**Abstract.** River deltas are sites of sediment accumulation along the coastline that form critical biological habitats, host megacities, and contain significant quantities of hydrocarbons. Despite their importance, we do not know which factors most significantly promote sediment accumulation and dominate delta formation. To investigate this issue, we present a global dataset of 5,399 coastal rivers and data on eight environmental variables. Of these rivers, 40% (n = 2,174) have geomorphic deltas, defined either by a protrusion from the regional shoreline, a distributary channel network, or both. Globally, coastlines average one delta for every ~300 km of shoreline, but there are hotspots of delta formation, for example in Southeast Asia where there is one delta per 100 km of shoreline. Our analysis shows that the likelihood of a river to form a delta increases with increasing water discharge, sediment discharge, and drainage basin area. On the other hand, delta likelihood decreases with increasing wave height and tidal range. Delta likelihood has a non-monotonic relationship with receiving basin slope: it decreases with steeper slopes but for slopes > 0.006 delta likelihood increases. This reflects different controls on delta formation on active versus passive margins. Sediment concentration and recent sea-level change do not affect delta likelihood. A logistic regression shows that water discharge, sediment discharge, wave height, and tidal range are most important for delta formation. The logistic regression correctly predicts delta formation 74% of the time. Our global analysis illustrates that delta formation and morphology represent a balance between constructive and destructive forces, and this framework may help predict tipping points where deltas rapidly shift morphologies.

## 1. Introduction

Deltas provide a variety of ecosystem services, such as carbon sequestration and nitrate removal (Rovai et al., 2018; Twilley et al., 2018), and they provide home to close to half a billion people (Syvitski and Saito, 2007) living within large agricultural and urban centers (Woodroffe et al., 2006). Deltas form at river mouths where fluvial sediment accumulates

nearshore long enough for the deposit to become subaerial. This simple view of delta formation is a statement of sediment mass balance; understanding where deltas form requires knowing how and why sediment accumulates. Sediment accumulates provided it is supplied and deposited at the coast faster than it is removed. Sediment supply and removal are chiefly determined by the river, waves, tides, rate of relative sea-level change, and offshore bathymetry. To complicate matters, most of these variables can be both sources and sinks of sediment, and their exact roles in the deltaic sediment mass balance remains uncertain. Previous research suggests that rivers are almost always sources (Bates, 1953; Coleman, 1976; Wright, 1977; Syvitski et al., 2005; Syvitski and Saito, 2007). The roles of waves and tides are largely ambiguous (Nienhuis et al., 2015; Hoitink et al., 2017; Lentsch et al., 2018), though there is some evidence to suggest waves are mainly sediment sinks in the delta formation process (Fisher, 1969; Anthony, 2015). The bathymetric characteristics of the offshore basin determine the nearshore hydrodynamics, wave power, and structure of the turbulent jet, which in turn influences sediment deposition patterns and delta formation (Fagherazzi et al., 2015; Jiménez-Robles et al., 2016). Sea level is also an important part of delta formation, and we know that slower rates of sea-level rise promote delta formation (Stanley and Warne, 1994; Porebski and Steel, 2006; Paola et al., 2011).

Despite these efforts, we do not fully understand how these different controls combine to create river deltas. We know the conditions for delta formation are not easily met—pick nearly any marine shoreline on earth and of the river mouths that intersect the coast, only some will have a delta. Previous studies on delta formation (Wright et al., 1974; Audley-Charles et al., 1977; Milliman and Syvitski, 1992; Syvitski and Saito, 2007; Nyberg and Howell, 2016) focused on large-scale patterns and concluded that major modern delta locations are influenced largely by tectonic margin type and drainage patterns. While useful, these datasets were biased toward the largest and most populated deltas. Expanding the prediction effort to deltas of all sizes is a logical next step, especially because smaller deltas are thought to be more resilient to rising sea levels (Giosan et al., 2014).

In addition to expanding the range of delta sizes to understand the controls on delta formation, we need to consider cases where delta formation is suppressed. In this paper we investigate why some rivers form deltas and others do not. Understanding conditions for modern delta formation should also help exploration for ancient deltaic deposits, which requires predicting where deltas might form under past environmental conditions (Nyberg and Howell, 2016). Similarly, as research

moves toward delta risk assessment due to global environmental change (Tessler et al., 2015) and improving efforts to build new deltaic land (Kim et al., 2009), we must understand how different environmental variables govern delta formation. For example, understanding the conditions for delta formation would help restoration efforts that seek to build new deltaic land in places like the Mississippi River Delta (Paola et al., 2011; Edmonds, 2012; Twilley et al., 2016).

To address these issues, we developed a global dataset that includes the locations of 5,399 coastal rivers, information on whether they form deltas or not, and the environmental variables that could influence delta formation. We use global datasets of coastlines (Dürr et al., 2011; Nyberg and Howell, 2016), sediment and water (Syvitski and Milliman, 2007; Milliman and Farnsworth, 2011), wave climate hindcasts (Tolman, 2009; Chawla et al., 2013), a tidal inversion model (Egbert and Erofeeva, 2002), ocean bathymetry data (Amante and Eakins, 2009), and rate of sea-level change (<https://www.aviso.altimetry.fr>). We use modern values of these environmental variables under the assumption that present day delta formation has adapted to current conditions. Of the 5,399 included rivers, 2,174 form geomorphic deltas that are visible in aerial imagery, defined either by a protrusion from the regional shoreline, a distributary channel network, or both. We use statistical relationships between independent environmental variables and the presence or absence of a delta to determine what controls the likelihood of a river to form a delta.

## **2. A global coastal and river delta dataset**

### **2.1 Identifying river deltas**

River deltas are fundamentally systems of sediment accumulation and distribution at the coastline. Accordingly, we identify coastal deltas by distinguishing geomorphic expressions of sediment accumulation and distribution at locations where rivers meet the coast. We consider a river to have formed a delta at the coastline if the river-mouth area contains an active or relict distributary network (Fig. 1e), ends in a subaerial depositional protrusion from the lateral shoreline (Fig. 1d), or does both (Fig. 1c). Distributary networks are an expression of sediment deposition and distribution (Edmonds et al., 2011) and we identify them by the presence of one or more channels that bifurcate and intersect the coast at different locations. We include relict channels, where they are clearly visible in imagery and connect to the main channel, because they are evidence of sediment distribution and accumulation through avulsion (Slingerland and Smith, 2004). We do not include channels that

bifurcate solely around non-deltaic topographic highs. Our second criterion is oceanward-directed shoreline protrusions. We classify a protrusion as deltaic if it has a relatively smooth depositional shoreline, as opposed to rough shorelines associated with rocky coasts (Limber et al., 2014), and if it extends more than ~5 channel widths oceanward relative to the position of the regional shoreline. We map only protrusions that are associated with the river, ignoring protrusions that may exist near the channel mouth that we judge to be pre-existing undulations in the shoreline. Examples of this include promontories associated with pre-existing geology or depositional protrusions created by other processes, such as wave-driven sediment transport (Ashton et al., 2001). Our delta identification method does not account for deltaic deposition with no geomorphic signature, such as a single-channel delta infilling a drowned valley that produces no protrusion from the regional shoreline. Although such features may be considered deltaic, we cannot unambiguously identify them as deltas based on aerial imagery alone and we do not include them in the dataset.

We applied the preceding criteria to a scan of marine coastlines, including most open ocean coasts and the Black sea, using Google Earth. First, we identified all rivers with width > 50 m reaching the coast that are connected to an upstream catchment (Figs. 1a, 1c–1e). Channels not clearly connected to an upstream catchment, such as tidal channels, were not included in the dataset (Fig. 1b). This was done to restrict the study to coastal depositional landforms that represent the interaction of upstream and downstream environmental variables. We selected rivers at least 50 m in width because they have corresponding data, such as basin area, that can be reliably determined on coarser resolution elevation models. This width designation was applied to the rivers' bankfull widths, and thus includes any visible mid-channel bars. Channel widths on rivers without a delta were measured at the shoreline or upstream from visible marine influence, such as significant tidal widening (Nienhuis et al., 2018). If a river empties into a gradually widening estuary or embayment, we measured the channel width where it is devoid of a significant downstream widening and thus representative of the river. Channel widths on rivers that have deltas were measured immediately upstream of the delta node, which we define as the location of the most upstream bifurcation. If no bifurcation exists, we use the intersection of the main channel with the regional shoreline (e.g., Fig. 1c and 1d, blue dot). In all cases, channel widths were not measured in areas of clear human influence. This includes, for example, man-made levees that can cause artificial widening or narrowing of channels.

We mapped rivers and deltas on the coastlines of Earth's continents and large islands (Fig. 2). We exclude small islands where rivers large enough for inclusion are rare and it is difficult to obtain environmental data. Thus, large islands, such as Papua New Guinea and Fiji, were included but not all the associated smaller islands. Coastlines dominated by fjords (as determined using Dürr et al. (2011)) were not included because offshore glacial over deepening and protection from coastal waves and tides make their comparison to most of the world's coastal deltas difficult. Ephemeral rivers in arid regions were included in the dataset, though the rivers in these regions are often difficult to identify due to poor imagery and difficulty distinguishing the channel banks when they are dry. If a clear distinction was not possible, the river was not included in the dataset. Thus, the total count of rivers and deltas in arid regions should be considered a minimum. Finally, we did not include river channels that do not clearly reach the coast to avoid conflating alluvial fans with deltas.

For each river we marked the latitude and longitude of the main river mouth (Figure 1, *RM*) (Supplemental Table 1). For rivers without a delta, this is the location where the river meets the coastline (Fig. 1a), and for rivers with deltas, this is the location of the widest river mouth in the distributary network (Fig. 1c–1e). For rivers sheltered by barrier islands or rocky islands, we mark the river mouth landward of those obstructions.

## 2.2. Environmental variables

To determine controls on delta formation we also compiled data on eight environmental variables (Table 1). We classify the environmental variables into two groups: (1) upstream variables include water and sediment supply from the river, sediment concentration, and the drainage basin area; and (2) downstream variables include wave height, tidal range, bathymetric slope immediately offshore of the river mouth, and the rate of sea-level change. We use modern data collected for each of these environmental variables, even though some deltas may have initially formed under different conditions 6000 to 8500 years ago as sea-level rise slowed after deglaciation (Stanley and Warne, 1994). We assume that the current river delta (or lack thereof) is adapted to the modern environmental variables because scaling analyses suggest the diffusive response time of river delta deposition and wave reworking is on the order of 100-1000 years (Jerolmack, 2009, Nienhuis et al., 2013). Of course, the diffusive response time depends nonlinearly on delta size, so larger deltas may still be adapting to changing environmental variables.

Notably absent in the collected environmental variables are tectonic data. At present, there are no globally available measurements of tectonic activity (e.g., uplift). However, we consider some of the variables to be reasonable proxies for tectonics. For instance, models predicting sediment flux to the ocean represent tectonics in the form of basin area (Sylvitski and Morehead, 1999; Sylvitski and Milliman, 2007). We also include bathymetric slope, which is a rough proxy for tectonics because, on average, tectonically active margins have steeper slopes than passive margins (Pratson et al., 2007).

### 2.2.1. Upstream variables

We compiled the four upstream variables from the global river dataset of Milliman and Farnsworth (2011) (hereafter referred to as MF2011). We matched rivers in this dataset with entries in MF2011 based on geographic proximity or by the river name. If neither matching method yielded a confident result, the MF2011 data were not included in this study. If two or more rivers in the MF2011 dataset combine to make one river in this study's dataset, the data from all relevant MF2011 rivers are included. In cases where matches were found, we included the river ID(s) from MF2011 in our dataset (Supplemental Table 1). Our dataset includes 1,217 MF2011 rivers, representing 1,158 entries in our dataset. 54 entries contain 2 or more MF2011 rivers, and in those cases we added the MF2011 values together to form one value for the river mouth or delta. There are 314 MF2011 rivers not included in this dataset because they are too small (< 50 m wide), exist on coastlines not included in our dataset, or could not be matched.

Water discharge ( $Q_w$ , expressed as mean annual volumetric flux,  $\text{m}^3\text{s}^{-1}$ ) data in MF2011 are compiled from various sources of reported gauging station measurements, where the downstream-most gauging station data is used.  $Q_w$  is computed from many years of data, though the number of records for each value is different. Where available, we used the pre-dam  $Q_w$ . As MF2011 note, water discharge values may be over- or under-estimated due to distance upstream of the river mouth. In many regions, additional water input downstream of the gauging station increases the true  $Q_w$  value reaching the river mouth. However, in arid regions, water volume may be lost due to evapotranspiration, groundwater recharge, or irrigation water removal. In total, 17% of rivers ( $n = 943$ ) in this dataset have  $Q_w$  data.

Sediment discharge ( $Q_s$ , expressed as mean annual volumetric flux,  $\text{m}^3\text{s}^{-1}$ ) data come from the MF2011 dataset of annual sediment load measurements and are converted to  $\text{m}^3\text{s}^{-1}$  assuming a density of  $2650 \text{ kg m}^{-3}$ .  $Q_s$  is computed from many years of data, though the number of records for each value is different. Where available, we used the pre-dam  $Q_s$ . The  $Q_s$  data

are compiled from various sources of reported loads and most often represent suspended load measurements rather than total load. Bedload is assumed to represent only 10% of total load (Milliman and Meade, 1983), but this estimation may be less valid for small mountainous rivers where relative proportion of bedload can be greater (Amante and Eakins, 2009). Like the  $Q_w$  data, many of these measurements may have been made upstream of the actual river mouth, and thus actual  $Q_s$  values that reach the river mouth likely vary (e.g., due to fluvial plain deposition downstream of measurement location). Finally, extrapolation of measurements taken over varying lengths of time to represent annual sediment loads is potentially risky (e.g., when considering the significance of event-driven discharge events). In total, 11% ( $n = 600$ ) of all rivers in this dataset have  $Q_s$  data. Sediment concentration ( $Q_s/Q_w$ ) is calculated from the sediment and water discharge data and 11% ( $n = 571$ ) of all rivers have  $Q_s/Q_w$  data.

We also include upstream drainage basin area ( $A_b$ , km<sup>2</sup>) in our dataset because it partly sets the magnitude of  $Q_w$  and  $Q_s$  (Syvitski et al., 2003; Syvitski and Milliman, 2007) and compensates for the relatively small number of rivers with water and sediment data.  $A_b$  data come from the MF2011 dataset. Although these values are often well documented for larger river systems, they may sometimes represent the total drainage area upstream of a hydrologic station, which would be a smaller value than total drainage area upstream of the river mouth. Given the potential error,  $A_b$  values should be considered a minimum.

### 2.2.2. Downstream variables

Four downstream variables are included in this dataset. Annual significant wave heights ( $H_w$ , m) were calculated using the NOAA WAVEWATCH III 30-year Hindcast Phase 2 for 1979–2009 (Tolman, 2009; Chawla et al., 2013). The model outputs 30 years of hourly significant wave height data on five different ocean grids with varying resolution, and the final product is interpolated to a global 0.5-decimal degree grid. We ran a nearest neighbor search from each  $RM$  location to the nearest grid cell with wave data that is within one grid cell diagonally, which is equivalent to 0.7071 decimal degrees, or ~80 km at the equator. Because some coasts are missing wave data not all 5,399 rivers have corresponding wave data. For each calendar year, we calculate the annual mean of the top 1/3 largest wave heights. The resulting 30 years of annual significant (mean of the largest 1/3) wave height data are representative of the strongest wave action that occurs at each location

within a year, or representative of a stormy season for areas with strongly seasonal wave climates. The mean of these 30 annual values is the mean annual significant wave height ( $H_w$ ).

Median tidal ranges ( $H_t$ , m) were calculated using the previously published Oregon State University TOPEX/Poseidon Global Inverse Solution TPXO model results (Egbert and Erofeeva, 2002). The model outputs tidal harmonics component data on a 0.25-decimal degree resolution grid derived from a barotropic inverse solution. Following Baumgardner (2015), we use the main tidal components, the lunar semidiurnal and the lunar diurnal, to calculate mean tidal range by building a composite tidal sine wave and calculating the average range. We ran a nearest neighbor search from each *RM* location to all grid cells with tidal data that are within the same distance used for the wave search. The median of the tidal range values within this search radius is used to represent each river mouth's tidal range.

Receiving-basin bathymetry is an important attribute of delta formation because it sets the size and shape of the volume to be filled from a mass balance perspective and influences the hydrodynamics (Jiménez-Robles et al., 2016; Carlson et al., 2018). The size of the basin could be characterized by the average depth whereas the shape is most simply characterized by the bathymetric slope. In most cases, we do not know basin depth prior to delta formation, and current depths offshore deltaic river mouths will be deeper than the initial depths if the basin has offshore-dipping bathymetric slopes. Thus, instead of using depth, we characterize the receiving basin with bathymetric slopes. Bathymetric slopes ( $S_b$ ) are calculated from ETOPO1 bathymetric data (Amante and Eakins, 2009) and *RM* locations. ETOPO1 is a global surface elevation model with 1 arc-minute resolution (1/60 decimal degree, or ~1,800 m at the equator). For each river, we collect all bathymetric elevations within a 20-km radius from the *RM* location. We calculate linear slopes between each point and the *RM* (assumed elevation = 0 m) and take  $S_b$  as the 75<sup>th</sup> percentile of all slopes. We chose the 75th percentile because it best captures the bathymetric slope when we compared our  $S_b$  values to spot measurements. We purposefully search far away from the shoreline because we want to characterize the offshore depths not affected by sediment deposition from the river.

Rate of sea-level change is calculated from AVISO (Archiving, Validation and Interpretation of Satellite Oceanographic data, <https://www.aviso.altimetry.fr>). The AVISO dataset combines sea-level change from different satellite altimetry missions from 1992-2018 using the delayed time Ssalto/Duacs multi-mission altimeter data processing system, which corrects biases among instruments and applies inter-calibration to the record. Sea-level change rates are calculated for every

0.25° x 0.25° cell by finding the best fit to the data over 26 years. These data are not corrected for glacial isostatic adjustments. We used modern rates that are measured (not modelled) to be consistent with the other environmental variables. An argument could be made that we should compare delta formation to sea-level change averaged over the lifespan of the delta. But, we do not know when each delta in this dataset started forming. Nonetheless, if we assume that all deltas started growing since the most recent deglaciation, we can compare modeled relative sea-level change rates since 26 kyr ago to delta formation (Argus et al., 2014). When we use these longer-term sea-level change rates, it does not increase the success of predicting delta formation using the method in section 3.2, and because of this we opt to use the modern sea-level change data for consistency.

### 3. Results

Our mapping reveals there are 5,399 coastal rivers with widths greater than 50 m, and 2,174 of those rivers (~40%) have a geomorphic delta. Herein, we refer to all 5,399 coastal rivers as “rivers”, the 3,225 that do not have deltas as “river mouths,” and the 2,174 with deltas as “deltas.” These terms are not completely accurate because, for example, an individual “river” that is considered a “delta” rather than a “river mouth” still has at least one main river mouth (*RM*) and may have additional river mouths for each distributary channel.

#### 3.1. Global distribution of rivers and deltas

River deltas are not distributed evenly on coastlines and there are locations on the world’s coastlines where deltas are unusually common (Fig. 2). These “delta hotspots” occur primarily in Southeast Asia (dashed box Fig. 2b). Notably, these areas are also densely populated with rivers (Fig. 2a), though river abundance does not always equate to delta abundance. For example, East Asia has high river density but low delta density (black box, Fig. 2b). Similarly, along the west coasts of Central and southern North America (from 5°N to 45°N) the coast is densely populated with rivers, but the northern portion is delta-poor compared to the southern portion. There are also a surprising number of deltas in arid environments. For instance, there is high delta density in the Red Sea and on Baja California. This largely arises because many alluvial fans coming off the nearby mountains reach the coastline and satisfy our definition of a delta.

Binning these data by latitude reveals preferential locations of rivers and deltas (Fig. 3). The largest numbers of rivers and deltas occur roughly from -12° to 45°, and 66° to 72° (Fig. 3a). This unequal distribution is partly explained by the unequal

latitudinal distribution of global shoreline length (Wessel and Smith, 1996) (Fig. 3b). River density, or rivers per shoreline kilometer, shows that globally there is one river for every 230 km of coastline and one delta for every 333 km of coastline. Coastlines within the  $-6^\circ$  to  $-3^\circ$  bin have the highest density of deltas with roughly one delta per 100 km of shoreline (Figure 3c, solid black line). River density is above average from  $-45^\circ$  to  $45^\circ$  (Fig. 3c, white bars). Delta density, however, is above  
5 average over a smaller range from  $-21^\circ$  to  $30^\circ$  (Fig. 3c, solid black line).

To determine which environments promote delta formation, it is perhaps most instructive to observe locations where the likelihood for rivers to create deltas is highest. Delta likelihood ( $L_d$ ) is defined as the number of deltas relative to the total number of rivers for a given set of samples (Fig. 3d, solid black line). For the entire dataset, 40% of rivers form deltas, and thus the global  $L_d$  is 0.40 (Fig. 3d, dashed black line). Regions where  $L_d$  is higher than the global mean exist from  $-27^\circ$  to  $30^\circ$   
10 and  $60^\circ$  to  $72^\circ$ , whereas rivers located from  $-57^\circ$  to  $-27^\circ$  and  $30^\circ$  to  $60^\circ$  are least likely to form a delta (Fig. 3d).

These latitudinal zones, where rivers are more likely to create deltas, coincide with peaks in environmental variables that influence delta formation. Both  $Q_w$  and  $Q_s$  have peaks from roughly  $-9^\circ$  to  $30^\circ$  and  $60^\circ$  to  $75^\circ$  (Fig 4a, b), which are similar in location to  $L_d$  peaks.  $A_b$  has a similar high latitude peak but is missing the equatorial peak (Fig. 4d), probably reflecting the importance of small mountainous rivers in those locations (Milliman and Syvitski, 1992). On the other hand, delta formation  
15 is infrequent where  $H_w$  and  $H_t$  are high, namely  $-57^\circ$  to  $-27^\circ$  and  $42^\circ$  to  $60^\circ$  (Fig. 4e, f). There are no latitudinal changes in  $Q_s/Q_w$ ,  $S_b$ , or  $H_s$  that are easily relatable to delta formation (Fig. 4c, g, h).

### 3.2. Relationships between environmental variables and delta formation

We explore controls on delta formation by analyzing how the likelihood of a river creating a delta varies with each environmental variable. River mouths and deltas have statistically different population distributions for seven of the eight  
20 environmental variables (all but  $Q_s/Q_w$ ) (Table 2), suggesting that deltas form under certain ranges of environmental variables. To determine this, we used the Kolmogorov-Smirnov test, which is a non-parametric, distribution-free test that uses the cumulative distribution functions of the two populations to estimate statistical difference. Although a few variable pairs show some correlation, such as  $Q_w$  and  $A_b$ , none have a strong statistical correlation (Pearson correlation coefficient  $> 0.9$ ), suggesting they exert largely independent controls on delta formation.

Delta likelihood ( $L_d$ ) generally increases as the upstream environmental variables increase (Fig. 5). Increasing  $Q_w$ ,  $Q_s$ , and  $A_b$  causes a linear increase in semi-log space in  $L_d$  (Figs. 5a-b, d). Deltas have characteristic  $Q_w$ ,  $Q_s$ , and  $A_b$  values that are an order of magnitude larger than those of river mouths (statistically significant,  $p < 0.05$ ) (Table 2). These data suggest that rivers with small water and sediment discharge and/or that come from small drainage basins rarely form deltas, whereas rivers with larger values of the upstream variables frequently create deltas. Sediment concentration ( $Q_s/Q_w$ ) exerts no clear control on  $L_d$  (Fig. 5c), and there is no statistical difference between the mean or median  $Q_s/Q_w$  values for rivers mouths versus those for deltas (Table 2).

Rivers are less likely to create deltas where  $H_w$  and  $H_t$  are large.  $L_d$  shows a clear linear decrease as  $H_w$  increases (Fig. 6a). Rivers that experience little wave energy at the coast ( $H_w < 1$  m) create a delta more than half of the time ( $L_d \approx 0.5$ -0.6), but delta formation becomes nearly impossible for larger wave heights.  $L_d$  also seems to show a linear decrease with  $H_t$  (Fig. 6b), if the long tail of the distribution is eliminated where the sample size is small ( $H_t > 7$  m). The population of river mouths has higher mean and median  $H_w$  and  $H_t$  than rivers with deltas (statistically significant,  $p$ -value  $< 0.05$ ) (Table 2).

$S_b$  displays a non-monotonic relationship where  $L_d$  decreases then increases across the range (Fig. 6c).  $S_b$  data are bimodally distributed for the rivers in our dataset, suggesting rivers empty into two types of receiving basins (separated by the dashed line in Fig. 6c). If these basin types are separated, there is a clearer relationship between  $S_b$  and  $L_d$ . For shallowly-dipping basins ( $S_b < 0.006$ ), there is a negative relationship between  $L_d$  and  $S_b$  (Fig. 6c, left of dashed line), and delta likelihood increases as slope decreases. In steeply-dipping basins ( $S_b > 0.006$ ),  $L_d$  is approximately constant to slightly increasing as slopes steepen (Fig. 6c). There is no clear relationship between sea-level change ( $H_s$ ) and  $L_d$  (Fig. 6d), which is somewhat surprising given that river mouths and deltas have statistically different mean and median  $H_s$  values (Table 2).

To quantify the relative importance of the environmental variables for delta formation, we develop an empirically-derived logistic regression. The result of a logistic regression is a statistical model that predicts a dichotomous outcome (in this case, a river creates a delta, or it does not) based on multiple independent variables. This dataset contains eight total independent variables collected on most rivers, where four are upstream variables ( $Q_w$ ,  $Q_s$ ,  $Q_s/Q_w$ ,  $A_b$ ) and four are downstream variables ( $H_w$ ,  $H_t$ ,  $H_d$ ,  $S_b$ ). Of the 5,399 rivers in this dataset, 490 of them (9.1%) have data available for all eight independent variables.

The data meet the assumptions of binary logistic regression because the dependent variable has two mutually exclusive outcomes and the sample size is large (45 samples or more per independent variable). Additional assumptions that the data must meet include having little to no multicollinearity and no outliers. We tested for multicollinearity by calculating the Pearson correlation coefficients ( $R$ ) between all continuous independent variables and no variables exhibited  $R > 0.9$ . We also remove 13 rivers that have outliers in any of the independent variables based on a modified  $z$ -score, where an absolute value modified  $z$ -score  $> 3.5$  is considered an outlier (Iglewicz and Hoaglin, 1993). The final subset of data used for the regression has  $n = 477$  rivers (249 rivers without deltas, 228 rivers with deltas). The samples were randomly separated into training (2/3 of the samples) and validation (1/3 of the samples) subsets, each of which represented similar distributions of independent and dependent variables. We do this to see how well the logistic regression can predict delta formation on river mouths not used in development of the equation.

The binary logistic regression between the probability that a river will create a delta and the eight environmental variables yields the following log odds relationship:

$$\ln(\pi_{\text{delta}}/(1 - \pi_{\text{delta}})) = 1.45 + 0.000589Q_w + 2.56Q_s - 0.974H_w - 0.187H_t \quad (1)$$

where  $\pi_{\text{delta}}$  is the probability that a river will form a delta, and ranges from 0 (river is unlikely to form a delta) to 1 (river is most likely to form a delta). This is different from the  $L_d$  values presented earlier in that it is predicted whereas  $L_d$  is measured. Environmental variables with  $p > 0.05$  ( $Q_s/Q_w$ ,  $A_b$ ,  $S_b$ , and  $H_s$ ) are not included in the final empirical relationship, because any controls these variables exert on delta formation are minimal (e.g., variations in  $Q_s/Q_w$  have no clear relationship with  $L_d$ , Fig. 5d) or are related to variations in the other important variables (e.g.,  $A_b$  influences  $Q_w$  and  $Q_s$ ).

Thus, the combination of environmental variables that comprises the right side of equation (1) predicts the log odds that a river will form a delta. When tested using the validation subset, equation (1) has a 74% success rate at predicting delta presence (Fig. 7), where  $\pi_{\text{delta}} > 0.5$  is considered a prediction that a delta exists, and  $\pi_{\text{delta}} < 0.5$  is considered a prediction that no delta exists.

This empirically derived relationship can be used to calculate the probability that a certain combination of the most important environmental variables will form a delta. For example, using environmental variable values for the Godavari River in the right-hand side ( $RHS$ ) of equation (1) results in  $RHS = 3.93$ . The probability that the Godavari River should form a delta

is  $\pi_{delta} = \frac{e^{RHS}}{1+e^{RHS}} = 0.98$ . Thus, the environmental variables that conspire to form the Godavari River are very likely to form a delta, which is not surprising given the existence of the large Godavari River delta.

## 4. Discussion

### 4.1. Which environmental variables most strongly control delta formation?

5 We have considered the relationships between eight environmental variables and delta formation. However, determining which variables are most dominant is not straightforward. After all, most combinations of environmental variables that exist globally completely suppress delta formation (60% of the rivers included in this dataset do not have a delta). Our likelihood analysis shows that deltas are more likely to form at river mouths with large water discharge  $Q_w$  (Fig. 5a), sediment discharge  $Q_s$  (Fig. 5b), and drainage basin area (Fig. 5c), and with small significant wave heights  $H_w$  (Fig. 6a), and tidal ranges  
10  $H_t$  (Fig. 6b). Results suggest that upstream variables exert a primary control. Increasing upstream variables ( $Q_w$ ,  $Q_s$ ,  $A_b$ ) across their value range accounts for the full range of delta likelihood—that is, the smallest  $Q_w$ ,  $Q_s$ , and  $A_b$  values have  $L_d \approx 0$ , and largest  $Q_w$ ,  $Q_s$ , and  $A_b$  largest have  $L_d \approx 1$  (Figure 5). Downstream variables seem to be of secondary importance for forming deltas. Increasing the downstream variables ( $H_w$ ,  $H_t$ ) decreases the likelihood that a river forms a delta but does not produce the full range of possible  $L_d$  values. At the lowest values of  $H_w$  and  $H_t$  delta likelihood is still 0.5. Furthermore, when we  
15 remove  $H_w$  and  $H_t$  from equation (1) the prediction success rate decreases by only 3%, from 74% to 71%.

These controls on delta formation explain first-order latitudinal variations observed in Figures 3 and 4. For example, the peaks in water and sediment discharge values from  $-9^\circ$  to  $30^\circ$  and  $60^\circ$  to  $75^\circ$  (Fig. 4) likely explain the similarly located peaks in delta formation (Fig. 3). The suppressing effects of waves and tides can also be seen at a global scale. Low delta formation rates from  $-57^\circ$  to  $-27^\circ$  and  $30^\circ$  to  $60^\circ$  are likely due to large  $H_w$  and  $H_t$  values in these regions, where  $Q_w$  and  $Q_s$  are  
20 low (Figs. 3, 4). Moreover, the zone from  $60^\circ$  to  $75^\circ$  that has increased  $Q_w$  and  $Q_s$  values (Fig. 3) also has some of the lowest  $H_w$  and  $H_t$  values (Fig. 4). Thus, while high  $Q_w$  and  $Q_s$  values in this region promote delta formation, the decreased  $H_w$  and  $H_t$  values also allow delta formation to occur.

Downstream bathymetric slope ( $S_b$ ) displays a complex relationship with delta likelihood. At slopes  $< 0.006$ , delta likelihood decreases with increasing slope (Fig. 6c). This is likely because, all else being equal, deeper areas should take longer

to fill with sediment and they are also less effective at damping incoming waves and tides. Interestingly, for slopes  $> 0.006$ , delta likelihood increases with steeper slopes, which is more difficult to explain. Based on visual observation, the steeply-dipping basins reflect active margins, and the shallowly-dipping basin types reflect passive margins, though we did not pursue a more robust confirmation. If these steeper slopes relate to active margins, then larger sediment sizes and higher supply on active margins may explain the different relationship with delta likelihood than that for the shallowly-dipping basin types (Audley-Charles et al., 1977; Orton and Reading, 1993; Milliman and Farnsworth, 2011). After all, the supply of coarser sediment to the coast is more easily retained nearshore (Caldwell and Edmonds, 2014), thereby increasing the likelihood of delta formation.

## **4.2. The roles of rivers, waves, and tides in delta formation**

Our data suggest that deltas are fundamentally created by water and sediment discharge, whereas waves, and possibly tides, suppress delta formation. This is consistent with the notion that delta formation is the result of constructive upstream forces set by the river, and destructive downstream marine forces (Fisher, 1969, Boyd et al., 1992, Anthony, 2015). This idea, initially proposed by Fisher (1969), provides a different perspective compared to the oft-cited study on delta morphology and formation from Galloway (1975). Galloway's diagram implies that deltaic formation and morphology is the result of the interplay of river, waves, and tides. In the case of a purely wave dominated delta, Galloway's diagram would predict a cusate delta. Instead, our data clearly show that the most wave-dominated delta is no delta at all, consistent with other studies (Nienhuis et al., 2013; Boyd et al., 1992). This suggests to us that the concept of delta formation and morphology might be better cast as a balance between constructive and destructive forces.

If we consider the perspective that delta formation is the result of a balance between constructive and destructive forces, then new questions emerge: How do wave and tidal processes influence the ability of fluvial processes to construct deltas? How stable is the balance between a given set of constructive and destructive forces? Regarding the last question, there are examples of rapid changes in delta morphology through time, which suggests that the balance can be precarious. The Rhône River delta shifted in morphology from channel-network dominated in the 16th century to its current wave-smoothed shape as floods and sediment loads declined during the Little Ice Age (14th-19th centuries) (Provansal et al., 2015). The Po River delta showed three morphological transitions each time the balance between river and waves changed over the last 4000 years

(Anthony et al., 2014). These examples from the past should direct our attention to how the current configuration of deltas might change in the future. We know that anthropogenic climate change is changing wave conditions (Reguero et al., 2019) and humans are drastically changing water discharge and sediment flux to coastal rivers (Syvitski and Milliman, 2007). It is unclear how the coastal deltas of the world will adapt as these changes in boundary conditions. Future work would benefit from linking our empirically derived delta likelihood predictor with metrics of delta morphology to understand when morphological shifts might occur.

## 5. Implications

River deltas are the final filters of sediment before it is discharged to the global oceans (Sawyer et al., 2015). Although only 40% of rivers in our dataset form deltas, our results show that 5.9 Bt/yr, or 85% of the measured global sediment flux (Milliman and Farnsworth, 2011), enters river deltas before reaching the ocean. This is not entirely surprising because the presence of a delta requires sediment and our data show that sediment rich rivers tend to create deltas. But, we currently do not know what proportion of that sediment is retained in the delta. This retention should be considered when calculating global sediment flux to the oceans (e.g., Milliman and Farnsworth, 2011), because deltas are exceptionally good at impounding sediment since channel networks are optimized to achieve this goal (Edmonds et al., 2011; Tejedor et al., 2016; Tejedor et al., 2017). Limited calculations suggest deltas can retain up to 30% of the sediment supplied to them (Goodbred and Kuehl, 2000; Syvitski and Saito, 2007; Kim et al., 2009). However, as we have shown here, certain environmental variables promote sediment accumulation via delta formation, and these same environmental variables may promote sediment retention by certain deltas. Thus, our results may prove useful for quantifying the full, and presently unaccounted for, deltaic sink in the global sediment cycle.

We also propose that our data and analyses have important implications for resource exploration and coastal restoration. Although using equation (1) to predict delta formation for modern rivers is somewhat redundant, it may prove useful for predicting past or future delta existence. Ancient deltaic deposits comprise significant hydrocarbon reservoirs, and provided our analysis holds through geologic time, we could predict the presence of deltaic deposits in the rock record if  $Q_w$ ,

and  $Q_s$  can be estimated via other paleohydraulic methods. If we use a logistic regression that does not include the less dominant limiting effects of waves and tides, then equation (1) becomes:

$$\ln(\pi_{\text{delta}}/(1 - \pi_{\text{delta}})) = 0.0016 + 0.0175Q_w + 0.0345Q_s \quad (2)$$

Using this simplified equation, which shows a 71% success rate when tested using the validation subset, we can predict the likelihood of delta formation for paleoenvironments where sediment and water discharge can be constrained. For example, water and sediment flux estimates for rivers of the Ferron Sandstone in the Cretaceous Western Interior Seaway of the United States (Bhattacharya et al., 2016) suggests the likelihood of delta formation is 99%, and indeed, the Ferron contains deltaic deposits. This example highlights how our results could be used to predict the presence of deltaic deposits in the rock record the absence of direct observational evidence.

Looking forward, this relationship can be used to predict future deltaic formation. Global environmental change will continue to put coastal environments at risk, largely by land loss due to accelerated sea-level rise and decreased sediment delivery to the coast. Coastal restoration and hazard-mitigation techniques often involve the creation of new deltaic land via controlled river diversions (e.g., Kim et al. (2009)), though it can be difficult to predict the risk related to such projects. Predictions made using equation (1) can help the decision-making process concerning setting controllable environmental variables, such as water discharge. For example, in a hypothetical environment where a river diversion is being considered, and the current set of environmental variables yields  $RHS = -0.2005$  (which suggests the probability of delta formation is  $\pi_{\text{delta}} = 0.45$ ), a  $600 \text{ m}^3 \text{ s}^{-1}$  increase in  $Q_w$  alone will increase the probability of delta formation 8% (from 0.45 to 0.54) (assuming the increased  $Q_w$  has no effect on other variables).

## 6. Conclusions

Based on analysis of a new dataset comprising 5,399 coastal rivers that are at least 50 m wide, along with eight environmental variables, we find that only 40% (2,174) of coastal rivers have deltas, and these are unevenly distributed geographically, with delta formation being more likely in latitudes  $-27^\circ$  to  $30^\circ$  and  $60^\circ$  to  $72^\circ$ . Likelihood of delta formation increases with increasing sediment flux, water discharge, and basin area, whereas likelihood decreases with increasing significant wave height and tidal range. Receiving-basin bathymetry has a bimodal effect on likelihood of delta formation. At

slopes less than 0.006, delta formation decreases with increasing slope, but the trend is reversed at slopes greater than 0.006. Recent sea-level change and sediment concentration have no clear effect on delta formation. Finally, we derive a logistic regression that predicts probability of delta formation with an accuracy of 74%. Together our results suggest that delta formation is a balance between the constructive forces of water and sediment discharge, and the destructive forces of waves and tides.

### 7. Acknowledgements

DAE would like to acknowledge funding and support from National Science Foundation grants 1135427, 1426997, and 1812019. Sea-level products were processed by SSALTO/DUACS and distributed by AVISO+ (<https://www.aviso.altimetry.fr>) with support from CNES. We thank M. Domaracki, I. Thomas, K. Rhodes, A. Whaling, and S. Adams for helping with data collection and organization.

For 5 a, c, and d the outliers have been cut off for viewing purposes.

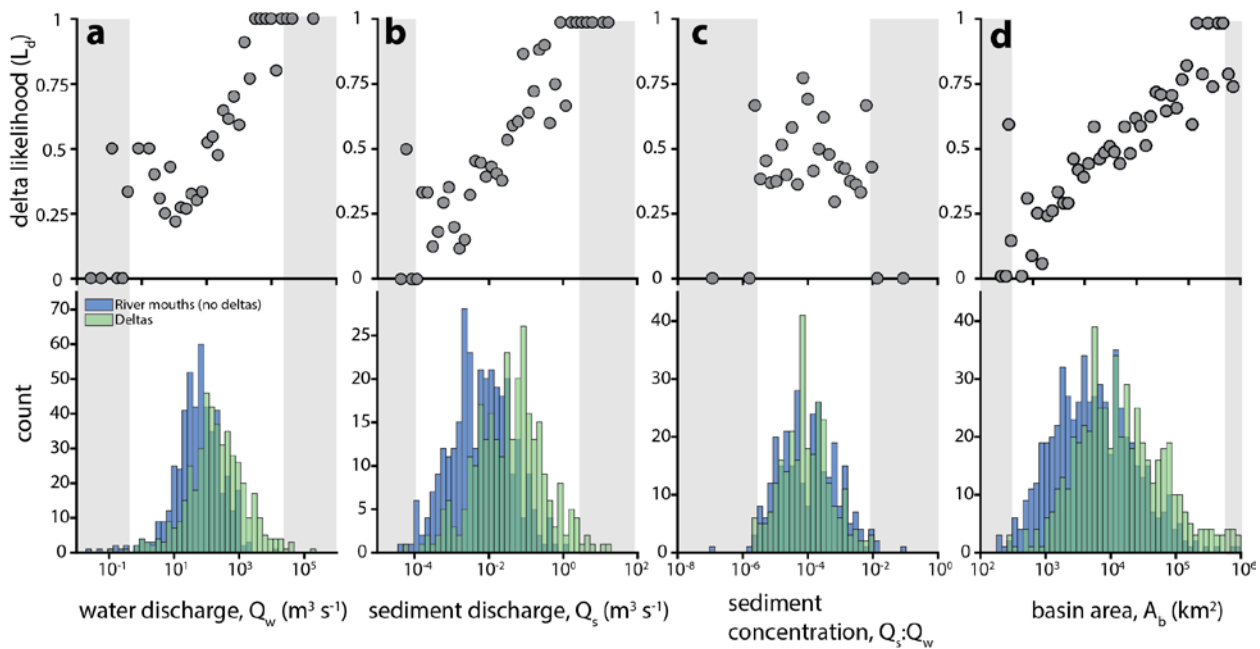

Figure 5. Differences in upstream environmental variables for rivers with and without deltas. (top panel) Scatter plots of delta likelihood, defined as number of rivers with a delta relative to total number of rivers in that interval. (bottom panel) Histograms binned into equal log-spaced intervals. Gray boxes outline ranges represented by 1% or less of total sample number.

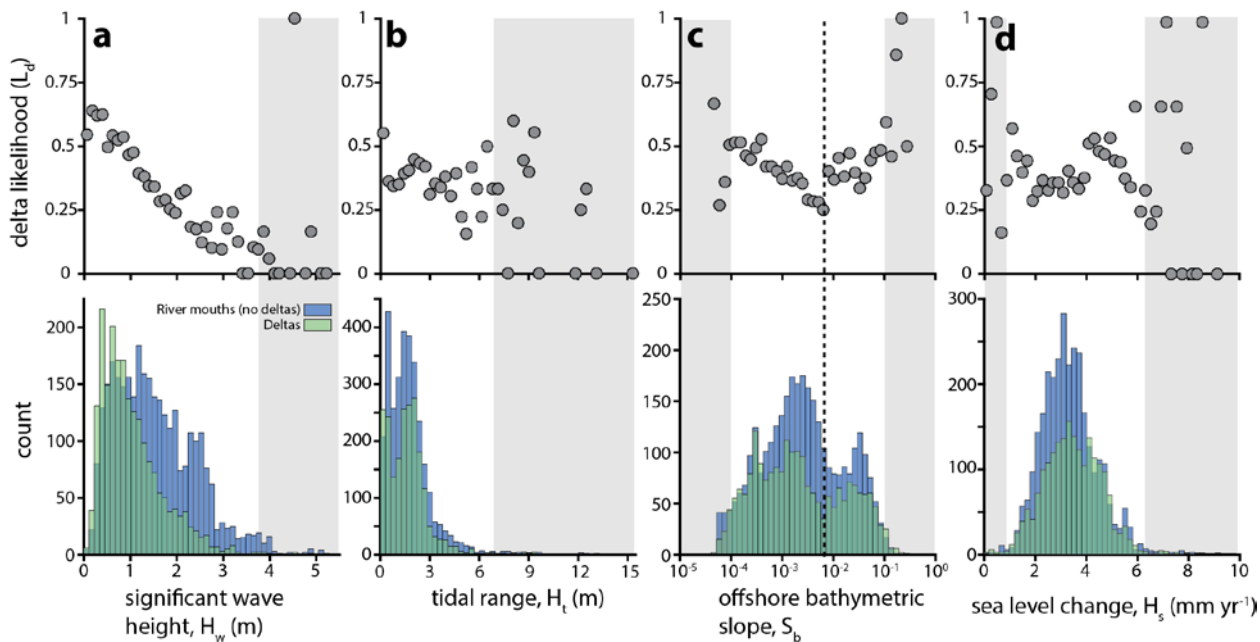

Figure 6. Differences in downstream environmental variables for rivers with and without deltas. (top panel) Scatter plots of delta likelihood, defined as number of rivers with a delta relative to total number of rivers in that interval. (bottom panel) Histograms binned into equal log-spaced intervals. Gray boxes outline ranges represented by 1% or less of total sample number.

Figure 7. Scatter plot of measured versus predicted delta formation. Equation (1) was used to calculate predicted probability of delta formation,  $\pi_{delta}$ , using rivers with necessary data available,  $n = 477$  (2/3 of which was used for training, and 1/3 used for validation). To compare predicted values from equation 1 to our collected data the binary observation of delta presence or absence was transformed into a continuous variable. To do this we created 20 equal intervals ( $\pi_{delta} = 0.05$  bin widths) and averaged  $\pi_{delta}$  values.  $L_d$  is calculated for each bin as the number of rivers with deltas divided by total number of rivers. Dashed line represents a 1:1 relationship.
