## Abstract

Considering the relationship between erosion rate and the relief structure of a landscape within a non-dimensional framework facilitates the comparison of landscapes undergoing forcing at a range of scales, and allows broad scale patterns of landscape evolution to be observed. We present software which automates the extraction and processing of relevant topographic parameters to rapidly generate non-dimensional erosion rate and relief data for any landscape where high resolution topographic data is available. Individual hillslopes are identified using a connected components technique which allows spatial averaging to be performed over geomorphologically meaningful spatial units, without the need for manual identification of hillslopes.

The software is evaluated on four landscapes across the continental United States, three of which have been studied previously using this technique. We show that it is possible to identify whether landscapes are in topographic steady state. In locations such as Cascade Ridge, CA a clear signal of an erosional gradient can be observed. In the Southern Appalachians, non-dimensional erosion rate and relief data is interpreted as evidence for a landscape decaying following uplift during the Miocene. An analysis of the sensitivity of this method to free parameters used in the data smoothing routines is presented which allows users to make an informed choice of parameters when interrogating new topographic data using this method. A method to constrain the critical gradient of the nonlinear sediment flux law is also presented which provides an independent constraint on this parameter for three of the four study landscapes.

## 1 Introduction

The Earth's surface evolves dynamically in response to the interplay of climatic, tectonic and other factors operating at timescales ranging from minutes to millenia. High resolution topographic data generated from terrestrial and airborne laser scanning, in combination with increased computational power has facilitated a revolution in geomor-

phology, allowing the quantitative interrogation of landscape form to provide insight into the forces shaping a landscape. Relationships have been found between topography and the tectonic (e.g., Wobus et al., 2006; Hilley and Arrowsmith, 2008; DiBiase et al., 2012; Hurst et al., 2013a), climatic (e.g., Gabet et al., 2004; Anders et al., 2008; Champagnac et al., 2012) and biotic (e.g., Roering et al., 2010; Milodowski et al., 2015a) forcing of a landscape in addition to links between topography and bedrock properties (e.g., Korup, 2008; Clarke and Burbank, 2010, 2011; Hurst et al., 2013b).

Such fundamental relationships provide important insight into landscape evolution, however many of these techniques are challenging to implement, require proprietary software or have varied or poorly defined methods published to obtain similar results. This highlights the need for standardized techniques and tools to allow the analysis of topographic data to be reproduced and falsified, strengthening our understanding of the processes that shape planetary surfaces. In this contribution we focus on methods exploiting high resolution topographic data in soil mantled landscapes that aim to elucidate both sediment flux laws (c.f., Dietrich et al., 2003) and the transient evolution of landscapes (e.g., Hurst et al., 2013a).

Our approach is rooted in a non-dimensional framework that describes relationships between erosion rates and hillslope topography in soil mantled landscapes (Roering et al., 2007). This framework facilitates the direct comparison of landscapes of widely varying morphology and process. It has been shown to provide compelling insight into the identification of landscape transience (Hurst et al., 2012), complex tectonic signals from topography (Hurst et al., 2013a), and process controls on the density of channels (Sweeney et al., 2015). Extracting the nondimensional parameters from high resolution topography can be difficult, subject to choices about how the metrics are calculated, and there has been no investigation into how different methods might influence results, and therefore the interpretation of landscapes.

Here we present a framework and methodology for extracting the required topographic parameters and processing the resulting data. Our software uses a clear methodology to allow researchers to generate this data for new landscapes and can

replicate published relationships between non-dimensional erosion rate and relief. Such relationships can be used to discriminate between landscapes in topographic steady state, where erosion rate is balanced by uplift rate, and those undergoing transience or topographic decay.

5 Additionally we present a method for generating spatially contiguous hilltop patches, required as a spatial averaging tool in many studies (e.g., Perron et al., 2009; Hurst et al., 2012, 2013a) to identify individual hillslopes for analysis. An analysis on the influence of spatial averaging and data smoothing on the interpretation of topographic data is undertaken and hillslope and basin average data is also used to estimate the  
10 critical gradient, a key parameter in the nonlinear sediment flux model.

## 2 Theoretical background

One end-member sediment flux law is the nonlinear sediment flux law (Andrews and Bucknam, 1987; Roering et al., 1999, 2001, 2007),

$$\bar{q}_s = \frac{KS}{1 - (|S|/S_c)^2}, \quad (1)$$

15 where  $S$  is the topographic gradient in dimensions of Length/Length (dimensions denoted in square brackets as  $[L]$ ength,  $[M]$ ass and  $[T]$ ime),  $S_c$  (dimensionless) is the hillslope critical gradient,  $K$  [ $L^2T^{-1}$ ] is a sediment transport coefficient and  $\bar{q}_s$  [ $L^2T^{-1}$ ] is a volumetric sediment flux per unit contour length. As  $S$  tends towards  $S_c$ , the sediment flux asymptotically increases towards infinity, corresponding to an increase in  
20 landsliding on an increasingly planar hillslope.

Roering et al. (2007) modeled the relief structure of theoretical one-dimensional hillslopes which evolve under Eq. (1) and found that relief, the difference in elevation between a hilltop and the point on the channel it is coupled to, is controlled by the erosion rate, hillslope length and the sediment transport coefficient. Equation (1) has

Interactive Discussion

been found to be consistent with observations of topography and erosion rates across several landscapes (e.g., Roering et al., 1999, 2007; Roering, 2008; Hurst et al., 2012)

Roering et al. (2007) normalized relationships describing these one-dimensional hillslopes using topographic parameters to produce a dimensionless erosion rate,

$$E^* = \frac{E}{E_R} = \frac{\rho_r}{\rho_s} \cdot \frac{2EL_H}{KS_c} = \frac{-2C_{HT}L_H}{S_c}, \quad (2)$$

where  $E [LT^{-1}]$  is the erosion rate,  $\rho_r$  and  $\rho_s [ML^{-3}]$  are the rock and soil bulk densities, respectively,  $C_{HT} [L^{-1}]$  is the hilltop curvature,  $L_H [L]$  is the hillslope length,  $E_R [LT^{-1}]$  is a reference erosion rate denoted as:

$$E_R = \frac{KS_c}{2L_H(\rho_r/\rho_s)}, \quad (3)$$

and the dimensionless relief is given as:

$$R^* = \frac{R}{S_cL_H}, \quad (4)$$

where  $R [L]$  is the topographic relief. Parabolic hillslope profiles are generated when  $E^*$  values are less than or equal to one, such that  $R^*$  increases approximately linearly with erosion rate. Planar hillslopes near the critical gradient,  $S_c$ , indicate that  $R^*$  is insensitive to erosion rate when  $E^*$  approaches or exceeds one. This prediction is consistent with observations that when erosion rates are high, relief becomes limited by a critical slope angle (e.g., Binnie et al., 2007; DiBiase et al., 2012). A combination of high  $E^*$  and  $R^*$  values indicates a landscape with steep, planar hillslopes and frequent landsliding whereas low values suggest more convex hillslopes with lower overall relief (Roering et al., 2007).

Interactive Discussion

For landscapes in topographic steady state with uniform erosion rates, values of  $E^*$  and  $R^*$  will plot on the steady state curve described by:

$$R^* = \frac{1}{E^*} \left( \sqrt{1 + (E^*)^2} - \ln \left( \frac{1}{2} \left( 1 + \sqrt{1 + (E^*)^2} \right) \right) - 1 \right). \quad (5)$$

Steady state hillslopes which experience spatially uniform erosion rates will plot on a single point on the curve (Roering et al., 2007), whereas landscapes experiencing an erosion gradient will plot at many points along this curve, as demonstrated by Hurst et al. (2012). These non-dimensional landscape properties have utility beyond steady state landscapes. Hurst et al. (2013a) used this formulation to distinguish between growing and decaying parts of a landscape by identifying hysteresis in  $E^*R^*$  space. Sweeney et al. (2015) has applied similar techniques to analogue landscape evolution models to demonstrate that the efficiency of hillslope sediment transport controls drainage density. These cases of differing landscape properties and histories highlight the power of using topography and  $E^*R^*$  analysis to interpret landscape evolution.

### 3 Hilltop patches

The extraction of signals from high resolution topographic data can often require smoothing of raw data to filter out both topographic and artificial noise (Lashermes et al., 2007; Roering et al., 2010; Sofia et al., 2013). This smoothing can be performed either by processing the raw DEM before any analysis is performed (e.g., Roering et al., 2010), or by smoothing the output data (e.g., Tucker et al., 2001; Tarolli and Dalla Fontana, 2009). In order to understand landscape properties at a hillslope scale it is often desirable to perform local smoothing to group individual DEM pixels into collections of pixels that correspond to individual hilltops and their connected hillslopes.

This was performed by Hurst et al. (2012) through a process of vectorizing hilltops, then splitting the vectors by a threshold length and discarding all split segments shorter than an arbitrary length of 50 m. The final split vectors are then converted back into

rasters, to create a network of hilltop patches of a defined minimum length. These patches are typically 2 pixels wide, spanning both sides of a drainage divide. This technique is challenging to reproduce, as it relies upon several user defined parameters and a subjective assessment of which vector segments to discard.

### 3.1 Automated generation of hilltop patches

Connected components analysis is a technique typically used in computer vision to label contiguous pixels in raster images (e.g. Rosenfeld and Pfaltz, 1966; Samet, 1981; Lumia et al., 1983; Dillencourt et al., 1992; Suzuki et al., 2003; He et al., 2013). Here, we implement a computationally efficient connected components algorithm developed by He et al. (2008) to generate contiguous hilltop patches, resulting in a network of hilltop patches, each coded with a unique ID number. Finally, in order to allow better replication of the original concepts used in Hurst et al. (2012) a minimum patch area can be supplied, which is used to remove any hilltop patches which are smaller than this user defined threshold.

This hilltop patch identification method is very efficient and has been demonstrated to operate effectively on large, complex images (He et al., 2008) without an impact on performance. This technique has utility beyond  $E^*R^*$  calculations, as it can be used in any work where discrete patches of hilltop need to be identified (e.g., Perron et al., 2009) or where individual hillslopes must be analyzed using topographic data.

## 4 Generating topographic data

### 4.1 Extraction of a channel network

A key component of most topographic analysis is the delineation of a channel network, without which many topographic parameters cannot be estimated. Channel networks can be extracted either by using a process based method which uses the stream power model to identify the point in a landscape where fluvial processes begin to dominate

over hillslope processes (Clubb et al., 2014) or by using a geomorphometric method which identifies channels using curvature thresholds (Passalacqua et al., 2010; Orlan-  
dini et al., 2011; Pelletier, 2013).

In order for the  $E^*R^*$  data to capture the true range of erosion rates and reliefs  
inherent in a landscape, it is important to define a channel network which correctly  
identifies the hillslope-fluvial transition, including the delineation of colluvial channels  
which are often challenging to identify using non-geomorphometric methods (Pelletier,  
2013). Here we follow Pelletier (2013) and apply a Wiener filter (Wiener, 1949) to re-  
move noise from the raw topographic data. Subsequently, channelized portions of the  
drainage network are identified based on a tangential curvature threshold (e.g., Pel-  
letier, 2013). The appropriate curvature threshold is identified from the properties of its  
quantile–quantile plot (e.g., Lashermes et al., 2007; Passalacqua et al., 2010). These  
channelized patches of the landscape are combined by performing a connected compo-  
nents analysis (He et al., 2008) which merges discreet patches of channel into a con-  
tinuous channel network. Following methods outlined in Grieve et al. (2015) floodplain  
masks are also created and combined with this channel network, which separates the  
landscape into two domains; hillslopes and channels. This has the effect of terminat-  
ing hillslope traces when they reach a hollow or enter the floodplain, ensuring that the  
trace properties only reflect the hillslope domain and the  $E^*R^*$  measurements are not  
contaminated by sampling parts of the landscape which the nondimensional framework  
does not apply to.

## 4.2 Extraction of topographic parameters

All of the key measurements required to generate  $E^*R^*$  data can be extracted from high  
resolution topography (Roering et al., 2007). Calculation of  $E^*$  using Eq. (2) requires  
hillslope length and hilltop curvature, and calculation of  $R^*$  using Eq. (4) requires the  
relief and hillslope length to be measured from high resolution topography.

Grieve et al. (2015) measured hillslope length by generating overland flow paths  
running from hilltop to channel pixels for every hilltop in a DEM, thereby generating

a diverse range of measurements shown to characterize the range of hillslope properties inherent within a landscape. From these traces, each hilltop's local relief is also measured by taking the difference between the elevation at the start (hilltop) and end (channel) of each trace. Finally, the hilltop curvature for each hilltop pixel is extracted following Hurst et al. (2012) whose techniques demonstrated that hilltop curvature scales linearly with erosion rate below hilltop gradients of 0.4. Correspondingly, we also sample the hilltop gradient ( $S_{HT}$ ) at the start of each trace, to allow data to later be filtered by this value. By using the methods outlined by Grieve et al. (2015) we can generate a four-tuple of information for each hilltop pixel in the landscape containing ( $L_H, R, C_{HT}, S_{HT}$ ).

**4.3 Smoothing topographic parameters**

In previous studies that generate  $E^*R^*$  data, some form of smoothing has been employed to extract meaningful trends from the inherently noisy topographic data. Roering et al. (2007) hand selected basins with uniform morphologies and minimal anthropogenic disturbance to measure topographic parameters from, effectively removing the majority of noise in the landscape and producing a small number of data points considered to be characteristic of their 2 steady state landscapes.

Hurst et al. (2012) used semi-automated methods to extract the required topographic parameters, and averaged the resulting data spatially over hilltop segments of a defined minimum length. Hurst et al. (2013a) utilized the same methodology, but further averaged the data by grouping segments into bins defined by their distance along the Dragon's Back Pressure Ridge, to explore the topographic expression of a transient uplift signal along the ridge. As these techniques do not self select idealized hillslopes or basins as in Roering et al. (2007) some filtering of the raw data was required (see Sect. 5.1). These latter methods allow  $E^*R^*$  data to be used to interrogate transient landscapes, increasing the power of the method and providing a vital tool in the topographic analysis of landscapes.

Interactive Discussion

Here, we extract topographic parameters from raw topographic data and smooth the resulting measurements, in accordance with previous authors' methods, firstly performing spatial averaging at a basin scale. The basins that are used to average the topographic parameters can be defined in an automated manner to produce an average value over all basins of a given stream order, or a more user defined approach can be undertaken to select basins manually, in order to more closely replicate the work of Roering et al. (2007). Secondly the parameters can be averaged at a hillslope scale by using the discrete hilltop patches generated using the technique outlined in Sect. 3.1. The data is filtered using the same constraints outlined in Hurst et al. (2012), removing hilltops with a  $S_{HT} > 0.4$  or a patch size  $< 50$  m, with the additional filtering of hillslope length and relief values below a user defined threshold, typically 2–5 m for each parameter; this ensures that hilltops sampled are true hilltops and are not interfluves sitting adjacent to a basin outlet, which will not conform to models of hillslope sediment transport. The data is also returned to the user filtered, but not averaged, allowing users to explore the raw data to ensure that the smoothed data is a good reflection of the overall trends inherent in a landscape.

## 5 Processing the topographic data

Once the topographic data has been extracted, it is filtered to ensure that only data which conforms to the nondimensional framework described by Roering et al. (2007) is used in any further analysis.

### 5.1 Filtering

The key filtering process which must be performed is the removal of any data points which have an  $S_{HT}$  above 0.4. This threshold gradient was shown by Hurst et al. (2012) to be the point at which hilltop curvature stops scaling linearly with erosion rate, for a range of  $K$  values representative of values published for our fieldsites (Roering et al.,

1999, 2007; Matmon et al., 2003; Hurst et al., 2012), and therefore cannot be used in Eq. (2) as a proxy for erosion rate. Across all of the datasets, gradients which exceed 0.4 are removed from further analysis. In the case of the two spatially averaged datasets individual hilltop pixels which exceed this threshold gradient within a patch or basin, are removed from the averaging process for each measurement ensuring that no invalid data contributes to the final calculations. To ensure the validity of each basin average measurement, a count of the valid pixels contained within each basin following gradient filtering is performed and any basins with fewer valid measurements than a user defined threshold can be removed from the analysis. This threshold is typically equal to the minimum patch size used in Sect. 3.1 as this provides consistency between measurements.

## 5.2 Log binning

One method of non-spatial averaging of geomorphic data used effectively to generate slope-area plots (e.g., Tarolli and Dalla Fontana, 2009) is log-binning. Such a method provides an opportunity to interrogate the data at a landscape scale while still removing the noise inherent in topographic measurements. Each  $E^*R^*$  pair is placed into evenly spaced bins in base 10 logarithmic space. The bin spacing is a function of the number of bins specified by the user and the range of  $E^*$  values within the dataset and its impact on interpretation of the data is considered in Sect. 6.2.3. To ensure that a valid number of data points make up each bin, a minimum bin size can also be specified by the user, this value will depend on the size and nature of the dataset.

This type of averaging will work best in landscapes where an erosion gradient is expected, as it will produce a range of  $E^*R^*$  values across the domain, as can be seen in Hurst et al. (2012). In presumed steady state locations such as Gabilan Mesa most of the data is expected to cluster around a single point (Roering et al., 2007), and so imposing evenly spaced bins in log space onto such data may construct an artificial trend. It is therefore recommended to consider the raw data in conjunction with the binned data to ensure that the trends in the data are valid.

### 5.3 Visualizing data

The software allows the user to plot any combination of the  $E^*R^*$  datasets, facilitating the rapid generation of basin and landscape average data following Roering et al. (2007), hilltop averaged and log binned data following Hurst et al. (2012, 2013a) and raw data which has previously not been available. It is also possible to interrogate the raw measurements as a density plot, which more accurately conveys the trends in the raw data as in large landscapes many measurements share the same location in  $E^*R^*$  space. By allowing simple inter-comparisons between plotting methods it becomes trivial to assess the most suitable data visualization techniques for a specific landscape.

## 6 Results and discussion

By using data from previous studies which utilize  $E^*R^*$  analysis it is possible to assess the ability of this software to reproduce existing results in addition to understanding how the varying techniques for smoothing the data, discussed in Sect. 4.3, can impact on the interpretation of the processes operating on a landscape. Four landscapes in the continental USA have been selected to evaluate the software, the Oregon Coast Range and Gabilan Mesa, used by Roering et al. (2007), Cascade Ridge, used by Hurst et al. (2012) and the Coweeta Hydrologic Laboratory (Fig. 1). High resolution LiDAR data is available from the National Center for Airborne Laser Mapping (NCALM) for each site and each site's point cloud data has been gridded to 1 m resolution DEMs following Kim et al. (2006) and accuracy information for each point cloud can be found in the Appendix A.

## 6.1 Reproducing previous work

### 6.1.1 Oregon Coast Range and Gabilan Mesa

The Oregon Coast Range in Oregon, USA is a steeply incised upland landscape with dense forest cover and a humid climate (Roering et al., 1999), leading to frequent debris flows, which initiate in colluvial hollows (Stock and Dietrich, 2003). The forests of the Oregon Coast Range are dominated by hardwoods, such as Oregon Maple (*Acer macrophyllum*), and coniferous forest such as Douglas Fir (*Pseudotsuga menziesii*) (Schmidt et al., 2001). Extensive work has been carried out to estimate the uplift rate of the range using marine terrace data (Kelsey et al., 1996), and these estimates of uplift rate correspond to erosion rates measured using cosmogenic radionuclides (e.g., Heimsath et al., 2001). This correspondence between uplift and erosion rate has been used to infer that the Oregon Coast Range is in steady state (e.g., Reneau and Dietrich, 1991; Roering et al., 2007).

Gabilan Mesa in California, USA is part of the Central Coast Ranges and has a semiarid Mediterranean climate with higher vegetation densities on northern slopes due to microclimatic variations (Dohrenwend, 1978). The vegetation of Gabilan Mesa is characterized by a combinations of oak savannah containing Blue Oak (*Quercus douglasii*) and chaparral shrubland containing Chamise (*Adenostoma fasciculatum*) (Shreve, 1927). The landscape is very smooth with a regular spacing of tributaries and valleys (Dohrenwend, 1978, 1979) and gentle transitions between hillslopes and channels, suggesting that diffusive processes dominate the transport of sediment on hillslopes (Roering et al., 2007). Hilltop curvature shows little variance across the landscape and in conjunction with the regularity of valley spacing, this suggests that the landscape is in approximate topographic steady state (Roering et al., 2007; Perron et al., 2009).

Roering et al. (2007) estimated the topographic parameters  $L_H$ ,  $R$  and  $C_{HT}$  for the Oregon Coast Range and Gabilan Mesa fieldsites. The characteristic hillslope length for each landscape was estimated by identifying the inflection point in a spline curve

fitted though a plot of local slope against drainage area. This inflection point is considered to correspond to the transition between the hillslope and channel domain in a landscape (Montgomery and Foufoula-Georgiou, 1993; Hancock and Evans, 2006; Tarolli and Dalla Fontana, 2009; Tarolli, 2014; Tseng et al., 2015).

5 Roering et al. (2007) estimated mean relief by calculating the mean of the differences between the maximum and minimum elevation within a kernel of radius equal to the characteristic hillslope length for each point on the landscape. Hilltop curvature was sampled from manually defined hilltops with a gradient below  $0.05S_c$  and averaged across each landscape. The critical gradient was calculated for the Oregon Coast Range to be 1.2 by Roering et al. (1999) and Roering et al. (2007) assumed that this value is also correct for Gabilan Mesa.

The data from Gabilan Mesa (Fig. 2a) reveals many hilltop patches which correspond closely to the predicted  $E^*R^*$  values from Roering et al. (2007). The data is predominantly clustered around a single point, showing strong agreement with observations that the landscape is in approximate steady state. However the majority of the basin average data points and a considerable amount of the hilltop patch data plots below the steady state curve, which could be interpreted as evidence for topographic decay. However the uniform hilltop curvatures and valley spacing, couple with measurements of long term erosion rates suggest that this landscape is not undergoing topographic decay (Roering et al., 2007; Perron et al., 2009). An alternative explanation for the data falling below the steady state curve is that an  $S_c$  value of 1.2 is too large for this landscape. Grieve et al. (2015) used similar topographic parameters to estimate the critical gradient for this landscape as 0.8. By replotting this data using this revised  $S_c$ , the data plots more closely to the steady state curve (Fig. 2b).

25 The Oregon Coast Range data is more tightly constrained than the Gabilan Mesa Data (Fig. 3a), and has a similar range of  $R^*$  values. However, as is the case for Gabilan Mesa, the majority of the data plots below the steady state curve. By using the  $S_c$  value of 0.79 constrained by Grieve et al. (2015), the data moves closer to the steady state curve (Fig. 3b). Using this  $S_c$  value several  $R^*$  measurements exceed 1. This

indicates that these hillslopes are too steep to sustain soil mantle in this landscape, which corresponds to field observations of the Oregon Coast Range, where frequent shallow landsliding is reported (e.g., Benda and Dunne, 1997; Montgomery et al., 1998) and where periodic wildfires expose large (tens of  $m^2$ ) patches of bedrock (Jackson and Roering, 2009).

As acknowledged by Roering et al. (2007) extracting the relief from a moving window fails to capture the complete range of relief values in a landscape, resulting in an average value which dampens the true signal, reducing  $R$  in high relief landscapes such as the Oregon Coast Range. Our method of measuring relief of individual hillslope traces circumvents this problem.

The majority of the data points in Figs. 2 and 3 have larger  $E^*$  values than those from Roering et al. (2007). Grieve et al. (2015) showed that estimating  $L_H$  using slope-area plots systematically underestimates  $L_H$  by as much as an order of magnitude in some landscapes. Such an underestimate would reduce the  $E^*$  value for a landscape and explains the systematic differences between this study and the results of Roering et al. (2007). The larger range of hilltop patch data highlights the range of  $E^*R^*$  values inherent in even a uniform landscape which is in approximate topographic steady state.

### 6.1.2 Cascade Ridge

Cascade Ridge is a section of the Northern Sierra Nevada in California, USA. The landscape is predominantly forested and the climate is semi-arid (Hurst et al., 2012). The characteristic topographic form of this landscape is a smooth, low relief relict surface which is heavily incised, creating steep canyons with an irregular spacing. The plateau surface is vegetated with oak forest including California black oak (*Quercus kelloggii*) and canyon live oak (*Quercus chrysolepis*) and pine forest containing ponderosa pine (*Pinus ponderosa*), Douglas fir (*Pseudotsuga menziesii*) and sugar pine (*Pinus lambertiana*), whereas the canyon is dominated by chaparral vegetation such as manzanita (*Arctostaphylos spp.*) (Gabet et al., 2015; Milodowski et al., 2015a). These contrasting landscape morphologies have been shown to be eroding at different rates, with the

plateau surfaces eroding an order of magnitude more slowly than the canyons (Riebe et al., 2000; Hurst et al., 2012). This produces a complex landscape exhibiting a range of erosion rates influenced by climate and tectonic signals which is not in topographic steady state (Riebe et al., 2000; Stock et al., 2004; Hurst et al., 2012; Gabet et al., 2015).

Cascade ridge is a more morphologically complex landscape than the Oregon Coast Range or Gabilan Mesa, correspondingly, the  $E^*R^*$  data for this landscape is predicted to plot along the steady state curve at a broad range of  $E^*$  values, as was demonstrated by Hurst et al. (2012). Using an  $S_c$  value of 0.8, as proposed by Hurst et al. (2012), produces data spanning a much wider portion of  $E^*R^*$  space than the data for the steady state landscapes of Gabilan Mesa and the Oregon Coast Range (Fig. 4a). The binned hilltop patch data shows good agreement with the data from Hurst et al. (2012), spanning a similar range of  $E^*$  values with the steady state curve falling within the standard error of each bin. This supports observations of a range of erosion rates and landscape morphologies and highlights the utility of this method in gaining a first order approximation of the tectonic and erosional setting of a landscape where no field data is available.

At the Cascade Ridge site, Grieve et al. (2015) estimated  $S_c$  to be 0.72, calculated from topographic parameters. Using this value there is little change in the trends in the data (Fig. 4b), most of the points now fall above the line and at high values of  $E^*$ , and more data points have  $R^*$  values in excess of 1. This is consistent with field observations of this transient landscape wherein rapid valley downcutting may decouple hillslopes from the channel network (Milodowski et al., 2015b) and drive shallow landsliding. In a complex landscape such as Cascade Ridge, which is known to have a broad range of erosion rates and hillslope morphologies, a landscape average  $S_c$  value will regress towards the mean. Consequently, as more of the landscape is covered by the low gradient plateau than the steeper canyons, the  $S_c$  value of 0.72 does not reflect the parts of the landscape with larger  $E^*R^*$  values, which may fall closer to the value of 0.8 used by Hurst et al. (2012).

### 6.1.3 Coweeta

The Coweeta Hydrologic Laboratory is in the Southern Appalachian Mountains in North Carolina, USA and is a densely vegetated landscape which exhibits classic ridge and hollow topography (Hales et al., 2012). Such topography produces many source areas for shallow landslides in colluvial hollows, which are triggered by high intensity storms connected to hurricanes (Swift Jr et al., 1988). The vegetation at Coweeta is a mix of shrubs, such as *Rhododendron maxima*, and Northern Hardwood forest, the distribution of which is controlled by wildfires which in many cases are managed through human intervention (Hales et al., 2009). It is debated whether the Southern Appalachians are in topographic steady state, as there is little tectonic activity, yet there is a large amount of relief preserved across the range (Baldwin et al., 2003; Matmon et al., 2003; Gallen et al., 2011, 2013).

The Southern Appalachian Mountains have never previously been investigated using  $E^*R^*$  methods and so can be used to evaluate the technique's ability to interrogate a complex landscape and assist in the interpretation of topographic signals. Figure 5 outlines the range of methods which can be used to interpret  $E^*R^*$  data. As in Sects. 6.1.1 and 6.1.2 the critical gradient used is taken from Grieve et al. (2015). The raw data in Fig. 5a shows the range of reliefs observed in the Southern Appalachians. The landscape median  $E^*R^*$  value falls within the zone of maximum probability density, this highlights the level of noise inherent in high resolution topographic data when interrogating them in  $E^*R^*$  space, outlining the requirement to smooth or bin the data in order to extract meaningful information from the topographic data.

Comparing Fig. 5b and c to data for steady state landscapes such as Gabilan Mesa or the Oregon Coast Range shows similar levels of clustering, with the location of the cluster of patch and basin average values corresponding with the Oregon Coast Range data (Fig. 3). This corresponds well to field observations of hillslope morphology in these two locations, with planar hillslopes and frequent shallow landsliding reported (Benda and Dunne, 1997; Montgomery et al., 1998; Roering et al., 1999) and this clus-

tering suggests that there is less spatial variation in erosion rate in Coweeta than in Cascade Ridge, an assertion supported by measured erosion rates from both locations (e.g., Riebe et al., 2000; Matmon et al., 2003; Hales et al., 2012; Hurst et al., 2012). Figure 5d shows the binned data for Coweeta and highlights the smaller range of  $E^*$  values for this landscape when compared to Cascade Ridge. It also draws attention to the need to analyze  $E^*R^*$  data using numerous methods to avoid an incorrect interpretation, as discussed in Sect. 5.2.

The Coweeta  $E^*R^*$  data clusters around a point on the steady state curve and it could be concluded that this landscape is in approximate steady state. However, the value of  $S_c$  used in Fig. 5 is significantly smaller than any previously published  $S_c$  value. Field observations of Coweeta reveal that many channels are alluviated and such deposition at the base of hillslopes will reduce the mean gradient of a hillslope, and move its idealized profile away from the model hillslopes defined by Roering et al. (2007). Such an alteration of mean hillslope properties could explain the considerable underestimation of the critical gradient when it is constrained through hillslope length-relief relationships.

By selecting an  $S_c$  value of 0.79, taken from the Oregon Coast Range, which is a broadly similar landscape based on the range of  $E^*$  values and field observations, the majority of the data plots below the steady state curve. Hurst et al. (2013a) observed  $E^*R^*$  data plotting below the steady state curve along the Dragons Back Pressure Ridge, where these sections of the landscape are understood to be topographically decaying following a pulse of uplift. If this  $S_c$  is correct it could lend support to the idea of a Miocene rejuvenation of topography in the Southern Appalachians (Gallen et al., 2013) followed by a period of gradual topographic decay into the present.

## 6.2 Sensitivity analysis of averaging methods

Several of the techniques utilized to average the raw  $E^*R^*$  data have free parameters, the selection of which can influence the final results. In the following section we explore

the influence of averaging technique, minimum patch and basin area, basin stream order and binning parameters can have on the interpretation of  $E^*R^*$  data.

### 6.2.1 Averaging methods

As outlined in Sect. 4.3 the topographic parameters,  $L_H$ ,  $R$ ,  $C_{HT}$ , and  $S_{HT}$ , must be smoothed in order to extract meaningful trends from the inherently noisy signal. The main technique for performing this smoothing is to spatially average the data over either hilltop patches or drainage basins. These averages can be computed as either the mean or the median of each spatial area. Figure 6 presents a comparison between hilltop patch data computed using means and medians for the Oregon Coast Range, showing little change between the measurements using the two techniques. As there is little difference between the two methods we use median values throughout this paper, as this ensures that any extreme values will have a lesser impact on landscape scale metrics.

### 6.2.2 Spatial averaging parameters

The hilltop patch identification process described in Sect. 3.1 requires one user defined parameter, the minimum patch area. This value is used to remove any small patches from the analysis and is included to ensure that patches conform to geomorphologically significant hillslopes, and not small patches of hilltop that are not representative of the hillslope as a whole. By varying the size of the minimum patch area from 0 through to 500 pixels it is possible to observe how this parameter can impact the interpretation of  $E^*R^*$  data (Fig. 7a). As the threshold is increased, fewer patches are considered valid and the density of the data is reduced, having the effect of removing many of the outlying data points. This reinforces the need to set a minimum size for a hilltop patch to ensure that a small number of measurements do not have too large an impact on the interpretation of the data.

Interactive Discussion

The technique in Sect. 3.1 has no method to limit the maximum size of the hilltop patches, as the aim is to find spatially contiguous zones of hilltop and artificially breaking these patches may result in oversampling some sections of a landscape. Large patches make up a very small proportion of the total population of patches and correspondingly do not have a large impact on the overall trends in an individual dataset.

The number of valid data points contained within a basin used to generate an average value is another free parameter that the user must set. As with the hilltop patch area, selecting a sensible value is important to ensure that each basin average data point corresponds to the basin as a whole and not just as a spatial subset. As the threshold is increased, outlying basins are removed (Fig. 7b), indicating that many outlying data points are generated by a small number of irregular hillslopes in otherwise typical basins. However, if the threshold is too large, too many basins will be excluded. In order to ensure consistency between spatial averaging techniques it is recommended that the minimum number of pixels in a basin be kept equal with the minimum patch area.

The stream order of the basin used to generate basin average values will also have an influence on the interpretation of the results. Grieve et al. (2015) used second order basins to generate basin average topographic parameters as this order generated a large number of basins which all had a large enough area to generate numerous data points per basin effectively sampling as much of a landscape as possible. Figure 7c shows the effect of increasing the stream order of the basins used in Coweeta from first to fourth order. As each increasing order basin can be considered a set containing the previous order basins, the basin average points all plot in very similar locations in  $E^*R^*$  space, suggesting that increasing basin order may be a useful method of smoothing basin average data in noisy landscapes. However, this comes with the limitation that as the basin order increases, the number of basins in a landscape decreases, resulting in fewer data points representing larger spatial areas and the possible homogenization of topographic signals occurring at spatial scales smaller than the average basin area.

### 6.2.3 Log bin parameters

When computing logarithmically spaced bins there are two free parameters, number of bins, equivalent to the bin width and the minimum number of data points which must fall within a bin for the binned point to be valid. Figure 8a highlights the influence of changing the number of bins on the interpretation of the Cascade Ridge data. If the number of bins are too low, it becomes difficult to identify a trend in the data as the nature of a landscape can vary considerably across large ranges of  $E^*$  and by homogenizing these measurements a transient signal can be lost.

However, as the number of bins is increased, fewer values are placed into each bin resulting in a single value significantly different to the rest of the values in the bin, vastly altering the result. It is also the case that as the number of bins increases, the chance of a bin being removed for having too few data points increases, which will be particularly apparent at low and high  $E^*$  values, where the data is sparser. We have found that using 20 bins reaches a good compromise between data density and data smoothing, and corresponds well with the 21 bins used by Hurst et al. (2012), where no filtering was performed based on bin size.

The minimum size of each bin can also have an impact on the final interpretation of the data. If no threshold is applied, some bins can contain a single value, while others can contain hundreds of values which makes interpreting the data difficult as we cannot be sure of the robustness of each binned value. If the threshold is placed too high, then valid data will not be included in the final analysis and the interpretation of a landscape's evolution could be incorrect. Figure 8b highlights this issue using data from Cascade Ridge at a range of bin size thresholds, identified as percentages of the total dataset size. We have found that using a minimum bin size of 1–5% of the total dataset ensures a good binning result.

### 6.3 Constraining $S_c$

Landscapes which are in topographic steady state should plot at a single location on the curve described by Eq. (5). In principle this would mean that an erosion gradient would be required in order to constrain  $S_c$ , by fitting the data to the steady state curve.

5 However, as observed in Figs. 2 and 3 even in idealized steady state landscapes, there is still considerable variability in the  $E^*R^*$  data. This variability is consistent with patterns of dynamic reorganization of low order drainage basins within models of steady state landscapes performed by Reinhardt and Ellis (2015). Therefore it becomes possible to estimate the critical gradient of the nonlinear sediment flux law (Eq. 1) for a landscape without a strong erosion gradient, using  $E^*R^*$  data.

10 As with previous analyses, the raw data must be spatially averaged in order to reduce the level of noise present in  $E^*R^*$  space before an estimate of  $S_c$  can be made. The optimal value of  $S_c$  is estimated using a nonlinear least squares method (Jones et al., 2001) which computes the sum of the square of the deviation between each measured  $E^*R^*$  value and the value predicted by Eq. (5). This calculation is performed for a range of critical gradients until the  $S_c$  with the lowest corresponding deviation from the steady state curve is found.

15 The accuracy of this optimized  $S_c$  value is constrained though bootstrapping the optimization procedure. The data are sampled with replacement to generate 100 000 datasets, consisting of values randomly drawn from the population of patch or basin average data. For each of these sampled datasets the optimal value of  $S_c$  which minimizes the error between the data and the steady state curve is calculated. The final  $S_c$  value for each landscape is the mean value of these 100 000 iterations, with a 95 % confidence interval.

25 Table 1 contains estimates of the critical gradient generated using both basin and patch average values alongside previously published values for Cascade Ridge, the Oregon Coast Range and Gabilan Mesa. The predicted patch and basin average values for Gabilan Mesa and the Oregon Coast Range are similar to those published by

Grieve et al. (2015) and suggest that values proposed by Roering et al. (1999) are too large for these landscapes. The data for Cascade Ridge shows better agreement with the value used by Hurst et al. (2012), which was also derived using  $E^*R^*$  data, than the lower estimate from Grieve et al. (2015). The pair of  $S_c$  values calculated for each landscape are very similar, suggesting that in large enough datasets, the constraint of  $S_c$  is insensitive to the spatial scale of data averaging. However, the scale of spatial averaging has been demonstrated to have an impact on the interpretation of  $E^*R^*$  data and thus care must be taken to select appropriate methods of spatial averaging and data processing in order to ensure that results generated are not simply a function of user defined parameters.

The values of  $S_c$  constrained using this bootstrapping procedure are similar to those derived from the relationship between hillslope length and relief demonstrated by Grieve et al. (2015), however there is no need to estimate material properties such as the soil and rock density and thus this method provides an independent constraint on  $S_c$ . However, the computational expense of bootstrapping the  $S_c$  fitting calculations from the  $E^*R^*$  data is very high, when contrasted with the estimation of  $S_c$  using  $L_H$ - $R$  relationships presented by Grieve et al. (2015). Additionally, using this bootstrapping method in landscapes which do not plot on the steady state curve in  $E^*R^*$  space can yield an incorrect  $S_c$  value with a low error estimate. Consequently, we recommend estimating the critical gradient of a landscape using this method and the method outlined in Grieve et al. (2015), when field data is available, in order to best constrain the critical gradient of a landscape.

## 7 Conclusions

We present a software package which automates the extraction and processing of high resolution topographic data to generate non-dimensional erosion rate and relief measurements. Topographic data can be averaged at a hilltop scale by generating unique hilltop patches or can be averaged over drainage basins automatically extracted from

Interactive Discussion

the channel network. Alongside the raw data, these spatially averaged datasets are shown to reproduce the findings of previous studies. In steady state landscapes such as the Oregon Coast Range and Gabilan Mesa  $E^*R^*$  data plots in a cluster around a single point on the steady state curve, supporting the conclusions drawn in previous studies (Roering et al., 2007); and in Cascade Ridge, a transient erosion signal similar to that identified by Hurst et al. (2012) is observed. This technique is also tested on a landscape in the Southern Appalachian mountains with the results suggesting that topography is decaying, supporting models of Miocene topographic rejuvenation proposed by Gallen et al. (2013). These compelling results, alongside the ability to reproduce previous work emphasizes the value of this software to the geomorphology community as until now, there has been no clear framework within which to produce non-dimensional erosion rate and relief measurements.

The critical gradient used in Eq. (1) is also constrained for three of the studied landscapes, with the values falling within expected ranges. However due to the noise inherent in this form of analysis and the challenges of evaluating the goodness of fit between such noisy data and a model, it is recommended that other methods to constrain  $S_c$  using the same raw data are utilized instead. Finally, the influence of free parameters on the final interpretation of the data is explored, providing the user clear guidance on how to select parameters which control the level of smoothing or binning performed on the topographic data. The most significant of which are the minimum patch and basin size thresholds which must be carefully selected to balance smoothing the data with preserving landscape scale trends.

**Appendix: Topographic metadata**

Table A1 provides the accuracy information for the four point clouds used to generate the 1 m resolution topographic data used in this study. This information is compiled from metadata available from OpenTopography.org.

**Table 1.** Previously published  $S_c$  values alongside the values generated from the best fit to the steady state curve for the patch and basin average data.

	Roering et al. (2007)	Hurst et al. (2012)	Grieve et al. (2015)	Patch Average <sup>1</sup>	Basin Average <sup>2</sup>
Oregon Coast Range	$1.2 \pm 0.2$	–	0.79	$0.83 \pm 0.01$	$0.83 \pm 0.01$
Gabilan Mesa	$1.2 \pm 0.4$	–	0.8	$0.8^{+0.06}_{-0.05}$	$0.8^{+0.05}_{-0.04}$
Cascade Ridge	–	0.8	0.72	$0.78 \pm 0.02$	$0.82 \pm 0.02$

<sup>1</sup> Calculated as the value which minimizes the sum of the squared residuals to the steady state line for the patch average data. Error is the 95% confidence interval generated by bootstrapping the calculation 100 000 times.

<sup>2</sup> As for <sup>1</sup> but using basin average data.

## A nondimensional relief framework

S. W. D. Grieve et al.

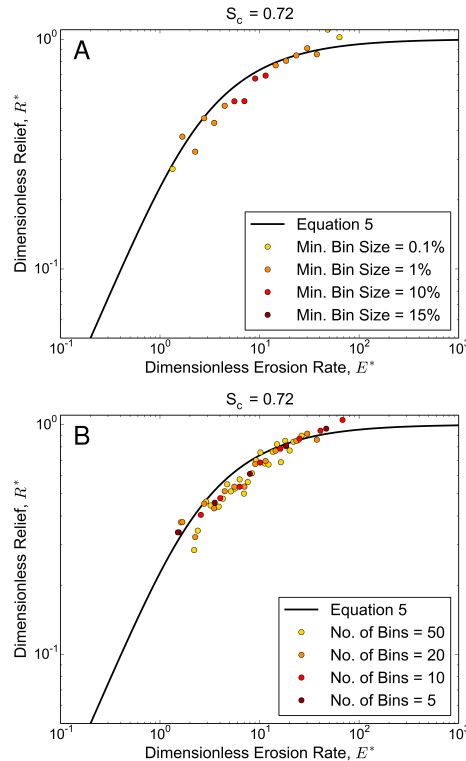

**Figure 7.** Comparison of the influence of changing spatial averaging method on the interpretation of  $E^*R^*$  data for Gabilan Mesa. **(a)** Variations in the minimum patch area threshold from 0 (no threshold) to 500 pixels highlighting the reduction in noise when a minimum patch area is applied. **(b)** Variations in the minimum basin pixels threshold. Outlying basins have very few data points, so are influenced more strongly by single atypical values. **(c)** increasing the basin stream order, which reduces variance in the data as bigger basins are sets containing basins of smaller orders, dampening any extreme values.

## A nondimensional relief framework

S. W. D. Grieve et al.

**Figure 8.** Comparison of the influence of binning parameters on the interpretation of  $E^*R^*$  data for Cascade Ridge. **(a)** varying the number of bins used, equivalent to the bin width in  $E^*$  space. As the number of bins reduces it becomes harder to identify patterns in the data and as the number of bins increases, the number of data points in each bin reduces, thereby reducing the power of the binning technique. **(b)** varying the minimum number of data points required in a basin. As this value increases fewer points are preserved, which compresses the range of the data and can obscure the observation of an erosional gradient. Too small a threshold can result in bins containing very few values which do not represent the landscape as a whole.
