**Abstract** Gravel soils generated by Wenchuan earthquake have undergone natural consolidation for the past decade. However, geological hazards, such as slope failures with ensuing landslides, have continued to pose the great threats to the region. In this paper, artificial model tests were used to observe the changes of soil moisture content and pore water pressure, as well as macroscopic and microscopic phenomena of gravel soil. In addition, the mathematical formula of the critical state was derived from the triaxial test data. Finally, the mechanical states of gravel soil were determined. The results had five aspects. (1) The time and mode of the occurrence of landslide were closely related to the initial dry density. The process of initiation was accompanied by changes in density and void ratio. (2) The migration of fine particle and the rearrangement of coarse-fine particle contributed to the reorganization of the microscopic structure, which might be the main reason for the variation of dry density and void ratio. (3) If the confining pressure was same, the void ratios of soils with constant particle composition would approach to approximate critical values. (4) Mechanical state of gravel soil can be determined by the relative position between state parameter ( $e, p'$ ) and  $e_c-p'$  planar critical state line, where  $e$  was the void ratio,  $e_c$  was the critical void ratio and  $p'$  was the mean effective stress. (5) In the process of landslide initiation, dilatation and contraction were two types of gravel soil state, but dilatation was dominant. This paper provided an insight to interpret landslide initiation from the perspective of critical state soil mechanics.

**Keywords** Mechanical state • gravel soil • landslide • critical state • Wenchuan seismic area

## 30 **1 Introduction**

31 In 2008, the gravel soil generated by Wenchuan earthquake produced a large amount of loose  
32 deposits (Tang and Liang 2008; Xie et al., 2009). These deposits had features such as wide grading,  
33 weak consolidation and low density. They were located on both sides of roads and gullies, and led to  
34 the formation of soil slopes (Cui et al., 2010; Qu et al., 2012; Zhu et al., 2011). Although gravel soils  
35 have subjected to natural consolidation process for nearly a decade, geological hazards, such as slope  
36 failures with ensuing landslides, are readily to motivate in rainy season. At present, geo-hazards still  
37 pose the great threats to the region (Chen et al., 2017; Cui et al., 2013; Yin et al., 2016).

38 The variation of mechanical state, such as the transformation from a relatively stable state to a  
39 critical state, has been commonly used to analyze the initiation of landslides (Iverson et al., 2010;  
40 Iverson et al., 2000; Liang et al., 2017; Sassa 1984; Schulz et al., 2009). Therefore, a deep  
41 understanding of the soil state is the scientific basis for the study of landslide occurrence (Chen et al.,  
42 2017). Generally, the critical void ratio is an important parameter to determine the state of soil  
43 quantitatively (Been and Jefferies 1985; Schofield and Wroth 1968). The theoretical research had its  
44 origins in Reynold's work in 1885. He defined the characteristic of the volumetric deformation of  
45 granular materials due to shear strain as dilatation (Reynolds 1885). Casagrande (1936) pointed out  
46 that loose soil contracted, and dense soil dilated to the same critical void ratio in the drained shearing  
47 test. He drew the F line to distinguish the dilative zone and the contractive zone. The F line's  
48 horizontal and vertical coordinate is effective normal stress and void ratio. Since the 1980s, critical  
49 state soil mechanics received extensive attentions (Fleming et al., 1989; Gabet and Mudd 2006;  
50 Iverson et al., 2000). Some of the observed landslides, such as the Salmon Creek landslide in Marin  
51 County (Fleming et al., 1989), Slumgullion landslide in Colorado (Schulz et al., 2009), and  
52 Guangming New Distinct landslide in Shenzhen (Liang et al., 2017), might be approximately  
53 explained by this theory. Based on the F line drawn by Casagrande (1936), Fleming (1989) found  
54 that the increase of pore water pressure contributed to the dilation, and causes the debris flow  
55 characterized by the intermittent movement. Iverson (1997; 2000) pointed out porosity played an  
56 important role in the occurrence of landslide; in the soil shearing process, the density of loose sand  
57 increased, and the density of dense sand decreased to the same critical density. The formula of the  
58 void ratio was derived, which was the function of the mean effective stress (Gabet and Mudd 2006).  
59 William et al (2009) found out the dilative strengthening might control the velocity of a moving  
60 landslide through the hourly continuous measurement of displacement of landslide. Liang et al (2017)  
61 found that the initial solid volume fraction affect the soil state of the granular-fluid mixture. Other  
62 scholars also found that in the shearing process, dilation or contraction was exiting in residual soil,  
63 loess and coarse-grained soil (Dai et al., 2000; Dai et al., 1999a; Dai et al., 1999b; Liu et al., 2012;  
64 Zhang et al., 2010).

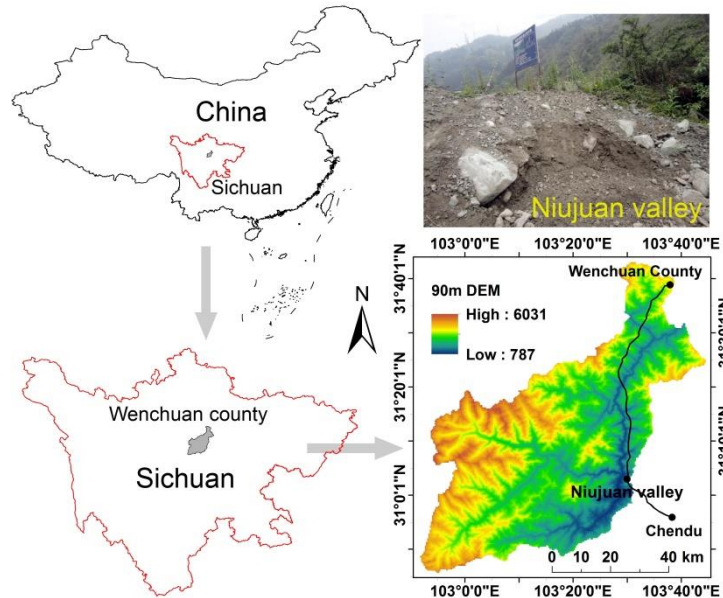

65 The above researchers provided the meaningful insights to explain the occurrence of landslides  
66 and drawn the instructive conclusion, such as the initial density or porosity can affect the mechanical  
67 state of soil (Iverson et al., 2000) and the formation of landslide (McKenna et al., 2011). However,  
68 most of them focused on qualitative results and lacked mutual verification between indoor test and  
69 model test. In addition, for the gravel soil generated by seismic, the study on its mechanical state is  
70 lacking. Some scientific issues need to be solved. For example, what are the differences and  
71 similarities of landslide occurrence? Why does the void ratio or the density change? Is the  
72 mechanical state, a contraction or dilation? The purpose of this paper is to solve the above issues  
73 through artificial flume model tests and triaxial tests. Firstly, the macroscopic phenomena were

74 observed and summarized. Secondly, the variations of soil moisture content and pore water pressure  
 75 were analyzed. Thirdly, the microscopic property of soil was obtained. Fourthly, the mathematical  
 76 expression of critical state of soil was proposed. Finally, the mechanical state of gravel soil was  
 77 determined by the relative position between state parameter ( $e, p'$ ) and  $e_c-p'$  planar critical state line.

## 78 2 Field site and method

### 79 2.1 Field site

80 Niujuan Valley is located in Yingxiu town of Wenchuan County, Sichuan Province, which is the  
 81 epicenter of 12 May 2008 Wenchuan earthquake in China (Fig.1). The main valley of the basin has  
 82 an area of 10.46km<sup>2</sup>, and a length of 5.8km. The highest elevation is 2693m, and the largest relative  
 83 elevation is 1833m. The gradient ratio of the valley bed is 32.7%~52.5% (Tang and Liang 2008; Xie  
 84 et al., 2009). Six small ditches are distributed in the basin. Most of the valley is covered with the  
 85 abundant gravel soil. Extreme complicate terrain and adequate rainfall triggers the frequent  
 86 landslides and the large-scale debris flows. Thus, this valley is the most typical basin in the seismic  
 87 area. Its excellent landslide formative environment can provide comprehensive reference models and  
 88 abundant soil samples for artificial flume model tests.

89  
 90 **Fig. 1** Study area

### 91 2.2 Soil tests and quantitative analysis

#### 92 2.2.1 Artificial flume model test

93 Based on the field surveys along Duwen highway, Niujuan valley and the literature review (Chen et  
 94 al., 2010; Fang et al., 2012; Tang et al., 2011; YU et al., 2010), most of the rainfall induced landslides  
 95 is shallow. The range of the slope angle is 25 °~40 ° and its average value is 27 °. The rainfall intensity  
 96 triggering the landslide is 10mm/h~70mm/h. As shown in Fig.2(a). The length, width and height of  
 97 the flume model are 300cm, 100cm and 100cm.

98 The gravel soil samples are from Niujuan valley. The specific gravity is 2.69. The range of dry  
 99 density is 1.48~2.36g/cm<sup>3</sup>; in addition, the minimum and the maximum void ratio is 0.14 and 0.82.  
 100 Fig.2(b) shows that the cumulative content of gravel (diameter<2mm) and silt and clay  
 101 (diameter<0.075mm) is 30.74% and 2.78%. The content of silt and clay plays the important role in

102 the mobilization of landslide and debris flow (Chen et al., 2010). Four initial dry densities are  
 103 designed as  $1.50\text{g/cm}^3$ ,  $1.60\text{g/cm}^3$ ,  $1.70\text{g/cm}^3$  and  $1.80\text{g/cm}^3$ . According to the previous investigations,  
 104 the water content mainly changes within a depth less than 50cm, and its average value varies from  
 105 6%~8%, while water content below 50cm basically keeps stable. Therefore, the total thickness of the  
 106 soil model is 60cm. In order to achieve a predetermined initial dry density, the soils of the models are  
 107 divided into four layers, and each layer is compacted respectively. The thickness of each layer is  
 108 20cm, 15cm, 15cm and 10cm (Fig.2(a)). Due to the experiment error, the actual initial dry density  
 109 (IDD) is  $1.54\text{g/cm}^3$ ,  $1.63\text{g/cm}^3$ ,  $1.72\text{g/cm}^3$  and  $1.81\text{g/cm}^3$  (Tab.1).

110 Artificial rainfall system, designed by the Institute of Soil and Water Conservation, Chinese  
 111 Academy Science, comprises of two spray nozzles, a submersible pump, water box and a bracket.  
 112 The range of nozzle sizes is 5~12mm, thus, the different rainfall intensity can be simulated. The rain  
 113 intensity triggering the large-scale debris flow on 21, August, 2011 is 56.5mm/h, which is the  
 114 designed rainfall for test. The real rainfall intensity is 47~50.2mm/h because the model test is  
 115 disturbed by the direction of wind. Three groups of sensors, including the micro-pore pressure  
 116 sensors (the model is TS-HM91) and moisture sensors (the model is SM300), are placed between  
 117 two layers of the soil to measure the volume water content and the pore water pressure (Fig.2(a)). A  
 118 data-acquisition system (the model is DL2e) is used to collect the data; it can scan 30 channels  
 119 within the same second. A camera is used to record the macroscopic process of the entire  
 120 experiment.

### 121 2.2.2 Triaxial test

122 Tests are performed by using a dynamic apparatus in Institute of Mountain Hazards and Environment,  
 123 Chinese Academy Science. The diameter and the height of sample are 15 cm and 30 cm (Fig.3). Test  
 124 is the saturated and consolidated drainage shear test at a shear rate of 0.8mm/minute, which  
 125 comprises of two sets: the initial dry density of 1.94 and  $2.00\text{g/cm}^3$ . The confining pressure  $\sigma_3$  is  
 126 50Kpa, 100Kpa and 150Kpa.

Factor Number	Initial volume moisture content (%)	Slope angle(°)	Rainfall intensity (mm/h)	Initial dry density ( $\text{g/cm}^3$ )
1				1.54
2				1.63
3	6~8	27	47~50.2	1.72
4				1.81

131

132 **Fig. 3** Dynamic triaxial apparatus

133 2.2.3 Quantitative analysis method

134 Quantitative analysis is mainly based on artificial flume model test and triaxial test. Firstly, the state  
 135 parameters of soil are represented by the void ratio  $e$  and the mean effective stress  $p'$ , which are from  
 136 the model test. In model test, at least three soil samples are collected by soil sampler in the same  
 137 depth of the line 1#, 2# and 3#, and are used to calculate their natural density  $\rho$ , mass moisture  
 138 content  $\omega$  and dry density  $\rho_d$ . Later,  $e$  can be calculated by the formula:  $e=G_s/\rho_d-1$  ( $G_s$  is the specific  
 139 gravity). The cumulative content of coarse  $P_5$  (particle diameter  $> 5\text{mm}$ ), gravel (particle diameter  $<$   
 140  $2\text{mm}$ )  $P_2$ , and silt and clay (particle diameter  $< 0.075\text{mm}$ )  $P_{0.075}$  is obtained from the particle grading  
 141 tests.  $p'$  can be calculated by the formula:  $p'=(\sigma_x+\sigma_y+\sigma_z)/3$ , where  $\sigma_z=\gamma h$  and  $\sigma_x=\sigma_y=K_a\gamma h$ .  $h$  is the  
 142 vertical distance between a certain point inside the slope and the surface of the slope;  $\beta$  is the slope  
 143 angle.  $\gamma$  is the unit weight of soil.  $K_a$  is the lateral pressure coefficient, which can be calculated by the  
 144 formula (1) (Chen et al., 2012).  $\phi$  is the internal friction angle of soil. In this paper,  $\beta=27^\circ$ ;  $\phi=33^\circ$ .

145

$$K_a = \cos \beta \frac{\cos \beta - \sqrt{\cos^2 \beta - \cos^2 \phi}}{\cos \beta + \sqrt{\cos^2 \beta - \cos^2 \phi}} \quad (1)$$

146 Secondly, the critical state line (CSL) is derived from the triaxial test. Finally, based on the  
 147 critical state soil mechanics, according to the relative position of the state parameter ( $e, p'$ ) at the  
 148 CSL, the mechanical state of the soil can be estimated. When the soil state ( $e, p'$ ) is located at the  
 149 upper right of the CSL, the soil is contracted. When the soil state ( $e, p'$ ) is located at the lower left of  
 150 the CSL, the soil is dilated (Casagrande A 1936; Schofield and Wroth 1968).

151 **3 Results**

152 **3.1 Macroscopic phenomena of experiment**

153 According to the record by a camera, when IDD is  $1.54\sim 1.72\text{g/cm}^3$  except  $1.81\text{g/cm}^3$ , the  
 154 landslide can be triggered by rainfall. The processes of the occurrences of landslides have their  
 155 similarity and difference. The similarity is that at the beginning of rainfall, the shallow soil is  
 156 compacted by seepage force and soil weight (Fig.4(a)). In addition, during the rainfall duration,  
 157 surface runoff cannot be observed, whereas muddy water appears and overflows the slope foot (Fig.  
 158 4(b)). This phenomenon indicates that the entire rainfall can seep into the internal soil, followed by  
 159 the formation of subsurface flow. At this moment, the fine particles along the percolation paths begin  
 160 to move in translation and rotation under the action of gravity (Gao et al., 2011; Igwe 2014) and  
 161 cause a re-distribution of the microstructure of soil (Chen et al., 2004; Zhuang et al., 2015). These  
 162 moving fine particles will fill the interval space of porosity, even block the downstream channels of  
 163 the seepage path (Fang et al., 2012; McKenna et al., 2011), which can lead to a decrease in void ratio  
 164 and an increase of the pore water pressure (Gao et al., 2011).

165 The difference of experiment is time and mode of the occurrence of landslide. When IDD is  
166  $1.54\sim 1.63\text{g/cm}^3$ , the total time of landslide occurrence is 30~40 minutes, including the time of partial  
167 sliding and overall sliding. The processes of landslide occurrence involve three steps. Firstly, the  
168 partial soil of the superficial layer slowly slides in the shape of mudflow when rainfall duration is  
169 about 8min (Fig. 5(a)). Secondly, small-scale slips occur in a layered manner (Fig. 5(b)). Thirdly, the  
170 overall sliding is motivated when the rainfall duration is about 33min (Fig. 5(c)). The above  
171 processes represent the mode of landslide is the progressive failure. This mode reflects four  
172 mechanisms. Firstly, in the early stage of rainfall, the shearing strength of shallow soil decreases and  
173 partial sliding appears due to the rapid infiltration of rainfall. Secondly, partial sliding takes away the  
174 saturated soil, which causes the internal soil exposed on the surface. Thirdly, the exposed soil slides  
175 again, which can change the geometrical shape of the slope and prompt the shearing force increase.  
176 Fourthly, when the increase of the shearing force can destroy the balance of the slope, overall sliding  
177 will appear.

178 When IDD is  $1.72\text{g/cm}^3$ , the total time of landslide occurrence is 18 minutes. Landslide  
179 formation process is divided into three steps. Firstly, the shear opening gradually occurs  
180 accompanied by the visible cracks developing in the slope foot (Fig. 6(a)). Secondly, surface cracks  
181 begin to develop on the slope top (Fig. 6(b)). Finally, landslide initiates accompanied by the  
182 instantaneous propagation of cracks (Fig. 6(c)~(d)), which takes 5s. The above steps imply the mode  
183 of landslide is the tractive failure. The mechanism includes three aspects. Firstly, an increase in soil  
184 weight causes an increase in shearing force, which breaks the equilibrium state of slope, so cracks  
185 can develop in the slope foot and cause the shear opening. Secondly, the instability of the slope  
186 continues to deteriorate, which leads to new cracks located at the top of the slope. Thirdly, the overall  
187 sliding is triggered by crack extension.

188 When IDD is  $1.81\text{g/cm}^3$ , the shearing opening appears at the slope foot (Fig. 7(a)). In the next,  
189 the muddy water can flow from the slope foot (Fig. 7(b)). Even though on the slope surface, fine  
190 particles disappear and coarse particles are exposed, rainfall could not trigger a landslide (Fig. 7(c)).  
191 One reason is that the fine particles within the surface soil move with the water seepage. After the  
192 fine particles of the shallow soil are all migrated, the soil skeleton begins to consist of coarse  
193 particles. This skeleton can provide some smooth paths for the subsurface runoff. The other reason is  
194 that when the soil is in a dense state, the change of volume moisture content is limited due to the low  
195 permeability. Even if the soil shows a small shearing strain, the loss of pore water pressure is difficult  
196 to recover in time due to the lack of rainfall infiltration. Therefore, the shearing strength can remain  
197 unchanged.

198 Macroscopic phenomena of experiments imply that the initial dry density can influence the time  
199 and mode of landslide occurrence. It coincides with the existing research (Iverson et al., 2000). As  
200 the IDD increases from  $1.54\text{g/cm}^3$  to  $1.72\text{g/cm}^3$ , the failure mode of soil changes from progressive  
201 sliding to traction sliding. When IDD is less than  $1.63\text{g/cm}^3$ , partial sliding is a dominant  
202 phenomenon that affects the entire deformation failure. When IDD is  $1.72\text{g/cm}^3$ , shear opening and  
203 cracks are responsible for deformation failure. Although the total time of overall sliding of loose soil  
204 is longer than that of relatively dense soil, the time of partial sliding is shorter. This difference may  
205 be associated with failure modes, and relative time scales of shearing strength loss and changes of  
206 pore water pressure.

### 3.2 Volume moisture content (VMC) and pore water pressure (PWP)

The maximum  $x$  label in Fig.8 ~ Fig.10 represents the total time for the occurrence of the landslide. This value is also the rainfall duration. In order to compare with Fig.8 ~ Fig.10, the maximum  $x$  label in Fig.11 is 1800s. As shown in Fig.8 to Fig.11, the first change is VMC of the depth of 10cm, followed by VMC of the depth of 25cm and 40cm. This change order of VMC is related to the process of rainfall penetration. Especially, rainfall penetration is from shallow soil to deep soil. Therefore, the VMC of 10cm can increase first. The variation of VMC at the depth of 10~25cm exhibits a similar tendency. The tendency consists of three phases. Since the beginning of rainfall, VMC has been in a constant state. When the rainfall seeps into soil, VMC increases rapidly and eventually grows steadily. The time when VMC of the depth of 10cm begins to increase is 203s, 292s, 313s for 1.54~1.72g/cm<sup>3</sup>. This result indicates these three densities have different permeability, the higher density, the lower hydraulic conductivity and the longer time of penetration. The time when VMC of the depth of 25cm begins to increase is about 900s for 1.54~1.72g/cm<sup>3</sup>.

When IDD is 1.54g/cm<sup>3</sup> and 1.63g/cm<sup>3</sup>, VMC at a depth of 40cm initially remains stable and eventually shows an increasing trend. Change trend of 1.54g/cm<sup>3</sup> is more obvious than that of 1.63g/cm<sup>3</sup>. When IDD is 1.72g/cm<sup>3</sup>, VMC at a depth of 40cm is almost constant. The reason is that when a landslide occurs, rain stops; at this time, no abundant water can penetrate to this depth. When IDD is 1.81g/cm<sup>3</sup>, if the rainfall duration is less than 1300 seconds, VMC of 40cm remains stable. When the duration is about 1300 seconds, compared to Fig.8 to Fig.10, VMC of 40 cm starts to increase. This difference between Fig.11 and other three figures may be attributed to the following aspect. As mentioned in section 3.1, the landslide cannot be triggered by rainfall. Therefore, there is sufficient time for rainfall to penetrate to a depth of 40cm, although the hydraulic conductivity is low. However, when the rainfall time is greater than 1800 seconds, VMC of 10~40cm keeps constant. This means due to the accumulation of fine particle, there may be an impermeable layer in the depth of 0~10cm. This layer can prevent rain penetrate deeper than 10cm. When rainfall continues, rainfall can be converted into the subsurface runoff, flowing out of the soil skeleton that consists of coarse particles.

252 As shown in Fig.8 to Fig.11, PWP at a depth of 10~25cm has a similar tendency. This tendency  
 253 consists of a sharp increase at first, a rapid decrease and a continuous dynamic fluctuation. However,  
 254 the variation of PWP is inconsistent with the variation of VMC. Before VMC increases, PWP with  
 255 the depth of 10cm~25cm has experienced the sharp increase and decrease. Soil inhomogeneity may  
 256 contribute to this inconsistency. As mentioned in 3.1, at the beginning of experiment, the surface  
 257 layer less than 10cm is compacted by seepage force and soil weight. The compaction and penetration  
 258 process leads to the increase of the force acting on the subsoil, which causes the increase of PWP.  
 259 During the saturation process of the surface layer, the fine particles of this layer are taken away and  
 260 fill the porosity of the subsoil, which prompt PWP to the peak value quickly. When the surface soil  
 261 slowly moves or cracks begin to develop in the slope foot, the internal deformation due to dilation  
 262 will occur, which causes PWP releases. When VMC increases, PWP has a dynamic fluctuation. This  
 263 fluctuation may be attributed to the rearrangement of the soil skeleton.

264 The curve of PWP with a depth of 40cm is drawn above that of 10~25cm. The variation has no  
 265 significant increase or decrease, but exhibits a smooth fluctuation. During the whole rainfall duration,  
 266 the corresponding VMC shows that the soil is not saturated. Therefore, the pore pressure of 40cm is  
 267 dominated by air pressure.

268 **Fig. 8** Volume moisture content and pore water pressure when IDD is  $1.54\text{g/cm}^3$

 273

274  
275 **Fig. 11** Volume moisture content and pore water pressure when IDD is  $1.81\text{g/cm}^3$

276 **3.3 Microscopic property of gravel soil**

277 As shown in Tab.2, when IDD is from  $1.54$  to  $1.72\text{g/cm}^3$ , the natural density and the dry density  
278 with the depth of  $5\text{cm}\sim 20\text{cm}$  are larger than those before the tests, and the void ratio is less than that  
279 before the tests. Of these three lines, the line 1# has the greatest change rate in density. When IDD is  
280  $1.63\text{g/cm}^3$ , the density of  $40\text{cm}$  is less than the value before the test. When IDD is  $1.81\text{g/cm}^3$ , the  
281 densities with the depth of  $5\sim 10\text{cm}$  are increased compared to that before the test.

282 **Tab 2.** Density and void ratio of gravel soil with initial dry density  $1.54\sim 1.81\text{g/cm}^3$

Number	Initial dry density ( $\text{g/cm}^3$ )	Line number	Soil depth $h$ (cm)	Natural density $\rho$ ( $\text{g/cm}^3$ )	Mass moisture content $\omega$ (%)	Dry density $\rho_d$ ( $\text{g/cm}^3$ )	Void ratio $e=G_s/\rho_d-1$	$\sigma_z=\gamma h$ (Kpa)	$\sigma_x=\sigma_y=K_a\gamma h$ (Kpa)	$p'=(\sigma_x+\sigma_y+\sigma_z)/3$ (Kpa)
1	1.54	3#	5	$2.08\pm 0.05$	$9.35\pm 0.85$	$1.90\pm 0.04$	$0.39\pm 0.03$	1.04	0.59	0.74
		3#	28	$1.93\pm 0.03$	$8.61\pm 1.16$	$1.77\pm 0.02$	$0.49\pm 0.02$	5.39	3.07	3.84

283 As shown on section 2.2.1,  $P_{0.075}$  before the test is  $55.32\%$ . Therefore, coarse particles and fine  
284 particles interact to form the soil skeleton, which affects changes in dry density (Guo 1998) and  
285 landslide characteristics (Li et al., 2014). In this paper, the particle content before and after the test is  
286 compared to understand the change in the void ratio. As shown in Tab.3, when IDD is  $1.54\text{g/cm}^3$  and  
287  $1.63\text{g/cm}^3$ , the loss of  $P_{0.075}$  of the shallow soil of line 3# is the largest, followed by that of line 1#.  
288 The result indicates that the fine particles of surface soil at the slope top begin to move along  
289 direction of gravity firstly. When subsurface runoff forms, these particles begin to move to the slope  
290 foot. This process causes two results. One is that the porosity of the position related to particle  
291 migration increases. The other is that the porosity filled by fine particles decreases (Fang et al., 2012;  
292 McKenna et al., 2011), which is the seepage-compacting effect (Jiang et al., 2013). As a result, the  
293 shallow soil of the slope top is looser than that of the slope foot. The loss of  $P_{0.075}$  ( $\Delta P_{0.075}$ , which is  
294 negative) at the slope top decreases significantly with depth. Especially, it is about  $-1.26\%$  at the  
295 depth of  $40\text{cm}$ . It implies that the depth of rainfall infiltration is about  $40\text{cm}$ . In the case of IDD of  
296  $1.72\text{g/cm}^3\sim 1.81\text{g/cm}^3$ , the variation of  $P_{0.075}$  of the slope top changes from negative to positive

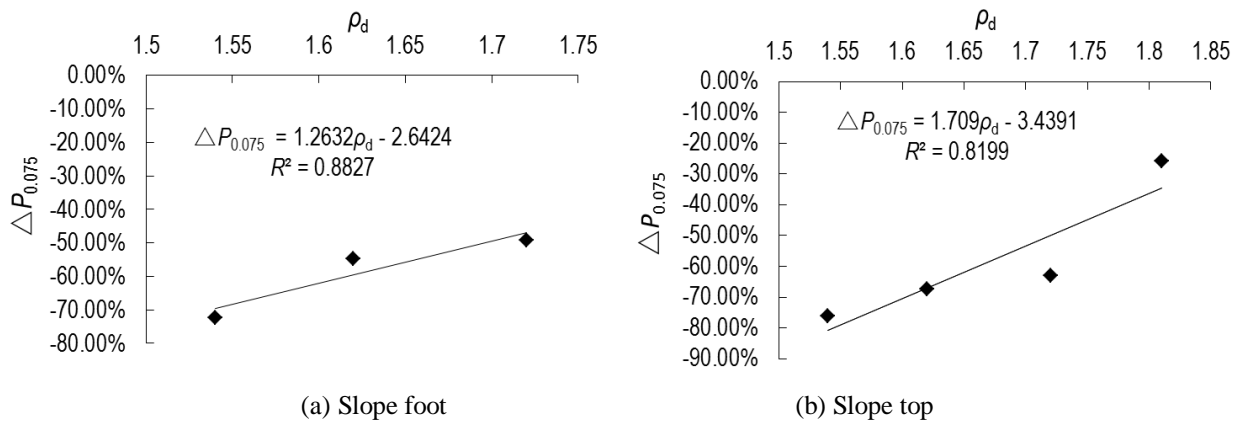

297 accompanied by the increase of depth. This trend indicates that the fine particles may concentrate at  
 298 the depth of 5~25cm. The depth range of particle concentration is 10~25cm, 5~10cm for 1.72g/cm<sup>3</sup>  
 299 and 1.81g/cm<sup>3</sup>.

300 **Tab 3.** Variation of coarse and fine particles contents

Number	Initial dry density (g/cm <sup>3</sup> )	Line number	Soil depth/h (cm)	$P_5$	$\Delta P_5$	$P_{0.075}$	$\Delta P_{0.075}$	$P_2$	$\Delta P_2$
1	1.54	3#	5	61.00%	10.25%	0.66%	-76.24%	30.69%	-0.16%
		3#	28	55.91%	1.05%	2.01%	-27.90%	34.36%	11.76%
		1#	21	58.98%	6.60%	0.77%	-72.36%	31.07%	1.05%
2	1.63	3#	5	58.69%	6.09%	0.91%	-67.23%	31.40%	2.15%
		3#	40	57.98%	4.80%	2.75%	-1.26%	31.69%	3.07%
		1#	13	67.66%	22.30%	1.26%	-54.81%	26.23%	-14.68%
3	1.72	3#	5	55.98%	1.18%	1.03%	-62.98%	32.70%	6.38%
		3#	10	54.01%	2.37%	1.78%	-36.14%	33.94%	10.40%
		3#	25	55.32%	0%	3.17%	13.85%	34.05%	10.75%
4	1.81	1#	10	56.15%	1.5%	1.42%	-49.09%	33.67%	9.53%
		3#	5	52.50%	-5.11%	2.06%	-25.83%	35.49%	15.45%
		3#	10	52.55%	-5.01%	2.86%	2.68%	33.91%	10.30%

301 Note: the positive value of the change represents an increase while the negative value represents a decrease.

302 On the slope top,  $P_5$  at a depth of 5cm changes from positive to negative with the increasing of  
 303 IDD, which range is from -5.11% to 10.25%. The reason is that the loss of fine particles contributes  
 304 to the relatively increase of the content of coarse particles. Both  $P_{0.075}$  on the slope top and  $P_{0.075}$  on  
 305 the slope foot decreases. The range of  $\Delta P_{0.075}$  is from -25.83% to -76.24% and from -49.09% to  
 306 -72.36% accordingly. The relationship between  $\Delta P_{0.075}$  and  $\rho_d$  is shown in Fig.12. The regression  
 307 equation is as follows:  $\Delta P_{0.075}=1.2632\rho_d - 2.6464$ ,  $\Delta P_{0.075}=1.709\rho_d - 3.4391$ , and  $R^2$  is 0.8827,  
 308 0.8199 respectively. The result indicates that  $\Delta P_{0.075}$  has a significant correlation with  $\rho_d$ . Especially,  
 309 the greater initial dry density causes the smaller loss of  $P_{0.075}$ . When IDD is 1.53g/cm<sup>3</sup>,  $P_2$  decreases  
 310 and its change value is -0.16%. When IDD is 1.63~1.81g/cm<sup>3</sup>,  $P_2$  increases, and the range of the  
 311 change are 2.15%~15.45%. The reason for the loss of  $P_{0.075}$  and  $P_2$  is that the fine particles are taken  
 312 away by subsurface runoff. The reason for the increase of  $P_2$  maybe that the particles larger than  
 313 2mm roll downward, which causes a relative increase in  $P_2$ .

316 **Fig. 12** Relationship between  $\Delta P_{0.075}$  and  $\rho_d$

317 **3.4 Critical state of gravel soil**

318 **(1) Definition of critical state and calculation of critical void ratio**

319 Under the action of continuous shear load, the state of soil is critical when principal stress  $q$  and  
 320 volume strain  $\varepsilon_v$  tends to be stable (Casagrande A 1936; Liu et al., 2011; Roscoe et al., 1963;  
 321 Schofield and Wroth 1968). In the triaxial shear tests, when the axial strain reaches 16%, the  
 322 deviation stress is stable, and the absolute value of the ratio of  $\Delta\varepsilon_v$  to the present  $\varepsilon_v$  is less than 0.01;  
 323 at this time, the soil enters the critical state (Liu et al., 2012). The formula (2) indicates that there is a  
 324 certain relationship between the current void ratio  $e$  and  $\varepsilon_v$ , wherein  $e_0$  is the initial void ratio (Xu et  
 325 al., 2009). Thus, the critical void ratio  $e_c$  also can be calculated by the formula (2).

326 
$$e = (1 + e_0) \exp(-\varepsilon_v) - 1 \quad (2)$$

327 **(2) The critical state line in the  $e_c$ - $p'$  plane**

328 Tab. 4 shows  $e_c$ ,  $q$  and  $p'$  for two initial dry densities:  $1.94\text{g/cm}^3$  and  $2.00\text{g/cm}^3$ . As shown in  
 329 Table 4, when the confining pressure is same, two densities have the approximate similar  $e_c$ . This  
 330 result has the consistent principle with existing research (Gabet and Mudd 2006; Iverson et al., 2000).  
 331 The principle is that the soil with the same granular composition can obtain the approximate critical  
 332 void ratio in the uniform stress condition (Casagrande A 1936; Roscoe et al., 1963; Schofield and  
 333 Wroth 1968).

334 **Tab 4.** Critical void ratio  $e_c$  of gravel soil

Confining pressure $\sigma_3$ (Kpa)	Initial dry density (g/cm <sup>3</sup> )	$e_c$	$q$ (Kpa)	$p'$ (Kpa)
50	1.94	0.32	93.41	95.98
	2.00	0.34	69.50	84.65
100	1.94	0.30	227.43	213.80
	2.00	0.30	159.14	178.13
150	1.94	0.27	324.79	312.39
	2.00	0.29	181.12	239.86

335 The fitting curve of  $e_c$  and  $\ln p'$  is shown in Fig.13(a). The correlation coefficient is 0.8566, which  
 336 indicates a statistically significant relationship between  $e_c$  and  $p'$ . According to the normalized  
 337 residual probability, P-value of 0.964 is greater than the selected significance level, which indicates  
 338 that the residuals follow a normal distribution. Therefore, the mathematical expression of  $e_c$ - $\ln p'$  of  
 339 gravel soil is as follows:

340 
$$e_c = 0.5241 - 0.04304 \ln p' \quad (3)$$

341 The fitting cure of  $e_c$  and  $\ln p'$  represents the critical state of soil. It can divide the graphical  
 342 space into two states. The space above this curve is the contractive zone, and the space below this  
 343 curve is the dilative zone. If the state parameter ( $e$ ,  $p'$ ) is determined, the soil state can be judged by  
 344 this line (Gabet and Mudd 2006; Iverson et al., 2000).

345 **(3) The critical state line in the  $q$ - $p'$  plane**

346 The fitting curve of  $q$  and the  $p'$  is shown in Fig. 13(b). The correlation coefficient is 0.9465,  
 347 which indicates a statistically significant relationship between  $q$  and  $p'$ . The mathematical expression  
 348 of  $q$ - $p'$  is as follows:

349 
$$q = 0.6641(p')^{1.063} \quad (4)$$

350  
351  
352 **Fig. 13** Critical state line of gravel soil

353 **4 Discussion**

354 The relative position of the state parameter  $(e, p')$  at the critical state line is shown in Fig.14. The  
355 critical states are from Tab.4 and represented by fill dots, and the state parameters of four densities  
356 are from Tab.2 and represented by the hollow dots. Fig.14 shows that when IDD is  $1.54\text{g/cm}^3$  and  
357  $1.63\text{g/cm}^3$ , contraction occurs at 28cm and 40cm of line 3#. In addition, dilation appears in the  
358 remaining positions. These positions include the surface layer of line 3# with the depth of 5~10cm,  
359 the depth of 20~33cm of line 2#, the depth of 10~21cm of line 1#. The results show that dilation and  
360 contraction are two types of the mechanical state of gravel soil when the landslide initiates. Dilation  
361 is the primary type.

362  
363 **Fig.14** The states of gravel soil

364 In this research, at the beginning of rainfall, the shallow soil is compacted by seepage force and  
365 soil weight. The consequent contraction causes the increase in pore water pressure. However, the  
366 process of the rapid rise of PWP is short. After PWP reaches the peak, PWP begins to release. The  
367 reason is that the surface soil slowly moves or cracks begin to develop in the slope foot, which  
368 causes the sliding force increase. Subsequently, the effective stress decreases and the shearing  
369 deformation occurs. At this moment, the loss of shearing strength because of strain softening can be  
370 restored. Soil deformation will stop eventually. If there is the sufficient water penetration, pore water  
371 pressure can recover, and the soil deformation can continue. It can be seen that the loss and recovery  
372 of PMP are the reasons for the dynamic fluctuations of PMP. When soil is dense (relative density  $D_r >$   
373  $2/3$ ) and the infiltration rate is less than the rainfall intensity, the soil will not reach the critical state.  
374 At this point, the slope can remain stable. The macroscopic phenomenon of soil deformation is  
375 mainly local deformation, such as circumferential cracks, partial collapse. If the infiltration rate is  
376 greater than the rainfall intensity, the abundant rainfall can break the mechanical balance of slope.  
377 However, its process still takes a long time. Therefore, the macroscopic deformation is progressive,  
378 such as frequent sliding. When the soil is in a medium dense state ( $1/3 < D_r \leq 2/3$ ), the loss of the pore

379 water pressure due to dilation will be recovered, and the shearing deformation will continue. At this  
380 moment, the macroscopic deformation will be a sudden failure (Dai et al., 2000; Dai et al., 1999b).

## 381 **5 Conclusion**

382 (1) The initial dry density can influence the time and mode of landslide occurrence. When IDD  
383 is  $1.54\text{g/cm}^3 \sim 1.72\text{g/cm}^3$ , the failure mode of soil changes from progressive sliding to traction sliding.  
384 When IDD is less than  $1.63\text{g/cm}^3$ , partial sliding is a dominant phenomenon that affects the entire  
385 deformation failure. When IDD is  $1.72\text{g/cm}^3$ , shear opening and cracks are responsible for  
386 deformation failure. Although the total time of overall sliding of loose soil is longer than that of  
387 relatively dense soil, the time of partial sliding is shorter.

388 (2) During the experiments, the first change is VMC of the depth of 10cm, followed by VMC of  
389 the depth of 25cm and 40cm. The variation of PWP is inconsistent with the variation of VMC.

390 (3) The occurrence of landslides is accompanied by change in density and void ratio. The slope  
391 foot has the greatest change rate in density. The migration of fine particle and the rearrangement of  
392 coarse-fine particle contributed to the reorganization of the microscopic structure, which might be  
393 the main reason for the variation of density and void ratio.

394 (4) The mathematical expression of the critical state line of gravel soil is  $e_c = 0.5241 - 0.04304 \ln p'$ .  
395 Mechanical state of gravel soil can be determined by the relative position between the state  
396 parameter ( $e, p'$ ) and the critical state line. Dilation and contraction are two types of soil state when  
397 the landslide initiates. Dilation is the primary type.
