timothee.sassolas-serrayet@umontpellier.fr

Received and published: 4 October 2019

RC1: I’ve completed my review of Sassolas-Serrayet et al’s paper entitled ‘Estimating the disequilibrium in denudation rates due to divide migration at the scale of river basins.’ In this manuscript, the authors analyze a series of landscape evolution models to try to ultimately assess the ability for one to measure the background rock uplift rate through basin averaged erosion rates in the presence of divide migration and find that there is a drainage area dependence on the ability to do so. Using this, they are able to provide some recommendations for planning of sampling for things like cosmogenic erosion rates. This study seems timely and interesting and is a good fit for Earth
Surface Dynamics. While I think the general results are strong and consistent with what others have shown (or rather what is implied by the results others have shown), I do have some concerns about whether they've biased their detailed results with the specifics of their model setups. Much hinges on whether or not the models were ran with an imposed threshold area or not (it is a little ambiguous in the text, so it's possible that my concerns are for naught and I simply misunderstood what they meant). These concerns (along with other comments that the authors hopefully find helpful) are outlined in my detailed comments below.

AC: Thank you for your constructive comments. The remarks concerning the potential bias associated with the use of a threshold area $A_c$ greater than zero leads to a great number of modifications, especially in the result and discussion sections. However, the results we obtained by using a $A_c$ value equal to zero does not affect the main finding of our study: divide mobility can lead to significant differences between tectonic uplift and basin-wide denudation rates even if topographic steady state is achieved at large scale. We updated the figures in order to represent the new results and take into account the referee's comments. We hope this offers an improved and clearer version of our manuscript.

RC1: L37-38: Probably important to clarify that the divides are migrating in response to the same change (it's implied, but not explicitly stated in the way you word it).

AC: Thank you for this remark. Indeed, the persistence of migrations is not related with change of other factors (i.e. tectonic or climate) during the landscape evolution. Action: We modify the concerned paragraph as following: "Although rivers exhibit a rapid adjustment to tectonic or climatic changes to maintain their profiles, Whipple et al. (2017) show that divides continue to migrate over time periods of 106-107 years as response to the same changes. This suggests that long-term transience might be pervasive in the planar structure of landscapes, even in the absence of new variations in landscape characteristics or forcings (e.g. tectonic or climate) (Hasbargen and Paola, 2000; Hasbargen and Paola, 2003; Pelletier, 2004)."
RC1: Equation 1: I think the top expression \((U + (dz/dt)_{fluv})\) should be for \(A > A_{sub c}\), correct?

AC: Thank you for pointing out this inconsistency. We use a value of \(A_{c}\) equal to 0 in the revised version of the manuscript in order not to separate hillslope and fluvial domains. That way diffusion and fluvial erosion affect simultaneously every pixel in the model. Action: we removed the condition that regards \(A_{c}\) in the equation 1.

RC1: L119 – 121: Is the stated critical drainage area applied in the model (i.e. the model is run with the rule set such that diffusion is only applied where \(A < A_{sub c}\) and incision is only applied where \(A > A_{sub c}\)) or is this simply the threshold area used for extracting the channels (and thus the channel heads) for analysis? My (anecdotal) experience has been that running TTLEM (or really any model that allows you to do so) with an explicit critical drainage area that is built in where it defines where incision/diffusion is applied can produce some odd behaviors and very odd drainage networks. If you were running TTLEM with the critical drainage area option turned on, did you experiment with the sensitivity of your results to turning this off (i.e. setting it to 0)? It’s important to note that this option is kind of atypical, i.e. it is not something allowed in CHILD, LandLab, etc. I think more importantly, if you are running with \(A_{c}\) (or AreaThresh as it’s named in the TTLEM setup) set to a value greater than zero you are artificially controlling the length of the hillslope (it would otherwise be set by the combination of \(K\) and \(D\) values you provide) and thus controlling the length scale over which the landscape responds to the divide migration (as this is happening mostly in the hillslopes based on prior results). This may in turn reflect some of your other results (e.g. erosion rates as a function of drainage area, etc).

AC: We agree. We tested the sensitivity of our results with \(A_{c}\) equal to 0. Results confirm the referee’s intuition, namely that a value of \(A_{c}\) greater than zero controls the length of hillslopes and thus produces odd behaviors. In the revised version of the manuscript, we use \(A_{c} = 0\) and modified the text and figures accordingly.
RC1: L125-126: This is the theoretical time to steady-state following a perturbation and assuming a fixed drainage area, which is not really applicable to the time to steady-state for a model ramping up (i.e. running from an initial random noise, low elevation topography to a stabilized topography). I don’t think this necessarily matters that much to your results as you are basically just exploiting the fact that this portion of a model run has a lot of drainage reorganization, but I would be careful about equating these.

AC: We agree. Action: We removed the sentence.

RC1: L205-207: This pattern in erosion rates as a function of drainage area pretty much follows from the observation discussed in Forte & Whipple 2018, namely that if considering simulated landscapes experiencing progressive divide motion (as opposed to discrete captures), the erosion rate contrasts across divides is very spatially limited to areas very near the divides (essentially hillslopes), thus as you move to larger drainage areas, the ability to ‘see’ this across divide contrast in erosion rate in basin averaged values would be expected to decrease as the signal is diluted by more and more of the drainage basin eroding very near the background erosion rate / uplift rate.

AC: We agree. Action: We added the sentence “As exposed by Forte & Whipple (2018), the erosion rate contrasts across divides is spatially limited to areas very near the divides.”

RC1: L232-236: This all seems logical, however it might be important to note that basin averaged statistics like this work best when a basin is either uniformly (or at least consistently) either expanding or contracting. This is probably (usually) the case in homogeneous models like the ones you use here, but in either more heterogeneous models or when applied to real landscapes, there is the danger of a basin appearing to be neutral because it is expanding in one direction and contracting in another (i.e. the metrics counterbalance when averaged over the whole basin). This could be especially noticeable when divide migration is driven by a lateral gradient in uplift rate with respect to the main drainage direction. Thus, I would (maybe somewhat self importantly) argue
that along-divide metrics are still quite useful to consider.

AC: We agree. Even in homogeneous models like the ones we use, basins may experience both expansion and contraction on different parts of their perimeter and a single metrics may not reflect compound behaviors. Action: We added an analysis of the standard deviation of cross-divide differences in metrics along basin perimeter (Figure 7) and associated details in the main text (“Figure 7c shows that the dispersion is related to the standard deviation of aggressivity metrics, $\Delta \chi_{\text{std}}, \Delta G_{\text{std}}$ and $\Delta H_{\text{std}}$. In other words, basins where different divide segments migrate at different rates or in different directions are more scattered.”).

RC1: L249: This is also consistent with what Forte & Whipple 2018 saw in natural landscapes, i.e. across divide contrasts in elevation were usually equivocal in terms of indicating potential for drainage divide motion compared to the other metrics.

AC: We agree. Our updated model shows the metric based on local slope seems less sensitive to basin-wide denudation from divide migration for area with rock uplift rates ($\leq 0.1$ mm/yr). Conversely, even if it depends on the average elevation at regional equilibrium stage, the metric based on elevation seems more relevant. However, this metric would likely display significant noise in natural landscapes.

RC1: L254-255: Why do any of these basins have knickpoints? You’re applying a constant uplift rate and progressive divide motion shouldn’t really impart knickpoints onto any profiles. Are they coming from captures? While I understand the logic of ignoring basins with knickpoints, it’s more that I wonder if the presence of knickpoints in this is suggesting that there may be some stability issues. One of the behaviors of the TVDFVM algorithm is to keep and accentuate any knickpoint (even if those are developed through numerical instability), so it would be good to try to diagnose why there are knickpoints in the first place to rule out model instability. You could try running one of your models with the same exact setup but using the implicit (fastscape) algorithm that’s built into TTLEM and see if you also are getting knickpoints.
AC: We agree, for uniform models knickpoints appear counter-intuitive. However, we observed two processes that produced actual knickpoints (1) the uplift of the initial plateau leads to the propagation of major knickpoints controlled by the edge of the plateau until ∼2Myr and (2) as you suggest, discrete stream captures occur occasionally. Overall, the great majority of basins (and therefore drainages) are not affected by any knickpoints. Action: We clarified this point by adding the sentence “In our simulations, knickpoints may develop due to (1) the dissection of the initial flat surface or (2) discrete drainage captures (see Sec. 3.1).”.

RC1: L274-278: I’m a bit confused by this statement. From my own simulations with TTLEM, if you’re starting with the same random noise and keeping everything else the same (i.e. not changing the length of timestep, etc), the drainage network evolution will be pretty much the same regardless of uplift rate. I would expect changes in the effective drainage density to manifest more in response to changes in the diffusion constant or ratios between K and D.

AC: We agree. This behavior was driven by Ac > 0 and our updated model shows a different pattern. We now observe no differences in general drainage geometry. However, we observe an inverse relationship between uplift rate and drainage density consistent with previous theoretical works. Tucker and Bras (1998) found a similar relationship when using a formulation of diffusive processes that includes a threshold slope Sc, as we use in our simulation.

RC1: L283-285: Again, this might be a result of setting the area threshold to a non zero value (assuming you did). I’m also not sure how to interpret Sc if the area threshold is set to a non zero value, because you’re artificially controlling the hillslope length and thus (I think) artificially controlling the maximum slope that can develop anyways. If I misunderstood your discussion of A sub c earlier and you were not running with A sub c set to a non zero value, feel free to ignore this comment.

AC: We agree, this is indeed driven by Ac>0. Action: We modified this part of the
discuss based on the updated results.

RC1: L340-345: This is neat, though (and as you mention in the following sentence) it would be interesting to think about the applicability of this in more heterogeneous environments where, as I mentioned before, there’s a greater chance that the basin averaged metric could be misleading (i.e. a low average metric because of coexisting drainage area loss and gain on different sides). Maybe a valuable approach to consider would be including the standard deviation (or min and max) in the basin averaged metric to try to capture this potential variability without having to look at the divide segments in detail?

AC: We agree. As we explained in the previous comment concerning L232-236, we assess the variability of cross-divide contrast in metrics by calculating the standard deviation of metrics along basin perimeter. This allows to discriminate between basins that are homogeneously stable and those that display both expansion and contraction along their perimeter. Action: See RC1: L232-236.

RC1: L349-372: This is a good thing to focus on, but I think you could add an interesting discussion here of considering the sampling strategy with regards to the goal of the study. At present, this gives a (valuable) set of ideas for how large a basin needs to be to get an accurate assessment of the uplift rate from the erosion rate, but alternatively you could point out that this gives you a sense of the size of basin you need to target if you’re explicitly interested in measuring divide migration rates, i.e. larger basins are not going to be helpful. Similarly, this speaks to the need to pre assess basins for their potential divide mobility before sampling (if your intention is to get at background uplift rate), i.e. if either the divide segment or basin average metrics suggest no divide mobility, you don’t need to worry about the size of the basins as much (except for all the other concerns we already have, that you mention).

AC: We thank you for this pertinent suggestion. Action: We developed this aspect as a new full paragraph in the discussion section.
Interactive comment on “Estimating the disequilibrium in denudation rates due to divide migration at the scale of river basins” by Timothée Sassolas-Serrayet et al.

Timothée Sassolas-Serrayet et al.

timothee.sassolas-serrayet@umontpellier.fr

Received and published: 4 October 2019

RC2: The paper in review presents a series of numerical models set up to investigate the impact of drainage divide migration on landscape denudation rates, as well as both presenting new topographic metrics and testing the ability of previous ones to detect divide migration. The authors then apply these metrics to provide some useful constraints for basin size for CRN sampling. I think the paper is interesting, well written, and builds well on previous work that quantifies the extent of drainage divide migration across landscapes, given the many papers that have been published in the last few years on the topic. However I have some concerns about the setup of the model, in
particular the use of a parametrised critical area threshold. I therefore think it will be very suitable for publication in ESURF provided that the comments detailed below can be addressed.

AC: Thank you for your positive and constructive comments. We carefully addressed every remark you formulated. Your concerns about threshold area Ac to distinguish hillslope and fluvial domains were justified. In the revised manuscript we produce a new set of results using simulations with no threshold area (Ac=0). This change largely corrects the atypical behaviors underline by both reviewers concerning the length of hillslope, the dependency of drainage network evolution to rock uplift, and the meaning of Sc, but it does not modify the major results concerning the impact of drainage migration on basin-wide denudation rates. We provide a revised version of the manuscript where we present our new results and addressing the referees comments.

AC: We agree. Action: We reworded the sentence accordingly.

RC2: Eq 1: I think the fluvial expression should be A > Ac?

AC: We agree. Action: As modified our model with Ac = 0, we removed this condition in Equation 1. See RC1 for details.

RC2: Eq 1: Similar to Reviewer 1, I agree that the model setup described in equation 1 makes it seem like the position of channel heads and resulting drainage divide metrics will be determined by the critical area threshold (Ac) parameter. I’m not convinced that, in real landscapes, there is a critical area threshold for determining channel head location or, if there is, that this should be fixed across the landscape as a whole. This setup seems a bit unintuitive to me - why not just combine fluvial incision with hillslope diffusion at each node and eliminate the need for an Ac parameter in the LEM at all?

AC: We agree. See RC1’s comment. Action: See RC1.

RC2: Line 118: Much work has shown that in many real landscapes it is most likely that
n > 1 [e.g. Lague, 2014; Harel et al., 2016]. This will again have a significant impact on the distribution of slopes and erosion rates within the model landscapes, and may influence the calculation of the divide migration metrics. I think it would be useful to run some test landscapes where n > 1 to determine i) the impact this has on the variability of erosion rate with basin area; and ii) the impact on the aggressivity metrics.

AC: We agree this would be a very interesting alley to explore. However, this would constitute an entirely new study that would go far beyond the scope of the present study. Action: We mentioned this as a perspective in the conclusions.

RC2: Line 121: Following on from this, I would suggest running a sensitivity analysis changing Ac in the model setup to see what effect this has on the calculation of divide migration metrics.

AC: We agree this could be a worthy path to follow. However, following comments from both referees we opted to set Ac = 0 in line with the majority of works published previously in order to produce results that can be compared.

RC2: Line 125: How is it determined whether the model runs have indeed reached steady state?

AC: As expected, the model does not actually reach a perfect steady state but a quasi-static equilibrium. First, we study the reorganization of the drainage after an initial perturbation keeping in mind that the drainage network shall not be affected by the initial model geometry. Next, in our simulations, we consider that the landscape reaches a regional steady state once transient topographies are completely eroded, i.e. once the mean model elevation remains constant and when the average denudation rate and the imposed rock uplift rates deviate by less than 2%. Finally, transient events such as discrete stream captures susceptible to form knickpoints are carefully detected and discarded from the results.

RC2: Line 135: It's a bit unclear how the elevation is calculated. Is this the average
elevation for all pixels in the basin at each time step?

AC: Basin-wide denudation rate is calculated using the average of differences of elevation in the basin borders during a 10 kyr interval.

RC2: Line 162: It would be good to include some more details here of how this averaging is carried out. Is local slope calculated using a moving window (including hillslopes), or is this just the slope of the first order channel? It wasn’t clear to me whether the elevation at each channel head was averaged, or whether the first order channel downstream of the channel head was included. Fig S2: I think it would be useful to edit this figure and move it to the main paper, as it was difficult to follow how the aggressivity metric is calculated from the text. I realise some of this is based on previous work, but the averaging of the cross-divide metrics to produce a new metric for each basin is novel in this paper. I didn’t understand how the segmenting shown in Fig S2 was done, or how the segment length over which the averaging should be performed is determined.

AC: We agree we did not provide enough detail on this. All metrics are measured at a reference drainage area. Across-divide metric differences are only calculated along divide segments shared by two reference basins. Hence, aggressivity metrics are the averaging of these documented segments along the perimeter of the sampled basin. Action: We reshaped section 2.3.2 and transferred Fig. S2 from the Supp. Mat. to the main text (now Fig. 2).

RC2: Line 221: As well as drainage divide migration, variability in erosion rate between basins could simply result from the transient propagation of knickpoints, especially in the earlier model runs. This seems to be supported by the fact that the variability decreases significantly through time as shown in Figures 4 (a) - (c). What is the evidence that this variability is in fact due to divide migration and not due to transient knickpoint propagation? In the text it’s stated that this is shown from Fig 2(e), but I didn’t understand how this figure shows that.
AC: It is true that transient propagation of knickpoints can affect basin-wide denudation rates. To avoid any erosion signal associated with these transient features, we do not take into account the first stage of the model (< 2Myr for the reference model), when as you highlighted it, major knickpoints are retreating along the edge of a plateau. We also discard from the analysis all basins that contain knickpoints generally formed by discrete stream captures.

RC2: Figure 6 and 7, and Lines 259 - 262: Is there any physical meaning/theoretical prediction for the linear trends on these figures, and how significant are they? If indeed there is a non-linear relationship between S and E, then I wouldn’t expect a linear relationship between \(_G\) or \(_H\) and E/U.

AC: We agree that the relationship between aggressivity metrics and E/U may be more complex than a simple linear relationship (especially when considering the different trends between aggressor and victim basins). We do not propose any physical meaning to explain this relationship, but we simply use it to compare results in regard to the different parameters. Action: We agree this may be misleading and we decide to remove this aspect from our analysis.

RC2: Figure 7: I was quite surprised how noisy some of these data are, especially for the smaller basins, considering that these are all from LEMs and not real landscapes. Maybe this could do with a bit more discussion in the text as to potential reasons for this noise? In the text it’s stated that it is due to the presence of significant knickpoints, but I was confused as to whether basins with knickpoints were excluded or not. It raises the possibility that some of these metrics, especially \(_H\), would be too noisy in real landscapes when additional factors such as variations in lithology, rainfall or uplift are taken into account.

AC: We agree the level of noise observed in Figure 7 is surprisingly high. However, it cannot be explained by knickpoints retreats because we excluded all associated basins from our analysis. Action: Following RC1, we now assess the standard deviation of \(_C5\)
cross-divide metric differences along basin perimeter and find that it explains part of the dispersion. We also assess via a “confidence index” the proportion of documented segments when calculating aggressivity metrics. These results are now presented in section 3.

RC2: Lines 275 - 277: I'm also surprised that there is an increase in drainage density with increasing uplift when n = 1 in the model runs. Previous theoretical work by Tucker and Bras [1998] predicted that drainage density should be independent of erosion rate when n = 1, which was then shown by numerical modelling using CHILD by Clubb et al. [2016] (Figures 4 and 5). Furthermore, and more qualitatively, when I have run LEMs with detachment-limited stream power in the past I have generally found that the geometry of the network remains fixed when increasing uplift rate, and only the slopes of the network increase. I think this could be discussed in more detail as to why there is this discrepancy with previous theoretical predictions and numerical modelling results.

AC: Both Tucker and Bras (1998) and Clubb et al. (2016) found that drainage density is independent of erosion rates with n=1 (and therefore, uplift rate in steady-state topography) when using a linear formulation for diffusion. However, when using a formulation that takes into account a threshold slope for hillslope, both studies show an inverse relationship between drainage density and uplift rate. Thus, the results exposed in our study are consistent with these previous theoretical works.

RC2: Line 279: ‘we obtain no significant changes in the relationship between the calculated aggressivity metrics and the E/U ratio for uplift rates...’ I’m not sure I agree with this statement - from Fig 7, some of the distributions look quite different for U = 0.5 and U = 2 mm/yr, especially for _H. This may be just because of the smaller basins, or that it’s difficult to get a sense of how dense the data are in the center of the plot.

AC: We agree the assertion may be misleading. We observe a clear decrease of dispersion for higher uplift rates. However, the trend remains the same regardless of the uplift rate value. In any event, results must be affected by a threshold area Ac fixed
to a non-zero value. Action: We present detailed results concerning sensibility to uplift rate using a $Ac = 0$ in section 4.1.1.

RC2: Lines 276 and 287: I think it would strengthen the paper to quantify this change in ‘river channelization’ proposed by the authors. At the moment this appears to be a qualitative statement which is difficult to verify from the current figures and analysis. It’s an interesting result that changing the value of $Sc$ influences drainage density, which makes sense from the theory and has implications for real landscapes where $Sc$ is difficult to determine. I think more could be made of this, and suggest simply calculating drainage density for the different model runs. This would put some more weight behind the statement that increasing drainage density is the mechanism by which changing $U$ and $Sc$ impact the aggressivity metrics.

AC: We agree. However, the updated model using $Ac = 0$ does not display significant discrepancies when $Sc$ varies. As pointed out by RC1, $Ac > 0$ can artificially control hillslope length and drainage density. Letting $U$ vary does have an effect on drainage density, though, and we agree this should be explored. However, we think that this topic may deserve a dedicated study that is beyond the scope of the present work.

RC2: Lines 314 - 315: I don’t understand what are the ‘expected quadrants’ that the basins are being compared to here. Is this compared to the reference model, or compared to Willett et al. (2014)?

AC: We agree we did not state our terminology clearly. We meant ‘expected when comparing to the reference model’. Action: We clarified this by adding the following paragraph: “In agreement with cross-divide metrics tested by Forte and Whipple (2018), graphs in Figure 7 must be divided into four quadrants. Aggressor (victim) basins have negative (positive) $\Delta \chi_{av}$ and $\Delta H_{av}$ values and conversely positive (negative) $\Delta G_{av}$ value (Fig. 2). Theoretically, aggressor (victim) basins have higher (lower) denudation rates than the underlying uplift rate.” We also explicitly labeled the aggressors and victims quadrants in the associated figures.
Estimating the disequilibrium in denudation rates due to divide migration at the scale of river basins.

Abstract. Basin-averaged denudation rates may locally exhibit a wide dispersion, even in areas where the topographic steady state is supposedly achieved regionally. This dispersion is often attributed to the accuracy of the data or to some degree of natural variability of the signal, but it can also be attributed to stochastic processes such as landsliding. Another physical explanation to this dispersion is that of local and transient disequilibrium between tectonic forcing and erosion at the scale of catchments. Recent studies have shown that divide migration can potentially induce such perturbations and they propose reliable metrics to assess divide mobility based on cross-divide contrasts in headwater topographic features. Here, we use a set of landscape evolution models assuming spatially uniform uplift, rock strength and rainfall to assess the effect of divide mobility on basin-wide denudation rates. We propose the use of basin-averaged aggressivity metrics based on cross-divide contrasts (1) in channel head elevation, an integral function of position in the channel network, (2) in channel local slope gradient and in elevation, (3) in channel height, measured at a reference drainage area. From our simulations, we show that the metric based on differences in channel head elevations across divides is the least reliable to diagnose local disequilibrium. For the other metrics, our results suggest a nonlinear relationship with are more suitable for relatively active tectonic regions as mountain belts, where contrasts in local gradient and elevation are more important. We find that the ratio of basin denudation associated with drainage migration to uplift, which can reach up to a factor of two, regardless of the imposed uplift rate, erodibility, diffusivity coefficient and critical hillslope gradient. A comparison with field observations in the Great Smoky Mountains (southern Appalachians, USA) underlines the difficulty of using the metric based on elevation of the outlet of the investigated catchment. Regardless of the considered metrics, we show that observed dispersion is controlled by catchment size: a smaller basin may be more sensitive to divide migration and hence to disequilibrium. Our results thus highlight the relevance of divide stability analysis from digital elevation models as a fundamental preliminary step for basin-wide denudation rate studies based on cosmogenic radionuclide concentrations.
1 Introduction

Topographic steady state, in which average topography is constant over time, is one of the key concepts of modern geomorphology (e.g. Gilbert, 1877; Hack 1960; Montgomery, 2001). Though simple, this paradigm provides a useful framework to study landscape evolution related to tectonic and/or climatic forcing (e.g. Willett et al., 2001; Reinhart and Ellis, 2015), to spatial variations in rock strength (Perne et al., 2017) or to the geometry of active crustal structures (Lave and Avouac, 2001; Stolar et al., 2007; Scherler et al., 2014; Le Roux-Mallouf et al., 2015). To define topographic steady state, the temporal and spatial scales of the processes involved are essential parameters. Compared to large scale geodynamic processes operating over 1-100 Myr timescales, river incision and sediment transport are rapid processes driving landscapes to stable forms over this long timescale, whereas rapid climatic fluctuations during the Quaternary may prevent modern landscapes from reaching the occurrence of steady-state conditions in modern landscapes (Whipple, 2001).

The timescale of river divide migration has received increasing attention in the recent years. Although rivers exhibit a rapid adjustment to tectonic or climatic changes to maintain their profiles, Whipple et al. (2017) show that divides continue to migrate over time periods of \(10^6 - 10^7\) years, suggesting as response to the same changes. This suggests that long-term transience might be pervasive in the planar structure of landscapes, even in the absence of new variations in landscape characteristics or forcings (e.g. tectonic or climate) (Hasbargen and Paola, 2000; Hasbargen and Paola, 2003; Pelletier, 2004, Dahlquist et al., 2018). In addition to the influence of spatial variability of rock uplift rate, rock strength or rainfall (e.g. Reiner et al., 2003; Godard et al., 2006; Miller et al., 2013), this long timescale could also explain the persistence of spatial variations in denudation rates observed in tectonically inactive orogens in spite of a supposedly and theoretically topographic achieved steady state (Willett et al., 2014).

As an example of this, in the Great Smoky Mountains in the southern Appalachians, uplift and erosion rates integrated over varying time periods from 10s kyr to 100 Myr give a similar average magnitude of \(0.025 - 0.030\) mm yr\(^{-1}\) ca. \(0.03\) mm yr\(^{-1}\) (Matmon et al., 2003a, b and Portenga and Bierman, 2011). These results suggest a regional quasi-topographic steady state over the last ~180 Myr, maintained by the isostatic response of the thickened crust since the end of the Appalachian orogeny (Matmon et al., 2003a, b). Beyond this average value, individual basin-wide denudation rates exhibit a strong dispersion (up to a factor of two, Fig. 1), which is not related to spatial variation in rainfall or in erodibility of the substrate (Matmon et al., 2003b). In a recent study, Willett et al. (2014) assess divide mobility from the contrast in the channel head topographic metric \(\chi\), taken here as a proxy for steady-state river profile elevation (Perron and Royden, 2012; Royden and Perron, 2013), and propose an explanation in which a significant part of the observed dispersion in denudation rates could be due to drainage divide migration associated with contrasting erosion rates across divides.

Divide migration is often assessed through the metric \(\chi\) (Willett et al., 2014). More recently, to characterize divide migrations Forte and Whipple (2018) introduced other metrics, referred as “Gilbert metrics” (Gilbert, 1877), based on the cross-divide contrast in channel head local slope gradient and elevation in order to characterize divide migrations. This last study indeed focused on cross-divide contrasts in headwater basin shape. Here, we model divide migrations and propose to extend these
approaches by modeling divide migration and by developing new metrics to assess divide stability at the scale of the entire watershed, which are an expansion of the aggressivity metric initially suggested by Willett et al. (2014). We use these metrics to assess the effect of persistent divide mobility on basin-averaged erosion rates at a timescale of $10^4$ yr. We use numerical landscape evolution models, taking into account both hillslope diffusion and fluvial incision. For the sake of simplicity and to avoid the influence of other factors such as topography, lithology, climate or vegetation, we restrict our analysis to synthetic orogens with spatially uniform uplift, rock strength and rainfall. After a brief presentation of the used landscape evolution model (LEM), we describe the methods developed to assess basin-wide denudation rates and aggressivity metrics, such as average cross-divide contrasts in headwater channel $x$, slope gradient and elevation. Next, we investigate transient time and location of morphologic adjustments to divide migrations. We explore the relevance and complementarity of tested relative stability metrics between neighboring basins. We then investigate the impact of uplift rate, erodibility and hillslope processes on the dynamics of divide migration and associated denudation rates. Finally, we apply our approach to the basin-wide denudation rates dataset of Matmon (2003a,b) in the case of the Great Smoky Mountains and propose new criteria to guide future sampling strategies to assess basin-wide denudation rates from river sands.

2 Methods

2.1 Landscape Evolution Model (LEM)

We use TTLEM (TopoToolbox Landscape Evolution Model) (Campforts et al., 2017), a landscape evolution model based on the Matlab function library TopoToolbox 2 (Schwanghart and Scherler, 2014). This LEM uses a finite volume method (Campforts and Govers, 2015) to solve the following equation of mass conservation for rock/regolith subject to uplift and denudation:

$$\frac{\partial z}{\partial t} = \left(\frac{\partial z}{\partial t}\right)_{td} + \left\{\left(\frac{\partial z}{\partial t}\right)_{flu} \text{ for } A < A_c \right\} + \left\{\frac{\rho_r}{\rho_s} U + \left(\frac{\partial z}{\partial t}\right)_{hil} \text{ for } A < A_c \right\} + \left\{\frac{\rho_r}{\rho_s} U + \left(\frac{\partial z}{\partial t}\right)_{flu} \right\}.$$

(1)

where $\partial z/\partial t$ is the variation of elevation with time, $(\partial z/\partial t)_{td}$ is the change of elevation due to tectonic horizontal advection, $U$ is the rock uplift rate, $\rho_r/\rho_s$ is the density ratio between the bedrock and the regolith, $A$ is the upstream area and $A_c$ is the critical drainage area which corresponds to the transition between hillslope and fluvial processes. We use a linear formulation of hillslope diffusion (Culling, 1963) limited by a critical drainage area which correspond to the transition between hillslope and fluvial processes. Hillside denudation is given by a non-linear formulation (Roering et al., 1999):
\[
\left( \frac{\partial z}{\partial t} \right)_{\text{hill}} = -\nabla q_{s} \quad \text{with} \quad q_{s} = -\frac{\frac{\partial z}{\partial t}}{\frac{\partial z}{\partial t} + \alpha_{z} D \nabla z},
\]

(2)

where \( q_{s} \) is the flux of soil-regolith material. This flux rate increases to infinity \( \frac{\partial z}{\partial t} \) when slope tends to a critical value \( S_{c} \). When slopes values exceed \( S_{c} \), they are readjusted to the critical value by using a modified version of the excess topography algorithm (Blöthe et al., 2015). The diffusivity \( D \) gives the rate of soil-regolith material creep. Its magnitude ranges from \( 10^{-3} \) to \( 10^{1} \) m\(^2\) yr\(^{-1}\) in natural settings and varies with soil thickness, lithology and vegetation (Roering et al., 1999; Jungers et al., 2009; West et al., 2013; Richardson et al., 2019). Hillslope diffusion is implemented in TTLEM using an implicit scheme, which is unconditionally stable at large time steps (Perron, 2011).

Non-linear diffusion formulation (Perron, 2011) is also implemented in TTLEM. However, we favored the use of a linear diffusion with a critical slope, which is more convenient \( \frac{\partial z}{\partial t} \) for the time step used in our simulations (\( \approx 5000 \) yr) and the set of parameters considered (see section 2.2). Due to the relatively coarse spatial resolution of our models (\( \approx 90\) m), any of these diffusion formulations generate negligible topographic differences on the direct vicinity of crest lines (Roering et al., 1999, Campforts et al., 2017) and do not affect our results (see Fig. S1). Fluvial incision is calculated with a stream power law:

\[
\left( \frac{\partial z}{\partial t} \right)_{\text{fluv}} = -KA^{m} \left( \frac{\partial z}{\partial x_{r}} \right)^{n},
\]

(3)

where \( K \) is the erodibility coefficient reflecting climate, hydraulic roughness, sediment load and lithology. Its value ranges between \( 10^{16} \) and \( 10^{9} \) m\(^{1-2m} \) m\(^{-1} \) yr\(^{-1}\) (Kirby and Whipple, 2001; Harel et al., 2016). \( A \) is the upstream area, \( x_{r} \) is the along stream distance from the outlet of the river. \( m \) and \( n \) are two parameters \( \frac{\partial z}{\partial t} \) which are usually reported as a \( m/n \) ratio ranging between 0.35 and 0.8. The River incision law is implemented in TTLEM using an explicit scheme based on a higher-order flux-limiting finite volume method that is total variation diminishing (TVD-FVM) [see Campforts and Govers (2015) and Campforts et al. (2017) for further details]. Its main advantage \( \frac{\partial z}{\partial t} \) is to eliminate numerical diffusion, which is present in most other schemes solving differential equations of river incision. This last point has a significant impact on the accuracy of basin-wide simulated denudation rates, making TTLEM a well-suited LEM for the purpose of this study.
2.2 Modeling approach and assumptions

2.2.1 Geometry and meshing

Since the computation is performed using a discretized land surface, smaller mesh sizes will lead to detailed topography but will lengthen the computation time and memory requirements. Hereinafter, we consider a reference square landscape model of 50 km side with a grid resolution of 90 m, which is a good compromise between computation time (3-5 hours on a PC workstation) and the total amount of basins that can be studied (>1000). Our results are not affected when the mesh resolution is increased to 30 m nor are they when the model size is multiplied by four (100x100 km). (See Fig. S4S2).

2.2.2 Boundary conditions

In order to isolate the effect of divide migrations on the variability of basin-wide denudation rates, we explore simple models with constant and spatially uniform uplift and precipitation rates and we assume no horizontal advection. We use a Dirichlet boundary condition: simulation edges are not affected by uplift on a one pixel band to represent a stable base level for rivers. The model presents no initial topography, except for gaussian noise ranging between 0 and 50 m so as to initiate a random fluvial network.

2.2.3 Set of parameters

Firstly, we consider a reference model with parameters commonly used for moderately active orogens: an uplift rate $U$ of 0.1 mm.yr$^{-1}$, a diffusivity $D$ of $10^{-2}$ m$^2$.yr$^{-1}$ (Roering et al., 1999), a threshold slope $S_c$ of 30° (Burbank et al., 1996; Montgomery et Brandon, 2002; Binnie et al., 2007), a $m/n$ ratio of 0.5 with $m = 0.5$ and $n = 1$, an erodibility coefficient $K$ of $3 \times 10^6$ m$^2$.yr$^{-1}$, a $\rho_c/\rho_s$ ratio of 1.3 and a critical drainage area $A_c$ of 0.2 km$^2$ (Montgomery et al., 1993).

Secondly, all other parameters held constant, we investigate the specific impact of uplift rate, erodibility and hillslope processes in other models by varying $U$, $K$, $D$ and $S_c$ between 0.501 and $21$ mm.yr$^{-1}$, $5 \times 10^5$ m$^{-2}$.yr$^{-1}$ and $5 \times 10^6$ m$^{-2}$.yr$^{-1}$, $10^3$ and $10^4$ m$^2$.yr$^{-1}$ and 20° and 40°, respectively.

In order to better constrain the variability of our results under similar conditions, we run for each model five simulations using the same parameters, but with different initial random topographies.

2.2.4. Timescale

The total duration of simulations is 10 Myr, which is nearly one order of magnitude longer than the theoretical time to reach general topographic equilibrium for our set of parameters (Willett, 2001). The implicit scheme used to simulate non-linear hillslope processes provides stable solutions regardless of the time step. In contrast, the explicit scheme used to model fluvial incision requires a time step that satisfies the Courant-Friedrich-Lewy criterion. Hereinafter, we choose a time step $\Delta t$ of 50,000 yr for hillslope diffusion. Our results are not affected when using a smaller $\Delta t$ (i.e., 1,000 yr) (see Fig. S1). Incision
computation is nested in this time step and uses another time step that is automatically determined to assure model stability (Campforts et al., 2017).

2.3 Basin-wide denudation rates and aggressivity metrics

2.3.1 Basin-wide denudation rates

We derive basins from the synthetic DEMs (Digital Elevation Models) using an accumulation map computed with a single flow direction algorithm implemented in TopoToolbox (Schwanghart and Scherler, 2014). Next, we calculate for each basin the variation in average elevation over a time interval of 10 kyr, which averages the results over 20 time steps. The drainage network can migrate during the simulation, so we only survey the basins that keep the same outlet location during this time interval. Furthermore, due to divide mobility, the geometry of watersheds can also change. Hence, we measure the average difference in elevation inside the basin perimeter after 10 kyr. Here we only assess the surface uplift \( U_s \) (England and Molnar, 1990). To obtain approximate the real-denudation rates \( E \) for each basin, we sum the surface uplift \( U_s \) with the rock uplift rate \( U_r \) assumed in our simulation and divide the result by the time interval, which is an approximation. However, calculating incremental denudation rates over each time step is prohibitive in terms of computation time for the number of extracted basins. By considering the relatively small period over which we integrate denudation (10 kyr), we then assume that these approximations have a negligible impact on the results at first order. Calculated that way, the denudation rate. If the basin is in a topographic steady state, \( U_s \) is equal to zero and \( E \) is equal to the background uplift rate. Thus, a positive (negative) value of \( U_s \), traduce a deficit (an excess) of denudation. Calculated that way, \( E \) is sensitive to divide migration but also to transient features like knickpoints that migrate along the river network. In our simulations, knickpoints may develop due to (1) the dissection of the initial flat surface or (2) discrete drainage captures (see Sec. 3.1). We use the knickpointfinder algorithm implemented in TopoToolbox (Schwanghart and Scherler, 2014) to identify the affected basins.

2.3.2 From cross-divide metrics to basin averaged aggressivity metrics

Most recent studies have focused on the relationship between drainage divide mobility and headwater cross-divide contrast in either \( \chi \), slope gradient, elevation or local relief values (e.g.-Whipple et al., 2017; Forte and Whipple, 2018). Here, in line with Willett et al. (2014, see Supp. Mat. therein) we focus on the specific influence of divide migration on denudation rates at the scale of the entire stream basin. Our approach aims to integrate cross-divide contrasts in drainage network properties along the entire basin perimeter. We then obtain basin-averaged aggressivity metrics that determine if a watershed is either growing or shrinking (Willett et al. 2014).

First we calculate \( \chi \), local slope and elevation map for each channel pixel. First, we assess \( \chi \), local topographic gradient \( G \) and height \( H \) of the drainage network at a reference drainage area \( A_{ref} \) (Fig. 2). Ideally, \( A_{ref} \) must be equal to the area at which channelization occurs (Forte and Whipple, 2018). However, it is challenging to locate the accurate position of channel
heads (Chubb et al., 2016). Hence, we use a constant value of $A_{ref}$ set to 1 km$^2$. The parameter $\chi$, is an integral function of position along the channel network (Perron and Royden, 2012) described by the equation:

$$\chi = \int_{x_h}^{x} \left( \frac{A_0}{A(x)} \right)^{\frac{m}{n}} dx,$$

where $A(x)$ is the upstream drainage area at the location $x$, $A_0$ is an arbitrary scaling area set to 1 km$^2$. The $m$ over $n$ ratio refers here to the reference concavity of an equilibrated river profile. Its value is set to 0.5 in accordance with the model parameters. For each independent drainage network, we integrate $\chi$ from the outlet $x_h$, located at the model boundary (< 1 m high), to the channel heads. We then Local gradient is determined for each DEM pixel from its eight-connected neighbors. Height is simply extracted from the DEM.

Then, we calculate the difference in channel head $x$, local slope of metrics (DA, AG and elevation $H$) across each first order basin segments of divide segment. Those shared by two reference basins. Finally, the aggressivity metric is finally obtained by averaging these first order across-divide differences along the perimeter of each extracted sampled basin (Fig. S3). This way, the sign of the aggressivity metric in a basin corresponds to the difference of the averaged value of considered metric (channel head $x$, slope or elevation difference (DA, AG and $H$)) in this basin with respect to its eight neighbors. This method has the advantage to ponderate the weight of individual divide segments by the number of pixels they contain, and then to provide a robust assessment of the basin aggressivity. Aggressivity metrics based on $\chi$, $G$ and $H$ are hereafter referred to as $\Delta \chi_{av}$, $\Delta G_{av}$ and $\Delta H_{av}$ respectively, which provide an accurate assessment of the basin aggressivity. However, due to topology issues, some parts of the perimeter of the sampled basins may be not shared by two reference basins (Fig. 2). We quantify this incompleteness by assessing the ratio of documented pixels over the total amount of pixel along the basin perimeter. We refer to this ratio as the “confidence index” CI, assuming that an higher CI is associated with a more robust basin aggressivity assessment.

### 3 Results

#### 3.1 Evolution of reference model

A detailed analysis of the DEM suggests that during the initial phase, the flat initial surface (Fig. 2a) is progressively uplifted to form a plateau. At the same time the edges of this plateau are gradually regressive eroded by drainage networks that spread from the base level toward the center of the model (Figs. 2b and c). This transient landscape is completely dissected after 2 Myr. From this time and until the end of the simulation, landscape changes are mainly due to competition between watersheds, resulting in continuous divide migrations with decreasing intensity as the model is moving toward a total topographic equilibrium (Fig. 2d to f; Supplementary Video n°1).
We define the time period of regional steady state, we measure the average elevation, the maximum elevation and the average denudation rate over the entire model for each time step (Fig. 3a and 4a). We identify two distinct stages during the evolution of our reference simulation. During the first million years, due to long wavelength topographic building, the calculated landscapes are far from steady state. This leads to a major increase of the mean elevation from 0 m to ca. 20075 m. In a second stage, this trend reverses and the mean elevation decreases asymptotically toward ca. 6000 m until the end of the simulation.

The evolution of the maximum elevation follows the same pattern but can be affected by temporal changes in the location and altitude of highest peaks. The maximum elevation increases between 0 and ca. 2200250 m over the first 2 Myr (Figs. 3a, 3b, 3c) and decreases progressively to reach a constant value of 1600200 m during the end of the simulation.

We compute the average denudation rate from the tectonic uplift rate and from average elevation change over the entire model between two time steps $\Delta t$.

\[
\frac{\Delta z}{\Delta t}_{av} = U - E_{av},
\]

where $(\Delta z/\Delta t)_{av}$ is the average surface uplift over the entire model on a time-step $\Delta t$, $U$ is the imposed uniform uplift rate (0.1 mm yr$^{-1}$) and $E_{av}$ is the average “real” denudation rate. During the first 0.25 Myr, the mean denudation rate falls abruptly from ca. 0.6 mm yr$^{-1}$ to nearly 0 mm yr$^{-1}$ as a consequence of diffusion over the initial flat topography. After that time and until the first 1 Myr, the mean denudation rate increases but remains lower than the uplift rate, leading to the increase in average elevation over this time period. Next in the following 0.51 Myr, $E_{av}$ exceeds the uplift rate to reach up to 1040 mm yr$^{-1}$. It then before it gently decreases to 0.1 mm yr$^{-1}$ during the remainder of the simulation. This shows that topography tends to - but never reaches - a strict steady state over the simulation time. Abrupt changes in $E_{av}$ after ca. 2 Myr, 2.5 Myr and 3.2 Myr can also be highlighted (Fig. 3b). These brief variations at 2.5, 3.5, 4.5 and 9.5 Myr (red circles in Figure 4b) are related to major local captures in the drainage network, which can be observed during the model evolution (red circles in Fig. 3d, 3e, and f and Supplementary Video n°1).

On the basis of these results, we will consider that quasi-a regular topographic steady-state is reached between 1.5 and 2 Ma, when the plateau relict topography is totally eroded and $E_{av}$ begins to decrease (Figs. 23 and 34). This time is consistent with the time required to reach topographic steady state proposed from models with constant uplift rate and no horizontal advection (Willett et al., 2001).

### 3.2 Basin-wide denudation rates variability

We calculate basin-wide denudation rates $E$ upstream of each stable drainage network confluence after 2.5 Myr, 5 Myr and 10 Myr of simulation (Figs. 4a, b and c). As explained in the method section, we compiled the results obtained for five runs using the same parameters as the reference model, in order to increase the number of sampled basins 5a, b and c.
Regardless of the duration, we observe a significant variability in the calculated denudation rates depending on basin size. As exposed by Forte & Whipple (2018), the erosion rate contrasts across divides is spatially limited to areas very near the divides. Thus, the variability is maximum for small basins (ca. 1 km²) and decreases with increasing basin area. In our approach, small basins are nested in larger ones. Hence, these results can be related to the averaging of denudation rates along the drainage network, in agreement with the measurements of Matmon et al. (2003b). This variability also decreases with time (Figs. 4a, b and 5a-c). For basins with an excess of denudation relative to the uplift rate $U$, the $E/U$ ratio can reach up to 3.25 after 2.5 Myr but only 2 after 5 Myr and 1.87 after 10 Myr. Basins with a denudation excess that stand out of the general trend at 10 Ma (Fig. 5c) are associated with a capture event visible in figure 4b. For basins with a deficit of denudation, the evolution of the ratio is less obvious. It can be lower than 0.255 after 2.5 Myr, but increases slightly to 0.4 after 56 until 10 Myr. These results reflect a significant spatial variability of the difference between basin-wide denudation rates and 0.5 after 10 Myr uplift rate. To assess more accurately the temporal evolution of this variability, we calculate $E$ every 0.5 Myr for three distinct categories of basin sizes: 1-2 km², 10-20 km² and 100-200 km². We then estimate the mean absolute deviation (MAD) from the uplift rate by considering separately basins with a denudation in excess or in deficit (Fig. 4d). Until 1.5 Ma, basins are located on the plateau where denudation rate is null. This leads to a low MAD for basins with a denudation deficit and to the absence of basins with a denudation excess. After 1.5 Ma, basins in deficit exhibit an asymptotic increase in MAD from nearly -0.315 to -0.0504 mm.yr⁻¹, regardless of the area class considered. For basins in excess, the MAD value decreases through time, depending on drainage area: from ca. 0.28 mm.yr⁻¹ to ca. 0.0507 mm.yr⁻¹ for basins with an area of 1-2 km² and 10-20 km², from ca. 0.142 mm.yr⁻¹ to ca. 0.0507 mm.yr⁻¹ for basins with an area of 100-200 km². These results reflect a significant spatial variability of 10-20 km² and from ca. 0.7 to ca. 0.04 mm.yr⁻¹ for the difference between basin-wide denudation rates and uplift rate in our reference models, largest basins. We also see a coherent evolution of this difference over the simulation time, consistent with the model progression toward a total topographic equilibrium.

The spatial variability of the denudation rates is neither homogeneous nor randomly distributed (Fig. 5a-d). The location of drainage basins with denudation rates far from the equilibrium value of 0.1 mm.yr⁻¹ coincides with migrating drainage divides (Fig. 2a-d) and with cross-divide contrasts in headwater channel $x$, slope gradient and elevation height (Figs. 5b, c and 6b-d). Following Willett et al. (2014) and Forte and Whipple (2018), the divide migrations predicted by these contrasts are consistent with the direction of divide mobility obtained from our model. One may note that the higher the contrast in these parameters across the divide, the higher the deviation of the denudation rate from the uplift rate, and therefore from topographic equilibrium. None of sampled basin in this data-set contains a knickpoint. Thus, these results based on simulations assuming uniform and constant properties as well as constant boundary conditions confirm that the dispersion observed in denudation rates is primarily controlled by divide migration. Basins that expand (shrink) show higher (lower) denudation rates compared to uplift rate, and are hereafter referred to as aggressors (victims), following the terminology adopted by Willett et al. (2014).
3.3 Deviation of denudation rates from the uplift rate, and basin aggressivity

Willett et al. (2014) showed that the basin-averaged cross-divide contrast in $\chi$, could be used to deduce an aggressivity metric for basins. We extend this basin-scale approach to the Gilbert’s metrics recently proposed by Forte and Whipple (2018) including cross-divide contrast in headwater slope and elevation. Hereafter, we refer to these aggressivity metrics based on cross-divide contrast in headwater $\chi$, headwater slope (gradient) and headwater elevation (height) as $\Delta \chi$, $\Delta G$ and $\Delta H$, respectively.

We here assess the relationship between the $E/U$ ratio and these aggressivity metrics. First, to exclude variability related to both basin area and time, we focus on a single class of basins with a size of $10-2024$ km$^2$ gathered from five computed reference models after a simulation duration of 2.5 Myr. Denudation rates may be affected by knickpoints, which are a source of transient perturbation at the scale of the catchment. Therefore, in order to focus only on perturbations associated with drainage divide dynamics, basins that contain knickpoints are ignored. In agreement with cross-divide metrics tested by Forte and Whipple (2018), aggressivity graphs in figure 7 must be divided into four quadrants. Aggressor (victim) basins have negative (positive) $\Delta \chi$,$\Delta G_{av}$ and $\Delta H_{av}$ values and conversely positive (negative) $\Delta G$,$\Delta G_{av}$ value- (Fig. 2). Theoretically, aggressor (victim) basins have higher (lower) denudation rates than the underlying uplift rate. Therefore graphs in figure 6 must be divided into four quadrants, with aggressors situated in the lower left one, and victims in the higher right one. This result is verified for ca. 89.88, 52% and 82.81 % of basins for aggressivity metric based on headwater $\chi$, slope and elevation values $\Delta \chi_{av}$,$\Delta G_{av}$ and $\Delta H_{av}$ respectively (Figs. 6a, b and c). Several basins depart significantly from the expected quadrants for $\Delta G$ and $\Delta H$: these exhibit significant knickpoints in their drainage network that increase measured denudation rates.

For this limited dataset, the evolution between $E/U$ and both $\Delta \chi$,$\Delta G_{av}$ and $\Delta G_{av}$,$\Delta H_{av}$ may be defined by a linear relationship (Figs. 6a and b). Part of the dispersion observed around this first order trend may be explained by approximations in the calculation of denudation rates and aggressivity metrics (Fig. 7b). Compared to other metrics, $\Delta H$ seems to be less sensitive to drainage migration and shows a more scattered distribution (Fig. 6c).

In natural settings, the stage of evolution of landscapes cannot be easily defined and the total amount of basins with a specific size may be limited. The large dataset provided by our model can provide further insights by gathering the results obtained every 0.5 Myr for seven classes of basin areas expanding geometrically with a multiplying factor of 2 from 1-2 to 64-128 km$^2$ (Figs. 6d, e and f). Denudation rates may be affected by knickpoints, which are an additional source of transient perturbation at the scale of the catchment. Therefore, in order to focus on perturbations associated with drainage divide dynamics, basins that contain knickpoints are discarded from the analysis. Our results highlight the major control of basin size on the dispersion $E/U$. When all classes of drainage areas are combined together, we still obtain a clear relationship between aggressivity metrics and $E/U$, with 77 %, 56 % and 78 % of basins lying in aggressors or victims quadrants for $\Delta \chi_{av}$,$\Delta G_{av}$ and $\Delta H_{av}$ respectively (Fig 7b). Our results highlight the major control of basin size on the dispersion $E/U$, $\Delta \chi$ and $\Delta G$ and $E/U$ (Fig 6d and e). One may note however Part of the variability intrinsic for each class of basin area may in turn be explained by heterogeneities in aggressivity between different
parts of a basin. Figure 7c shows that this dispersion is related to the standard deviation of aggressivity metrics, $\Delta \chi_{std}$ and $\Delta H_{std}$. In other words, basins where different divide segments migrate at different rates or in different directions are more scattered. The lower the confidence index, the more scattered the results (Fig. 7d). Thus, some dispersion may come from approximations due to undocumented divide segments performed when averaging metrics differences between reference basins (Fig. 2). One may note two different trends for victim and aggressor basins. Aggressors show a more scattered distribution for $\Delta \chi_{av}$ and $\Delta G_{av}$ metrics. When compared to victims, these basins have hillslopes closer to the critical value $S_c$ (Fig. S3). Hence, the dispersion may be explained by the non-linear relationship existing between denudation rates and basin slope (Montgomery and Brandon, 2002; Binnie et al., 2015). Therefore, a simple linear trend is no longer sufficient to properly fit our results. Hence we consider victim and aggressor basins independently assuming two linear trends between $E/U$ and each aggressivity metric.

4 Discussion

4.1 Sensitivity tests

The reference model involves various parameters related to uplift, fluvial incision and hillslope denudation and fluvial incision. A systematic analysis of all parameters-trade-off between all parameters is out of the scope of this manuscript. Here, we do not investigate the effect of erodibility, because it remains poorly constrained in nature and because our study is mostly focused on channel head properties. In this section, we assess the sensitivity of the results to both tectonic and hillslope erosion processes, by studying the specific impact of uplift $U$, erodibility $K$, diffusivity $D$ and critical hillslope gradient $S_c$ taken separately. Varying these parameters may change the simulation time required to erode the plateau associated with the initial boundary conditions. In this section, to reduce sensitivity dependence on these initial conditions, we only consider results obtained between 5 Ma and 10 Ma.

4.1.1 Sensitivity to uplift rate

We vary the tectonic rock uplift rate from rates of 0.501 mm yr$^{-1}$, 0.1 mm yr$^{-1}$ (hereafter called reference model) and 1 mm yr$^{-1}$ to 2 mm yr$^{-1}$, which is in cover the range observed in moderately active mountain belts; e.g. the Alborz, the Alps or the Caucasus of a large variety of geodynamic settings (Champagnac et al., 2009; Djamour et al., 2010; Vincent et al., 2011, 2012). It is well-known that a river responds to a fall in base level (due to changes in rock uplift rate or other forcing) by cutting downward into its bed, deepening and widening its active channel. In our simulations, changes in uplift rate lead to variations in the geometry-density of the drainage network. Compared to the reference model, an uplift rate of 2.1 mm yr$^{-1}$ (0.501 mm yr$^{-1}$) results in an increase (decrease) of river channelization—increasingly proportional to drainage density—which induces larger (smaller) river basins; a lower (higher) range of values for $\Delta \chi$ and $\Delta G$ and a higher (lower) range of values for $\Delta H$ (Fig. 7). More importantly, our simulations suggest a linear. These results are consistent with
previous studies that show an inverse relationship between tectonic uplift, drainage density and denudation erosion rates. As a result, assuming no climate tectonic feedback we obtain no significant changes in equilibrium topography when using a threshold slope for diffusion processes (Tucker and Bras, 1998; Clabb et al., 2016). An increase in uplift rate favors river entrenchment leading to increase the range of $AG_{av}$ and $AH_{av}$ (Fig. 8) relationship between the calculated aggressivity. Hence, these two Gilbert’s metrics and the $E/U$ ratio for appear to be well suited to diagnose local disequilibrium for higher uplift rates ranging between 0.5 (i.e. $1 \text{mm yr}^{-1}$ and $2 \text{mm yr}^{-2}$). Conversely increase uplift rate induces a lower range of values for $\Delta \chi_{av}$. This last observation is explained by the decrease of drainage density, and associated stream length. Maximum variability of $E/U$ reaches a factor regardless the assumed uplift rate between 1 mm yr$^{-1}$ and 0.01 mm yr$^{-1}$. The observed small differences suggest that limited uplift rate promote diffusive processes (see Sect. 4.1.3).

4.1.2 Influence of erodibility

Fluvial erosion is proportional to the erodibility coefficient $K$ that may reflect, among others, rock strength and climate. We let this parameter vary between $5 \times 10^{-6} \text{m}^{1.2}\text{yr}^{-1}$ and $5 \times 10^{-5} \text{m}^{1.2}\text{yr}^{-1}$. As expected from (Eq. 1 and 3), we find that erodibility and uplift rates have opposite effects. Lower (higher) values of erodibility lead to higher (lower) average topography. Thus, an increase (decrease) in erodibility decreases (increases) the range of all aggressivity metrics (Fig. 9). Lower values of erodibility also increase the range of the $E/U$ ratio. Models with higher (lower) erodibility reach a quasi-topographic steady state earlier (at a later stage). Hence, differences in the variability of $E/U$ may be related to different stages of evolution for each models over the period we consider (5 to 10 Ma) (Fig. 5d).

4.1.3 Influence of hillslope processes

Hillslope denudation is proportional to the diffusivity coefficient $D$ and depends on the critical slope $Sc$ (Eq. 2). To test the effect of hillslope processes, we first vary $D$ between $10^{-2}$ and $10^{-1} \text{m}^{2}\text{yr}^{-1}$. We find and $10^{-1} \text{m}^{2}\text{yr}^{-1}$. Compared to the reference model, we find no major difference with the reference model over that range of values for $D$ (Fig. differences in the case of a lower diffusivity (i.e. 0.001 m$^{2}$yr$^{-1}$) (Fig. 10c). In contrast, for models with higher diffusivity coefficient (i.e. 0.1 m$^{2}$yr$^{-1}$), this parameter has a significant effect on both the range of $E/U$ and the aggressivity metric $AG_{av}$ (Fig. 10a). This result derives from a stronger impact of diffusive processes in the upstream parts of the drainage network, consistent with the observations described in section 4.1.1. Denudation intensity also varies inversely to the square of the critical hillslope gradient $Sc$ (Eq. 2). Assuming a critical slope between 20° and 40°, we find that $Sc$ is parameter influencing aggressivity metrics (Fig. 9). As in the case of variations in uplift rate, changes in $Sc$ lead to differences in the organization of the drainage network. Compared to the reference model, a low $Sc$ leads to large river channelization, reducing the range of all aggressivity metrics, but does not affect significantly the relationship between the $E/U$ ratio and the studied metrics.
These observations are consistent with a landscape where hillslopes are completely determined by the assumed critical slope value—(Fig. 11).

Altogether, these sensitivity tests demonstrate the robustness of our findings—Δχ and ΔG. Regardless of the tested parameter values, we observe a relationship between aggressivity metrics and deviation of denudation rates from uplift rates. Thus, aggressivity metrics are, to the first-order, reliable metrics to assess the effect of divide mobility on basin-wide denudation rates inferred from simulations. In the following section, we apply this approach to field observations and discuss the consequences for sampling and interpretation.

4.2 Implication for the interpretation of basin-wide denudation rates

Over the last decades, measurements of cosmogenic radionuclides (CRN) concentration in alluvial sediments (see Granger et al., 2013 and references therein), of suspended sediments (Gabet et al., 2008) and of detrital thermochronology (Huntington and Hodges, 2006) have become common practices to assess basin-wide denudation rates. However, their interpretation remains debated, even in settings where topographic steady state is supposedly achieved regionally.

4.2.1 Application to the Great Smoky Mountains

As previously mentioned (Matmon et al., 2003a, b), while the Great Smoky Mountains in the southern Appalachians are expected to be in a quasi-topographic steady state, basin-wide denudation rates show a strong dispersion up to a factor of 2 when compared to the estimated uplift rate (402.6 ± 9.3 mm yr⁻¹, see Fig. 1). Basins in We use the Great Smoky Mountains as an example because they exhibit average slope values ranging between 20 and 30° (Matmon et al., 2003a). This may suggest that hillslopes are close to the critical angle of repose. On the basis of these assumptions, we consider that our approach is applicable to the Great Smoky Mountains, and that the data associated with 40 basins originally sampled by Matmon et al. (2003a, b), even though estimated uplift rates differ by nearly two orders of magnitude when compared to the uplift rates used in our models. We use the data associated with 40 basins originally sampled by Matmon et al., (2003a) and for which denudation rates were re-calculated by Portenga and Bierman (2011). Following our method, we calculate the three basin-averaged aggressivity metrics Δχ, ΔGΔχ̂av, and ΔHΔĤav associated with these 40 catchments (Fig. 4). We assume that the calculation of Δχ requires to define the elevation of the catchment outlet (Hₜ) and the m/n ratio (Eq. 4). As underlined by Forte and Whipple (2018), the choice of the “correct” outlet elevation is non-trivial in natural settings. We thus consider a local base level given by the Tennessee river. To test the relevance of this choice, we also assume a base level located at a fixed arbitrary elevation Hₜ = 400 m. We assume the same m/n ratio value of 0.45 as used in the study of Willett et al. (2014) for the Great Smoky Mountains. For all calculated metrics, the majority (ca. 73% for ΔGΔĜav and 55% for ΔHΔĤav) of the basins are located in the expected quadrants (see Fig. 7). However, more attention must be given to the results based on ΔχΔχ̂av. For this metric, 62% of the analyzed basins lie in the expected quadrant when we consider the Tennessee river as the local base level...
versus ~67 ca. 68% for \( H_b = 400 \) m (Fig. 10). Although the general result remains overall results are similar here, we show that the choice of a different base level \( H_b \) leads to significant variations in \( \Delta \bar{\psi} \Delta \chi_{av} \) for individual basins. This highlights the main weakness of the \( \Delta \bar{\psi} \Delta \chi_{av} \) metric, which is highly sensitive to the choice of the proper base level \( H_b \). Nevertheless, our results confirm the findings of Willett et al. (2014), suggesting that a significant part of the data variance observed in the Matmon et al. (2003a, b) can be explained by divide migration (Fig. 1012), raising this possible explanation for the variability of most natural data-sets. One may note that the Southern Appalachians exhibit migrating knickpoints that can locally affect denudation rates (Gallen et al., 2011; Gallen et al., 2013). This last point can also explain part of the observed variability in this dataset but this specific impact is beyond the scope of the present manuscript study.

4.3.2 Assessment of topographic disequilibrium

Topographic steady-state is a very convenient assumption and concept to deduce the uplift pattern in mountains ranges from denudation rates, and thus to obtain significant information on the geometry of active structures and on orogen dynamics (Lavé and Avouac, 2001, Godard et al., 2014; Scherler et al., 2014; Le Roux-Mallouf et al., 2015). However, this assumption is seldom verified at the scale of sampled watersheds. On the basis of our modeling, we show that the competition between low-order basins has a significant impact on basin-wide denudation rates. The proposed approach provides a new tool to assess the potential maximum deviation from topographic steady state based on aggressivity metrics and drainage area, which can both be inferred from a simple DEM. The closer to zero the aggressivity metrics and the lower the standard deviation of cross-divide metrics, the more representative roof uplift rate are the measured denudation rates. However it still remains dispersion of denudation rates values, especially for smaller catchments.

Based on our sensitivity tests for moderately active orogens (with uplift rates between 0.5 and 2 mm/yr), the empirical relationship between \( \Delta G \) and \( E/U \) obtained from the reference model (Fig. 6) can be used to assess the topographic disequilibrium of basins. Especially for victim basins \( \Delta G < 0 \), this relationship exhibits a linear relationship:

\[
\frac{E}{U} = 0.03\Delta G \quad \text{for area} > 50 \text{ km}^2.
\]
4.4.3 Improvement of sampling strategy

Basin-wide denudation rates obtained from CRN concentration measurements, suspended sediments or detrital thermochronology depend on many parameters including lithology, ice cover, rainfall, landslide activity or tectonic uplift (Vance et al., 2003; Bierman and Nichols, 2004; Wittmann et al., 2007; Yanites et al., 2009; Norton et al., 2010; Godard et al., 2012; Whipp and Elhers, 2019). Hence, to unravel the influence of tectonics from other processes, a specific sampling strategy is usually recommended: (1) to sample catchments with homogeneous lithologies to limit the effect of spatial variations in the abundance of target minerals in bedrock formations; (2) to select catchments with no ice cover (past or present) because the input of glacier-derived sediments can significantly complicate the interpretation of CRN concentrations; (3) to choose areas with spatially uniform rainfall distribution; and (4) to consider watersheds where the relative contribution of landslides to long-term landscape evolution is low. Unfortunately, these different criteria imply to select watersheds with variable sizes. The first three criteria favor the sampling of small catchments, whereas the last one requires basins large enough to be less affected by landslides. Indeed, Niemi et al. (2005) proposed that mixing effects efficiently dampen the stochastic nature of hill-slope sediment delivery by landsliding above a critical catchment area. Considering an uplift rate of 0.5–2 mm yr$^{-1}$, the recommended minimum area needed to mitigate these biases associated with the stochastic input from landslides is of 50 to 200 km$^2$.

Our approach suggests the need to pre-assess targeted basins for their potential divide mobility before sampling for CRN concentration measurements. If the objective is to quantify the background uplift rate, one should sample basins that satisfy the conditions we previously enounced in the current section and also display an aggressivity close to zero and with the smallest associated standard deviation. Conversely, to quantify the specific denudation rate associated with the migration of drainage divides, small aggressor or victim basins should be favored.

Based on our simulations, a relationship between the maximum of erosion variability (0.5 and 99.5 percentiles, respectively) due to divide mobility $[(E - U)/U]_{max}$ and the catchment size $A$ can be derived (Fig. 4.13). Our results suggest a logarithmic dependence between these two parameters, regardless of the assumed $U$, $K$, $D$ and $S_{\gamma}$.

$$ [(E - U)/U]_{max} = c_1 \log(A) + c_2 \quad \text{for} \quad 1 \text{km}^2 < A < 100 \text{km}^2, \quad (7) $$

For victim basins ($\Delta G < 0$), $c_1 \approx 0.05$ and $c_2 \approx -0.5$, whereas for aggressor basins $c_1 \approx -0.14$ and $c_2 \approx 1$. This provides a new additional guideline for the design of sampling strategies in terms of basin size. For instance, considering a quasi-steady state mountain belt with an uplift rate of 1 mm yr$^{-1}$, the minimum basin area required for an erosion rate variability...
lower than 0.5 mm.yr$^{-1}$ is ca. 1 km$^2$ for victim basins and 30–40 km$^2$ for aggressor basins, with $c_1$ and $c_2$ two parameters that depend on balance between erosion processes, uplift rate and state of evolution of the landscape.

5 Conclusions

Calculations from a Landscape Evolution Model assuming spatially uniform uplift, rock strength and rainfall confirm that the concept of topographic steady state is relevant at the scale of entire mountain belts, but represents an oversimplification at the scale of individual watersheds. Our simulations underline the role of divide mobility on deviations from equilibrium, which can lead to significant differences between tectonic uplift rate and basin-wide denudation rates even if an overall topographic steady state is achieved at large scale.

To better assess these deviations, we propose new basin-averaged aggressivity metrics $\Delta X_{av}$, $\Delta G_{av}$ and $\Delta H_{av}$ based on the approach of Willett et al. (2014) and Forte and Whipple (2018). They include mean cross-divide contrasts in channel-head $\chi$, local slope gradient and elevation at the scale of entire river basins - height. From our calculations, contrasts in channel-head elevation $\chi_{av}$ is the most reliable aggressivity metric to be weakly sensitive to assess local disequilibrium, whereas, but is highly dependent on the basin denudation to chosen base level, which remains hard to constrain. Gilbert’s metrics $\Delta G_{av}$ and $\Delta H_{av}$ are more suitable for relatively high uplift rate $E/\dot{U}$ exhibits a nonlinear relationship with $\Delta \chi$ and $\Delta G$. Together, these two parameters (i.e. $\geq 1$ mm.yr$^{-1}$). Altogether, our metrics reveal that $E/\dot{U}$ deviation of denudation rates from uplift rate related to divide migrations depends on both basin aggressivity and basin area. This last parameter has a key control on the dispersion in $E/\dot{U}$, which can reach a factor of two, regardless of the imposed uplift rate (here $0.5–2$ mm.yr$^{-1}$), erodibility (here $5.10^5–5.10^6$ m$^{-1}$yr$^{-1}$), diffusivity (here $10^{-3}–10^1$ m$^2$.yr$^{-1}$) and hillslope gradient (here $20^\circ–40^\circ$). By comparing our results to CRN measurements from the Great Smoky Mountains (Matmon, 2003a, b), we show that this approach can be used to improve field sampling strategies and provides a new tool to derive a minimal uncertainty in basin-wide denudation rates due to topographic disequilibrium.

For the sake of simplicity our models involve spatially homogenous and time invariant parameters. Additional simulations are now needed to test this approach in more complex settings, including spatial and temporal variability in climate and tectonic forcing or parameters like stream power equation exponents $n$ and $m$.

Acknowledgments

We are greatly indebted to referees Fiona Clubb and Adam Forte for providing constructive reviews that significantly improve the quality of the manuscript. We thank Wolfgang Schwanghart and Benjamin Campforts for providing the TopoToolBox and TTLEM codes to analyze and to simulate landscape evolution. Denudation rates are reprocessed by Portenga and Bierman, (2011). Dashed black line shows the estimated background uplift rate for the region of 0.03 mm yr$^{-1}$. 
Figure 2: Conceptual relationship between cross-divide contrast in $\chi$ and Gilbert’s metrics and divide migration as exposed by Willett et al. (2014) and Forte and Whipple, (2018). For $\chi$ and height, divides migrate toward the drainages that present higher values. For channel gradient, divides migrate toward the drainages that present lower values. In our study, channel $\chi$, local gradient and height are measured at the outlet (indicated by red circles) of basins for a reference area (basins bounded with thin black lines). Aggressivity metrics are then calculated for a given basin (represented in grey) by averaging along its perimeter the individual across divide differences in metrics between reference basins. The proportion of perimeter which is not shared by two reference basins is measured to give a confidence index of the calculated aggressivity.
