because bubbles from breaking waves obscured the seabed. The rapid rise rate of mean water level (3 m h^{-1} at mid-tide) places a stringent constraint on the ripple formation time (see Sect. 4).

The roughness time series also indicates that after initial formation, the ripples gradually decayed under the action of the waves as the mean water level continued to rise to high water and then fall. Importantly, the ripples were still present during the ebb up until the point that the sonars could no longer detect the bed. Figure 9 illustrates the persistence of the ripples, with little change in wave length despite the decay in ripple amplitude. Note too the slight offshore migration – by about a $1/4$ wavelength – during the hour after the first profile. This short duration, short distance migration – also observed in the fanbeam images – was typical: migration distances longer than half a wavelength were not observed.

Interactive Discussion

3.3 Beach face grain size response

Significant changes in the grain-size distribution of the surficial sediments were observed during the course of the experiment. As indicated by the time series of photographic estimates of mean size (Fig. 10), a pronounced *minimum* in the median grain size of the surficial sediments – averaged over the lower 2/3 of the beach face – coincided with the wave event. Grain size based on the sieve analysis indicates a similar fining of the surficial sediments during more energetic wave-forcing. The gravel and sand size fractions by weight, based on samples collected along the same cross-shore distance interval as the photographic results in Fig. 10 and the Udden–Wentworth scale, were 74 % and 26 % respectively on YD125 (10 samples), and 48 % and 52 % respectively on YD131 (8 samples).

Thus, perhaps counter-intuitively, *energetic* wave forcing led to *fining* of the beach face material. This result is surprising, as finer material is typically removed from a beach during the initial stages of a storm and during the winter storm season (e.g. Komar, 1998, chap. 7). Given the bed roughness results in the previous Section, the clear inference is that the fining of the surficial sediments was associated with the occurrence of the ripples, and was very likely due to infilling of the troughs with the fine material in the crests as part of the planing off process by the shorebreak and swash during the falling tide. (See Sect. 4.)

3.4 MFDop results

3.4.1 Vertical structure

One of the main goals of the Advocate Beach experiment was the deployment of the MFDop in the field for the first time. A primary scientific objective was to measure the vertical structure of the wave orbital motion, including the WBBL, because of the pronounced difference in the theoretically-predicted vertical structure of the wave shear

Interactive Discussion

stress above a sloping bed in breaking and non-breaking wave conditions (Rivero and Arcilla, 1995; Zou et al., 2006).

The vertical structure of the oscillatory motion in the wave band is presented in Fig. 11. The expected phase relationship between the cross-shore velocity, v ($-v$ is plotted so as to be positive shoreward), and the vertical velocity w (positive up) is evident: i.e. close to the bed, v and w are in phase, necessitated by the bottom slope and the condition of no flow normal to the bed so $w = v \tan \beta$ (β being the bed slope). Farther from the bed v and w tend toward quadrature (Fig. 12a) with shoreward velocity leading w , as expected for shoreward propagating waves. The magnitude of the corresponding wave shear stress is shown in Fig. 12b: the near-bed peak due to vertical turbulent momentum flux within the WBBL, and the decay of $\langle vw \rangle$ as height above the bed increases, are both consistent with the theoretical predictions (Zou et al., 2006).

The data in Fig. 11 correspond to a time of weak wave forcing when the bed was nominally flat (Figs. 6 and 7). As the existing theory has been developed for flat bed only, however, the development of the large-amplitude ripples during energetic conditions has so far precluded comparisons between theory and experiment under breaking waves within the context of this data set.

3.4.2 Wave bottom boundary layer turbulence

The MFDop is designed to be turbulence-resolving in order to obtain estimates of the Reynolds stress in the WBBL. The vertical velocity spectral density, S_{ww} , at 3 cm height above bottom is plotted in Fig. 13. Three spectra are shown. Because of the 5-transducer geometry of the MFDop (Fig. 2), three independent measurements of the vertical velocity are obtained: one from the centre transducer, and one from each of the two opposed outboard transducer pairs. The spectra in Fig. 13 exhibit a well-defined inertial subrange. The noise level in the spectrum for the vertical beam is noticeably higher: this is because the signal level from the centre transducer is attenuated by the transmit/receive switch in the analog electronics.

Interactive Discussion

3.4.3 Bed material velocity

The MFDop was also developed to measure the velocity of material moving on the bed surface – i.e. the velocity of bedload material – and ultimately the bedload transport. The poorly sorted nature of the bed material at Advocate is such that estimating the transport was not tractable. The velocity of the bed material was measured, however, as Fig. 14 demonstrates. Plotted in Fig. 14 are: (a) net along- and cross-shore bed material displacements – i.e. the time integral of the bed velocities from the MFDop – over the 260 s length of the record; (b) the time series of u and v outside the WBBL as registered by the Vector ADV; (c) the cube of the envelope – i.e. the amplitude v_0 – of the cross-shore velocity, obtained via the Hilbert transform of v in panel b. There is a clear relationship between v_0^3 and the times of significant cross-shore displacement of bed material.

4 Discussion

We now return to the connection(s) between grain size segregation during ripple formation and the decrease in the median diameter of the beach face sediments during energetic wave forcing. There are eight main points to consider: (1) the ripples formed rapidly; (2) they are orbital-scale ripples; (3) the energetic shorebreak; (4) the very broad sediment size distribution; (5) the always planar beach face at low tide; (6) the $O(10\text{ cm})$ thickness of the fine sediment veneer; (7) the constant mean elevation of the beach face at the frame location; (8) the constant height of the pencilbeam above mean bed level.

The rate of water level rise at mid-tide was 3 m h^{-1} , so the length of time between mean water level arriving at the frame location and then rising to the 1 m height of the pencil beam sonar would have been 20 min. Thus, no more than 20 to perhaps 30 min were available for the ripples to form.

Interactive Discussion

Orbital scale ripples – sometimes called vortex ripples – are characterized by wavelength, $\lambda = K d_0$, where K is a proportionality constant and d_0 is the near-bed wave orbital excursion: i.e. with U_0 the near-bed orbital velocity amplitude and T_p the peak wave period, $d_0 = U_0 T_p / \pi$. For equilibrium ripples K is between 0.6 and 0.7 and the aspect ratio d_0 / λ is 0.2 (Clifton and Dingler, 1984; Traykovski et al., 1999, many others). The ripples in Fig. 7 are 20 cm high and 1.5 m long, yielding 0.13 for the observed aspect ratio. During ripple formation $U_0 \sim 1 \text{ ms}^{-1}$ (Fig. 5c), and $5 \lesssim T_p \lesssim 7 \text{ s}$ based on the pressure sensor power spectra (not shown). Thus, the expected – equilibrium – wavelength would be between 1.7 and 2.4 m, comparable to but longer than the observed value. The 20 min formation time and 6 s typical wave period correspond to only 200 wave cycles, and during this time the wave orbital velocity at bed level would not have been quasi-steady due to the rapidly changing water depth. Consequently, the ripples were unlikely to have been in equilibrium with the forcing during formation, consistent with the fact that the steepness and wavelength are somewhat low. Furthermore, lower steepness is expected in irregular wave conditions, as demonstrated by Nielsen (1981). The gravel lag in the troughs might also have been a contributing factor. See below.

The height of the pencilbeam sonar above mean bed level is plotted in Fig. 15a. Each point represents the vertical distance from the sonar head to the least-squares best-fit straight line through the bed profile within $\pm 2.3 \text{ m}$ of the sonar's cross-shore location. (This best-fit line was subtracted from the measured profile to obtain the bed elevation profiles with the slope removed in Fig. 7, and the RMS bed roughness values in Fig. 6.) The values of bottom slope, β , obtained from the best fit are shown in Fig. 15b, indicating that the local bed slope remained essentially constant at its 6.3° average value prior to the storm, and changed by at most 0.5° during the storm. The data points in Fig. 15a demonstrate that the height of the pencilbeam above mean bed level remained essentially constant, varying by less than 1 cm even during the rippled bed interval, YD130–133. Simulations (not shown) – with 1 to 1.5 m wavelength, 20 cm high sinusoidal ripples on a 4.6 m long 6.5° slope centred at $x = 0$, $z = -1 \text{ m}$ – indicate that the 1 cm variations in height and 0.5° variations in bed slope during the storm interval

can be attributed to the non-integral number of ripples within the 4.6 m long profile. The implication is that – to a first approximation – sediment was locally conserved: i.e. the ripples were built up mainly from local sediments, and then when later planed flat the troughs were infilled mainly with the sediments from the nearby crests.

The fact that as little as 20 min are available for ripple formation indicates that the fine-grained material in the ripple crests could not have come from elsewhere. The source had to be the local beach face. Thus, as illustrated in Fig. 16 and described below, a four-stage scenario is indicated involving: (a) non-size-selective sediment mobilization by the shorebreak; (b) ripple formation; (c) partial decay; and (d) erasure. *Mobilization*: it is highly likely that the intense shorebreak played an important role, generating forces sufficient to produce movement of the larger stones as well as the finer material. We do have evidence – from a second experiment in October–November 2013 – of the swash and shorebreak displacing stones and cobbles. It is also possible that a step in the beach profile – a common feature at the shore break on steep beaches (e.g. Buscombe and Masselink, 2006) – was a contributing factor in the development of the ripples (last paragraph, this Section), although we have no direct evidence of a step being present. Regardless of the presence/absence of a step, the physical picture is of the shorebreak advancing rapidly up the beach face with the rising tide, and mobilizing sediment of all sizes. *Formation*: after the passage of the shorebreak, the ripples would have started to form. Typically, vortex ripples develop from smaller ripples (Bagnold, 1946; Sleath, 1984, many others). Once the lee vortex forms, growth continues as the vortex sweeps material out of the troughs toward the crests. In our case, material too big to be mobilized by the turbulent stresses in the lee vortex would have remained in the troughs, creating the cobble lag seen in the sonar images. At this point growth would have stopped, providing an additional reason for the somewhat low steepness: i.e. crests starved of sediment supply. *Decay*: as the flood progressed the ripple amplitudes gradually decayed, by as much as 50 % (Fig. 6). This decay was due to depth-controlled reduction in wave forcing at the bed – the associated nearbed orbital excursion would have been incompatible with the scale of the ripples – and the

background turbulence associated with the waves and mean current (which peaked at high tide). The ripples did not rebuild on the ebb. *Erasure*: as the swash and shore-break passed the frame again on the ebb, the ripple crests were planed off, and the troughs infilled with fine sediment, resulting in the layer of fine sediment on the beach face. The observed thickness of this layer was 5 to 10 cm, consistent with the 20 cm trough-to-crest height of the ripples.

Laboratory studies of vortex ripple formation in heterogeneous sediments have been carried out by Foti and Blondeaux (1995, FB95) and by Rousseaux et al. (2004, R04). Binary mixtures of sand-size (glass) particles were used: 0.65 mm and 1.5 mm diameter (FB05); and 0.15 mm to 0.355 mm (R04). The finding in both studies was that coarser-grained material accumulated at the ripple crests, not in the troughs. However, the larger and smaller particle diameters differed by less than a factor of 3, compared to the factor of 200 between the mm-sized sand and 20 cm diameter cobbles at Advocate Beach. It is clear that the coarsest sediment in the FB05 and R04 experiments was mobile during ripple formation, whereas our observations indicate that the stone/cobble-sized material was likely not (i.e. certainly not once the the shorebreak had passed the frame location at least).

Segregation of fine/coarse material in the crests/troughs of *dunes* in unidirectional flow – i.e. “downward coarsening” – dates back to Bagnold in 1941, and was recently investigated in a flume experiment by Blom et al. (2003). Three points regarding the latter study are particularly relevant here: (1) the grain size distribution was broad, a factor of 10 separating the large and small particle diameters, and so more comparable to Advocate than the FB05 and R04 studies; (2) coarse-grained layers formed at trough level beneath the migrating dunes; (3) sweeping of finer material from the troughs by turbulence in the lee vortex was suggested as a contributor to the coarse lag in the dune troughs.

We briefly consider the possible role of hydraulic conductivity, which Mason and Coates (2001) considered “perhaps the most distinctive property which distinguishes a mixed beach”. In the Advocate 2012 experiment a pressure sensor was buried in the

tions showed this process generated undulating bedforms of mixed sand and gravel to the limit of breakpoint step migration (Fig. 10a and b)". The "process" IK06 refer to is the migration across the beach face of intense sediment reworking in the breaker zone. The IK06 beach was exposed to Pacific Ocean swell, so waves were breaking on the beach even between their two wind-wave events, and hence the ever-present step. In contrast, Advocate Beach faces the fetch-limited Bay of Fundy/Gulf of Maine system and is therefore seldom subjected to ocean swell, and was not during the 2012 experiment (as indicated by the low wave-band orbital velocities in Fig. 5). Thus a step was not present at low tide level during the time periods with weak wind-wave forcing. Although we have no direct evidence of a step being present during the storm, it is conceivable that a step was present – but possibly nascent given the rapidity of the shorebreak advance up the beach face – and passed the frame location before the sonars were able to detect the bed. If the IK06 undulating bedforms are taken to be orbital (vortex) ripples, their visual observations suggest that the ripples at Advocate Beach might have formed in the wake of a (possibly nascent) breakpoint step associated with the shoreward-migrating breakpoint. Then the usual initial stages in vortex ripple development from flat bed – the formation and subsequent coalescence through wavelength doubling of short-wavelength low-amplitude ripples – would have been short-circuited. Instead, ripples would form at a scale commensurate with the amplitude and steepness of the nascent step, a scale necessarily much larger than that of small-scale rolling grain or anorbital ripples (Bagnold, 1946; Sleath, 1984). Thus, with the migrating (nascent) step being the initial perturbation of an otherwise flat bed, vortex ripples would have formed much more rapidly than otherwise.

5 Summary and conclusions

During active transport conditions dominated by wind-wave forcing, ripples up to 1.5 m (20 cm) in wavelength (height) were observed to form at the mid-tide level. Textural differences in the rotary sonar imagery indicate that the ripple crests were composed

Interactive Discussion

of fine-grained sediment, while the ripple troughs were lined with gravel and cobbles up to 20 cm in diameter. We infer that the finer material was gathered into the ripple crests, leaving a gravel-and-cobble lag in the troughs. Following their formation on the rising tide, the ripples persisted – though with decreasing amplitude – until the last observations on the falling tide when the instruments were no longer continuously submerged. At low tide, when the beach was again fully exposed, the ripples were no longer present, and the beach face had returned to its planar state. We conclude that the ripple crests had been planed flat by the high bed shear stresses under the swash and shorebreak.

The grain size of the surficial sediments in the intertidal zone, sampled at low tide when the beach face was fully exposed, exhibited a pronounced *minimum* coinciding in time with *maximum* wave-forcing: the average median diameter was reduced from that during calm conditions by a factor of 4. We conclude that the flattening of the ripple crests by the swash/shorebreak during ebb was accompanied by infilling of the troughs with the finer-grained crest material, resulting in a uniform, O(10 cm) thick veneer of sand-sized sediment and return to a planar beach face at low tide.

The MFDop results are promising. The vertical structure of wave-band motions exhibits the features predicted by theory over a sloping bed: i.e. transition from vertical and cross-shore velocities being in quadrature far from the bed to in-phase as the bed is approached; a near-bed maximum in the wave shear stress associated with the wave bottom boundary layer; and – under non-breaking waves – a linear decay in the wave shear stress with height above the bed. Vertical velocity spectra exhibit a well-defined inertial subrange indicative of turbulence within the wave bottom boundary. Finally, the measurements of the velocity of material at bed level indicate a u^3 -dependence, and thus promise for field measurements of bed material transport in the future.
