Dear Professor Mudd,

We submit a revised version of our manuscript entitled "Denudation systematics inferred from in situ cosmogenic ^{10}Be concentrations in fine (50–100 μm) and medium (100–250 μm) sediments of the Var River basin, southern French Alps" for consideration for publication in *Earth Surface Dynamics*. We would like to thank the two referees for their helpful reviews of paper, which helped us improve the overall quality of the manuscript.

Both referees have suggested a more detailed discussion of the impact of grain size on the ^{10}Be concentration, which we now have added to the manuscript. Please find attached our detailed responses to the referee #1 with edits in red and to the referee #2 with edits in blue. We have also added unprompted edits in green to specify native ^{9}Be amounts and modify the author's contributions and as well as the acknowledgements.

We hope that our manuscript is now suitable for publication.

Yours sincerely,

Apolline Mariotti (on behalf of all authors)

In their paper "Denudation systematics inferred from in situ cosmogenic 10Be concentrations in fine (50-100 um) and medium (100-250um) sediments in the Var River basin, southern French Alps", Mariotti and colleuages demonstrate that fine grained sediments produce similar denudation rates to more traditional sediment sizes in a mountain catchment. The study is well designed for the goal of this work, and the manuscript is well written and presented. The data are convincing; however, they might be over interpreted in a couple places. Overall, this is a good contribution.

We thank Reviewer 1 for his/her appreciation of our work. We have revised our manuscript to avoid overinterpretation.

As the authors point out, the ability to measure in-situ produced cosmogenic nuclides in fine grained sediment would dramatically increase our ability to undertake paleodenudation studies in lacustrine and marine sediments. This work is certainly taking steps in that direction. However, one of the key conclusions, that this work demonstrates the ability to use 10Be in fine grained off shore sediments, is unfortunately not supported. There are two main reasons for this. First, the analyzed catchment is quite small compared to those that will be contributing most of the fine-grained sediment:

We are not sure of what mechanism Reviewer's 1 is referring here. If they are thinking about attrition (that is supposed to be more efficient in larger catchment), then this should be an issue, since grain size reduction during transportation has no chance to affect the signal. Moreover, the mechanisms involved in the control of the link between the ^{10}Be signal and the grain size should not depend on the size of the watershed. It is more efficient to work on "small" watersheds to efficiently assess the impact of individual parameters, such as lithology, slope, temperature, landslides depth and frequency. The Var basin and its sub-catchments represent an appropriate setting to document the in situ ^{10}Be systematics on fine and medium size sand and we did that survey on purpose, to ensure that the ^{10}Be signal recorded in the 50-100 microns of the Var marine cores is relevant. Nevertheless, we agree that the systematics of the grain size impact on the ^{10}Be signal would have to be confirmed in different settings, and larger watershed.

Consequently we added the following sentence in our revised manuscript to mention this potential caveat:

page 9, line 14
"However, more data are required from different settings to thoughtfully document the influence of climate on the potential links between grain size and ^{10}Be concentrations."

Second, the most distal samples in this study are still taken from the channel. As such, they have not undergone long-shore transport, mixing, bioturbation, density flows, etc. that characterise many offshore environments. I would recommend that the authors rephrase this slightly.

We agree that such processes can affect the ^{10}Be signal and alter its interpretation in sediments archives. We thus have reworded the abstract and the conclusion to mention this caveat and meet the Reviewer 1's recommendation:

page 2, line 17:

Our results demonstrate that fine-grained sediments (50–250 μm) may return accurate denudation rates and are thus potential suitable targets for future [10]Be applications, such as studies of paleo-denudation rates using offshore sediments.

page 11, line 8:

"Our results demonstrate that fine-grained sediments (50–250 μm) may return denudation rates similar to those of coarser sediments typically used in [10]Be studies (250 μm to 1 mm) and are thus potential suitable targets for future [10]Be applications, such as studies of paleo-denudation rates using offshore sediments. However, marine sedimentary dynamics such as long-shore transport, mixing, density flows and sea level changes, might alter the validity of this statement. Hence, an additional test will be to analyze [10]Be concentrations in both fine and coarse sand subaliquots of marine core samples."

Their work does demonstrate that fine-grained quartz can be used over short transport distances and in a fairly complex geomorphic setting. This is significant, even without an offshore connection. The authors do a good job of reviewing Alpine denudation studies and placing their work in this context. I appreciated the quick overview offered by figure 4.

Thank you.

It is interesting that the [10]Be results are similar to the modern sediment flux despite the different timescales and spatial averaging. I am somewhat surprised that the limestones would be eroding at an equivalent rate (especially since they would be undergoing relatively more chemical weathering than the quartz bearing regions). Are there any sediment flux data for subcatchments that are predominantly quartz? That might help pull this apart more convincingly.

This is a good point but as far we know no sediments flux data from carbonate lithology exist in the studied region. Nevertheless, we added a reference to a paper by Thomas et al. (2016) where the authors use [36]Cl to measure denudation rates on carbonates rocks near (100 km) the Var catchment.

page 7, line 19:

"Given different lithologies may have different erodabilities, this observation might be questionable. Thomas et al. (2017) measured [36]Cl derived denudation rates in carbonates rocks located about 100 km from the Var basin. They obtained denudation values ranging between 0.10 mm yr^{-1} and 0.20 mm yr^{-1}, comparable to those of the quartz bearing rock of the lower Var catchments, which have similar climatic and geomorphologic settings."

The lack of an interannual signal, despite significant torrents, is also a bit surprising given previous examples of this (i.e. Kober et al., 2005, etc.).

We agree with Reviewer 1 and we believe that temporal variations are more prone to be observed in small and upper catchments, such as we do observe with proximal samples VAR-16-2 and VAR-17-2 (see discussion in section 4.5) but are buffered downstream. This behavior has already been observed in different settings (e.g. Lupker et al., 2012). To better discuss this point we add the following sentence to the main text:

page 10, line 32:

"This scale effect on the [10]Be signal buffering - larger watershed reducing the temporal stochasticity - has already been observed in other settings (e.g. Lupker et al., 2012)."

I would have liked to have seen a more developed discussion of grain size dependence of cosmogenic nuclide data. The authors do note that some have reported trends and some not and provide a few examples of drivers. Since this is a fairly short manuscript, there is space to expand this to discuss when we might expect a grain size dependence and why (i.e. Lukens et al., 2019, etc.). This could be incorporated into a broader summary of the development of the method presented here.

Following Reviewer1's wishes we added a paragraph regarding grain-size dependent [10]Be concentrations processes in the introduction part.

page 3, line 22:

"~~Furthermore~~ However, grain size distributions are not always uniform across continental basins (Lukens et al., 2016), and [10]Be concentrations in fine sands and silts at river outlets may not be representative of their entire drainage area. Furthermore, since the production rate of in situ [10]Be is depth-dependent, any vertical variations of the granulometric distribution may induce a grain size control on the measured [10]Be concentrations. Several geomorphological processes are potential controls of such grain-size dependence (Aguilar et al., 2014; Attal et al., 2015; Brown et al., 1998; Carretier et al., 2015; Codilean et al., 2014; van Dongen et al., 2019; Lukens et al., 2016; Puchol et al., 2014; Riebe et al., 2015): landslides can bring [10]Be-poor coarse material to the surface that is then mixed with fluvial sediments (Aguilar et al., 2014; Attal et al., 2015; Belmont et al., 2007; Brown et al., 1998; Carretier et al., 2015; Puchol et al., 2014). The basin slope and precipitation also exert a control on the thickness of mixed soil on hillslopes, as well as the depth of erosion process, which all may impact the relationship between grain-size and the [10]Be concentrations (van Dongen et al., 2019). At last, the sediment transport time, which may differs for coarse and fine grains, as well as attrition, may both yield a grain-size effect control on [10]Be concentrations (Attal et al., 2015; Belmont et al., 2007; Carretier et al., 2015; van Dongen et al., 2019; Lukens et al., 2016; Matmon et al., 2003). It is worth noting that most of the studies investigating grain-size dependent [10]Be concentrations processes do so using medium sand grain-size to pebble-sized sediments (125 μm to > 1 mm). There is only one study presenting data on a fraction smaller than 125 μm (Brown et al., 1995)."

page 8, line 41:

"In the Var basin, we observe no systematic impact of grain size on the [10]Be concentration (Fig. 2). All but two samples have similar [10]Be concentrations for the 50–100 and 100–250 μm size fractions."

General comments

This is a very appealing, well-written paper supported by nice figures that looks at differences in in situ 10Be concentrations with grain sizes, specifically between the very fine sand and fine sand fraction. For in situ cosmogenic nuclide applications to marine archives that have so far largely been avoided as very fine sand is often the only fraction that is available, this paper now demonstrates that such archives will be much better accessible in the future. I therefore welcome its publication with only minor comments.

We thank Dr. Wittmann for her review and appreciation of our work. We have included the revisions according to each comment in blue, as well as the revised manuscript at the end of this document.

The authors present this work in a clear way that I find very logical, and it´s obvious that the authors spend a lot of time and thought on this. They have made a time series analysis, investigated sediment mixing, and they have included all necessary comparisons with other datasets from the Alps. The two things that I can identify what are missing are 1) a discussion or statement of why the fine grain size fraction should, in a geomorphological sense, even have a different nuclide concentrations. I mean, what controls nuclide concentrations in different grain sizes in the first place? Abundance of landslides, transfer time…? In line 24, p. 3, you have mentioned landslides, but this is in my view a bit too general.
In Fig. 5 as another example, you plot the data against slope, MAT, etc, but it´s not so clear for me how these parameters precisely control 10Be conc. in different grains sizes. The presentation on the discharge variability in the two different sampling years touches a bit on this.

Both reviewers have made similar comments. To follow their requirements we have significantly improved the discussion about the potential mechanisms inducing the impact of grain size on ^{10}Be concentrations.

page 3, line 22:
"~~Furthermore~~ *However, grain size distributions are not always uniform across continental basins (Lukens et al., 2016), and ^{10}Be concentrations in fine sands and silts at river outlets may not be representative of their entire drainage area. Furthermore, since the production rate of in situ ^{10}Be is depth-dependent, any vertical variations of the granulometric distribution may induce a grain size control on the measured ^{10}Be concentrations. Several geomorphological processes are potential controls of such grain-size dependence (Aguilar et al., 2014; Attal et al., 2015; Brown et al., 1998; Carretier et al., 2015; Codilean et al., 2014; van Dongen et al., 2019; Lukens et al., 2016; Puchol et al., 2014; Riebe et al., 2015): landslides can bring ^{10}Be-poor coarse material to the surface that is then mixed with fluvial sediments (Aguilar et al., 2014; Attal et al., 2015; Belmont et al., 2007; Brown et al., 1998; Carretier et al., 2015; Puchol et al., 2014). The basin slope and precipitation also exert a control on the thickness of mixed soil on hillslopes, as well as the depth of erosion process, which all may impact the relationship between grain-size and the ^{10}Be concentrations (van Dongen et al., 2019). At last, the sediment transport time, which may differs for coarse and fine grains, as well as attrition, may both yield a grain-size effect control on ^{10}Be concentrations (Attal et al., 2015; Belmont et al., 2007; Carretier et al., 2015; van Dongen et al., 2019; Lukens et al., 2016; Matmon et al., 2003). It is worth noting that most of the studies investigating grain-size dependent ^{10}Be*

concentrations processes do so using medium sand grain-size to pebble-sized sediments (125 μm to > 1 mm). There is only one study presenting data on a fraction smaller than 125 μm (Brown et al., 1995)."

Overall, with regard to this, it would be nice to acknowledge the work on TCN in grain sizes by Renee van Dongen from our group (ESurf, 2019). May be you have overlooked it (it should be published. If not, I will check and send you the paper).

Thank you for your insightful suggestion, it was an oversight on our part and we now quote this study several times.
See previous point and page 9, line 1:

"following previous studies (van Dongen et al., 2019; Lukens et al., 2016; Riebe et al., 2015)"

page 9, line 21:

"which is in line with the global compilation by van Dongen et al., (2019) where average basin slope has been found to be the primary driver of grain-size-dependent ^{10}Be concentrations."

2) In section 3.2, it would be nice to more specifically address is the fine grained samples were treated in a specific way (regarding mineral separation, I mean). Perhaps this was not done? If etching and final meteoric leach-off were done in a standard way for both grain sizes, then say so.

Thanks for pointing that out. Fine-grained samples (50 -100 μm) were treated in a standard way but with careful consideration regarding the leaching process. We thus added a sentence to clarify this:

page 5, line 10:

"We sieved the samples to obtain 50–100 and 100–250 μm grain size fractions. Quartz grains were isolated from both fractions by magnetic separation and successive $HCl + H_2SiF_6$ baths following the standard procedure. For the fine-grained fraction (50–100 μm), samples were first decanted during few minutes, then the supernatant was carefully removed."

Specific comments:

Swop 3.1 with section 3.2. One usually starts with the samples and their measurement.

Done.

Line 17. p. 7: This sentence about nested catchments is a bit out of place. Move to 4.3

We removed the sentence and added citation to 4.3

Page 9, line 3:

"For basins with nested upstream subbasins (VAR-16-2 and VES-16-2), we calculated subbasin ^{10}Be concentrations by removing the contribution of their upstream subbasins (COU-16-1 and VES-16-1, respectively; Table 2, Fig. S1) following the method of Portenga et al. (2015)."

Line 23, p.8: Is frost cracking preferably producing finer grain sizes? If yes, please clearly say so. See my general comment above.

We have no proof that frost cracking produce finer grains (however note that our data require the opposite: higher erosion rate of larger grain); we thus have re-worded this section to clarify.

page 9, line 9:

"*A plausible temperature-altitude control could be related to frost cracking, an erosion mechanism enhanced by cold conditions. ~~Indeed, in the nearby Ecrins Pelvoux massif (~120 km north of the Var basin), Delunel et al. (2010) found a positive correlation between elevation and ^{10}Be-derived denudation rates.~~ It has been previously shown that frost cracking, an erosion mechanism enhanced by cold conditions, can be the principal driver of ^{10}Be-derived denudation rates in the nearby Ecrins Pelvoux massif (~120 km North of the Var basin) (Delunel et al. 2010). However, more data are required from different settings to thoughtfully document the influence of a potential frost cracking impact on a grain size dependent erosion rate.*"

Section 4.2: I assume that these mean values of e.g. slope you discuss here have been calculated for the entire basin or subbasins. However, for the sake of comparison with denudation rates, and deciphering the controls on grain size, it would be better to calculate the slope of the areas only containing quartz, as only these, and not the entire basin, supply the quartz and hence "see" the denudation rates and react to slope or elevation.

This is a good point. For the Var basin and subbasins, all metrics have been calculated only on quartz bearing surfaces. However, the Octopus database does not account for the lithological differences. We thus added a caution to underline out this difference.

page 8, line 1:

"It is worth noting that the Octopus database takes into account all lithologies when calculating morphometric values (such as mean elevation and mean slopes as shown in Fig. 4); whereas in this study all metrics have been calculated on quartz bearing surfaces only."

Conclusion, first sentence: Please change the word "modern" to "millennial" or "cosmogenic-derived". "Modern denudation" is usually used with regard to erosion rates from sediment gauging. If called so in the MS throughout, please change there, too. Haven't checked.

Done, we also made sure to use "modern" to refer to sediment flux only in the manuscript.

page 4, line 7:

"*Here, we measured in situ ^{10}Be concentrations in the 50–100 and 100–250 μm size fractions of ~~modern~~ present-day quartz sediments of the Var River.*"

page 10, line 39:

"*We documented ~~modern~~ millennial denudation rates in the Var basin (southern French Alps) using ^{10}Be concentrations measured in quartz grains in the 50–100 and 100–250 μm size fractions of detrital river sediments.*"

Line 9, p. 10: Change "previous" studies to "published"

Done.

page 11, line 2:

"The dominant control on denudation rates in the Var basin appears to be the average slope of the subbasin, consistent with ~~*previous*~~ *published studies."*

Figures and Tables:

Table 1: Please give two significant decimals for each denudation rate number and error (i.e. for the error on Denudation rates, sometimes there is only 1 significant decimal, like 0.03. Please change to e.g. "0.031"). In contrast, the integration time is probably given too precisely (see Table 2, where this is fine).
Please include total basin area, too.

We thank Dr. Wittmann for this suggestion, however we feel that two significant numbers is to enough to convey the uncertainties on the denudation rates. If needed, the Excel table in the supp data can provide more precision. We did however change the integration time and added total basin area in the Table 1.

Fig. 2: The overall look / behavior of the data reminds me of the Po basin data. There is also higher variability upstream, but then downstream the variability decreases. Even though there is not a large floodplain, it may be worthwhile to discuss this behavior a bit.

We added references to this behavior and to the Po and Ganga plains.

page 6, line 35:

"Importantly, the most distal samples collected at the outlet of the Var River (VAR-16-5A and VAR-16-5B) had undistinguishable ^{10}Be concentrations in both size fractions, ranging from (4.02 ± 0.78) × 10^4 atoms g^{-1} to (4.40 ± 0.64) × 10^4 atoms g^{-1}. We also note a decrease of the variability of the ^{10}Be concentration from upstream to downstream (Fig 2.)."

page 10, line 13:

"This confirms that the overall decrease of ^{10}Be concentrations from upstream to downstream (Fig. 2) is due to the efficient mixing of sediments across the basin. This behavior has previously been observed in other basins with much larger floodplains such as the Po (Wittmann et al., 2016) or the Ganga (Lupker et al., 2012)."

Fig. 4: Wouldn´t it make more sense to color code by "min" grain size instead of "max" grain size (I mean the published data?) I would think that the comparison to the smallest grain size is most interesting. Or is this always 125 um?

We changed the color code to reflect the minimum grain size used accordingly.

This is a very long caption. You might want to shorten it.

Done, we moved the hillslope transport model to the main text and deleted repetitive information from the caption.

page 8, line 17:

"~~The hillslope transport model of Montgomery and Brandon (2002), based on the model of Roering et al. (1999), can explain the nonlinear relationship between average slope and denudation rate observed in our data (Fig. 4a).~~ We explain the nonlinear relationship between average slope and denudation rate observed in our data using the hillslope transport model of Montgomery and Brandon (2002), based on the model of Roering et al. (1999), (Fig. 4a). In this model we assume a chemical weathering rate of 0.023 mm yr^{-1} for the Var (the mean value between spring and winter from Donnini et al., 2016), a critical slope of 33° (similar to Ouimet et al., 2009) and diffusivities (K) of 0.001 m yr^{-1} and 0.008 m yr^{-1}, which are within the range of global values complied by Hurst et al. (2013)."

Fig 4 caption:

For the COU-16-1, EST-16-1, TIN-16-2 and VES-16-1 subbasins, we used denudation rates from Table 1. For the VAR-16-2, TIN-16-1 and VES-16-2 subbasins, we used subbasin ^{10}Be denudation rates (Table 2) ~~to exclude their nested upstream subbasins (COU-16-1, TIN-16-2 and VES-16-1, respectively)~~. We used the OCTOPUS database (Codilean et al., 2018) to acquire data from the Alps (Buechi et al., 2014; Chittenden et al., 2014; Delunel et al., 2010; Dixon et al., 2016; Glotzbach et al., 2013; Grischott et al., 2016; Molliex et al., 2016; Norton et al., 2008, 2010, 2011; Savi et al., 2014; Wittmann et al., 2007, 2016). ~~The nonlinear denudation model is from Montgomery and Brandon (2002) using a chemical weathering rate of 0.023 mm yr^{-1} for the Var (the mean value between spring and winter from Donnini et al., 2016), a critical slope of 33° (similar to Ouimet et al., 2009) and diffusivities (K) of 0.001 m yr^{-1} and 0.008 m yr^{-1}, which are within the range of global values complied by Hurst et al. (2013).~~

Fig. 6: Write "calculated" on the x-axis instead of "cal". You have the space and it is otherwise a bit odd (used in C14 dating).

Thank you for pointing that out, we changed the x-axis as well as any mention of "C_{cal}" to "$C_{calculated}$" in the main text: page 9, line 34 and page 10, line 8.

Other edits

We added a precision on the amount of native ^{9}Be measured in three samples.

page 6, line 30:

"Native ^{9}Be amounts have been measured in three samples (VAR-16-5B 100–250 μm, TIN-16-2 100–250 μm and VES-16-1 100–250 μm). All three samples have been found to have negligible amounts of native ^{9}Be, accounting for at most 0.3 % of the ^{9}Be carrier added to each sample."

We corrected the author's contribution.

page 11, line 23:

"AM wrote the initial manuscript, ~~all authors~~ PHB, JC, CP and SM commented and contributed to the final version."

We added to the acknowledgments.

page 11, line 32:

"ASTER Team is Georges Aumaître, Didier L. Bourlès and Karim Keddadouche."

page 11, line 38:

"We also thank Hella Wittmann and an anonymous reviewer for their constructive reviews that improved the quality of the manuscript."

Denudation systematics inferred from in situ cosmogenic [10]Be concentrations in fine (50–100 μm) and medium (100–250 μm) sediments of the Var River basin, southern French Alps

Abstract

Marine sedimentary archives are well dated and often span several glacial cycles; cosmogenic [10]Be concentrations in their detrital quartz grains could thus offer the opportunity to reconstruct a wealth of past denudation rates. However, these archives often comprise sediments much finer (<250 µm) than typically analyzed in [10]Be studies, and few studies have measured [10]Be concentrations in quartz grains smaller than 100 µm or assessed the impacts of mixing, grain size and interannual variability on the [10]Be concentrations of such fine-grained sediments. Here, we analyzed the in situ cosmogenic [10]Be concentrations of quartz grains in the 50–100 and 100–250 µm size fractions of sediments from the Var basin (southern French Alps) to test the reliability of denudation rates derived from [10]Be analyses of fine sands. The Var basin has a short transfer zone and highly variable morphology, climate and geology, and we test the impact of these parameters on the observed [10]Be concentrations. Both analyzed size fractions returned similar [10]Be concentrations in downstream locations, notably at the Var's outlet, where concentrations ranged from $(4.02 \pm 0.78) \times 10^4$ to $(4.40 \pm 0.64) \times 10^4$ atoms g_{quartz}^{-1}. By comparing expected and observed [10]Be concentrations at three major river junctions, we interpret that sediment mixing is efficient throughout the Var basin. We resampled four key locations one year later, and despite variable climatic parameters during that period, interannual [10]Be concentrations were in agreement within uncertainties, except for one upper subbasin. The [10]Be-derived denudation rates of Var subbasins range from 0.10 ± 0.01 mm yr^{-1} to 0.57 ± 0.09 mm yr^{-1}, and spatial variations are primarily controlled by the average subbasin slope. The integrated denudation rate of the entire Var basin is 0.24 ± 0.04 mm yr^{-1}, in agreement with other methods. Our results demonstrate that fine-grained sediments (50–250 µm) may return accurate denudation rates and are thus potential suitable targets for future [10]Be applications, such as studies of paleo-denudation rates using offshore sediments.

1 Introduction

Understanding landscape dynamics and denudation processes is crucial for human activities: for example, soil formation rates (Heimsath et al., 1997; Stockmann et al., 2014) control agricultural resources (Montgomery, 2007) whereas landslide occurrences (Hovius and Stark, 2007; Yu et al., 2019) are key to managing natural hazards (Kirschbaum et al., 2010). Denudation is the combined effect of physical erosion and chemical weathering processes, and may vary with time. Because climate exerts a strong control on denudation (Molnar, 2004; Yanites and Ehlers, 2012; Zhang et al., 2001), it is important to predict how landscapes will respond to the large and rapid climate changes expected in the future. Terrestrial cosmogenic nuclides (TCNs) in river sediments provide a means to determine denudation rates at the basin scale (Bierman and Steig, 1996; Brown et al., 1995; Granger et al., 1996; von Blanckenburg, 2005). Thus, for decades, TCN (mostly [10]Be) concentrations have been measured in present and past river sediments across a wide variety of climatic and geological contexts (see review by Portenga and Bierman, 2011) over different time scales (Bekaddour et al., 2014; Charreau et al., 2011; Granger and Schaller, 2014; Grischott et al., 2016, 2017; Marshall et al., 2017; Puchol et al., 2017; Schaller et al., 2002). However, although offshore marine sedimentary archives are well dated and often record several glacial cycles, they have remained unused for reconstruction of paleo-denudation rates, mainly because their grain sizes are too fine to facilitate standard in situ [10]Be analyses in quartz. Indeed, typical cosmogenic dating samples have grain sizes of 250 μm to 1 mm. In deep (>200 m water depth) marine environments, sediments of such grain sizes are restricted to submarine canyons in which the stratigraphic record is poorly preserved. Thus, analyzing TCNs in fine sand fractions (50–100 μm) is prerequisite to reconstructing past denudation rates from marine sediments because this granulometric range often dominates in offshore, turbidite-rich sedimentary cores (Bonneau et al., 2014; Jorry et al., 2011).

~~Furthermore~~ However, grain size distributions are not always uniform across continental basins (Lukens et al., 2016), and [10]Be concentrations in fine sands and silts at river outlets may not be representative of their entire drainage area. Furthermore, since the production rate of in situ [10]Be is depth-dependent, any vertical variations of the granulometric distribution may induce a grain size control on the measured [10]Be concentrations. Several geomorphological processes are potential controls of such grain-size dependence (Aguilar et al., 2014; Attal et al., 2015; Brown et al., 1998; Carretier et al., 2015; Codilean et al., 2014; van Dongen et al., 2019; Lukens et al., 2016; Puchol et al., 2014; Riebe et al., 2015): landslides can bring [10]Be-poor coarse material to the surface that is then mixed with fluvial sediments (Aguilar et al., 2014; Attal et al., 2015; Belmont et al., 2007; Brown et al., 1998; Carretier et al., 2015; Puchol et al., 2014). The basin slope and precipitation also exert a control on the thickness of mixed soil on hillslopes, as well as the depth of erosion process, which all may impact the relationship between grain-size and the [10]Be concentrations (van Dongen et al., 2019). At last, the sediment transport time, which may differs for coarse and fine grains, as well as attrition, may both yield a grain-size effect control on [10]Be concentrations (Attal et al., 2015; Belmont et al., 2007; Carretier et al., 2015; van Dongen et al., 2019; Lukens et al., 2016; Matmon et al., 2003). It is worth noting that most of the studies investigating grain-size dependent [10]Be concentrations processes do so using medium sand grain-size to pebble-sized sediments (125 μm to > 1 mm). There is only one study presenting data on a fraction smaller than 125 μm (Brown et al., 1995).

Several studies have suggested that sediment mixing is not always efficient in mountainous environments (Binnie et al., 2006; Savi et al., 2014), which would further bias interpreted denudation rates. Finally, [10]Be concentrations integrate the denudation signal over time periods dependent on the denudation rate that correspond to the time needed to erode 60 cm of rock (Lal, 1991). Perturbations in the sedimentary routing process, such as human-induced erosion or stochastic events like landslides or flash floods, can potentially affect [10]Be concentrations over much shorter time scales and therefore bias the interannual consistency of the [10]Be signal (Dingle et al., 2018; Lupker et al., 2012; Sosa Gonzalez et al., 2017).

The effects of spatial mixing, grain size and temporal variability on TCN concentrations have mostly been tested on sand fractions coarser than 125 µm. With the exception of Brown et al. (1995, 1998), who investigated grain sizes as small as 63 µm, these processes remain largely unexplored in fine size fractions <125 µm. Therefore, it is critical to understand how fine sediments capture denudation rates in onshore basins and if these processes alter the observed TCN concentrations.

Here, we measured in situ [10]Be concentrations in the 50–100 and 100–250 µm size fractions of ~~modern~~ present-day quartz sediments of the Var River. The Var drains a mountainous basin in the southern French Alps, is characterized by a steep mean slope of 23°, and its small alluvial plain limits sediment storage (Bonneau et al., 2017). The Var sedimentary system responds quickly (i.e. within 1000 yr) to climatic forcings, and is thus an ideal setting to test the suitability of fine-grained sediments to record paleo-denudation rates (Bonneau et al., 2017). We analyzed multiple samples within the Var basin to assess the spatial variability of denudation rates across a high diversity of geomorphic and climatic contexts. We then traced the upstream to downstream evolution of [10]Be concentrations in both analyzed size fractions to monitor the impact of grain size on the observed [10]Be concentration, the sediment mixing efficiency at major fluvial junctions, and the interannual variability of the denudation signal.

2 The Var basin

The Var and its main tributaries (Vésubie, Tinée, Estéron and Coulomp Rivers) drain a mountainous basin of 2800 km^2 in the southern French Alps (Fig. 1). This steep basin is characterized by a mean slope of 23° and elevations ranging from 0 to 3143 m above sea level with a mean elevation of 1200 m (Fig. 1). The Var basin can be divided into two main geological regions: crystalline basement in the north and sedimentary terrains in the south. In the northern and highest part of the basin, the Mercantour-Argentera Massif comprises migmatites, gneiss and granite (Fig. 1) inherited from the Paleozoic Hercynian orogen (El Bedoui et al., 2011). The late Paleozoic to Cenozoic sedimentary cover of the southern and western parts of the basin mainly comprises Mesozoic marls and limestones (Kergkhove and Montjuvent, 1977; Roure et al., 1976). These sediments also include Permian pelites and sandstones (locally overlain by Cenozoic marls, limestones and sandstones) at the southern edge of the Mercantour-Argentera Massif and in the inner part of the Var basin (Fig. 1). In the southernmost part of the basin, the Pliocene to Quaternary Gilbert delta developed after sea level rise in the Mediterranean Sea following the Messinian salinity crisis (Mulder et al., 1996).

Stochastic erosional processes such as landslides – the most studied being La Clapière landslide in the Tinée valley (El Bedoui et al., 2009; Casson et al., 2003) – and screes occur in the steepest part of the basin (Julian, 1977). Four hydropower dams have been built in the upper part of the basin (Fig. 1), but only the Lac Long dam (2500 m elevation) has a significant water storage capacity (4 700 000 m^3). Nine sedimentary dams were built in the lowest part of the basin in the 1970s to enhance sediment deposition and protect the city of Nice (Anthony and Julian, 1999). The climate in the Var basin is mostly controlled by elevation and is thus highly variable, from a Mediterranean climate in the south to a mountainous climate in the north. Between 1981 and 2010, the mean annual temperature and mean annual precipitation recorded at Nice (2 m above sea level; Fig. 1) were 16 °C and 733 mm yr^{-1}, respectively, and those at Guillaumes (790 m above sea level; Fig. 1) were 10.7 °C and 910 mm yr^{-1}, respectively (Meteo France database; https://donneespubliques.meteofrance.fr).

3 Methods and results

3.1 Sampling and ¹⁰Be analyses

We collected eleven sediment samples (2 kg each) from active riverbeds of the Var River and its main tributaries (Vésubie, Tinée, Estéron and Coulomp Rivers) in November 2016. Sampling locations were carefully selected to avoid any human-induced perturbations in the basin, such as dams (Fig. 1). The Tinée and Vésubie Rivers were each sampled at two locations: one within the crystalline massif (TIN-16-2 and VES-16-1) and one just upstream of their junctions with the Var River (TIN-16-1 and VES-16-2) (Fig. 1). The Coulomp and Estéron Rivers were each sampled upstream of their junctions with the Var River (COU-16-1 and EST-16-1). The Var River was sampled at five locations throughout the basin: one upstream of the Tinée confluence (VAR-16-2), one upstream of the Vésubie confluence (VAR-16-3), one upstream of the Estéron confluence (VAR-16-4) and two at the river outlet near the Mediterranean Sea (VAR-16-5A and VAR-16-5B). In November 2017, we resampled three of the rivers in four of the same locations: VAR-17-2, VAR-17-5B, VES-17-1 and TIN-17-2. We sieved the samples to obtain 50–100 and 100–250 μm grain size fractions. Quartz grains were isolated from both fractions by magnetic separation and successive HCl + H$_2$SiF$_6$ baths following the standard procedure. For the fine-grained fraction (50–100 μm), samples were first decanted during few minutes, then the supernatant was carefully removed. The pure quartz grains were then leached three times in HF to dissolve 30 % of the total weight of quartz and eliminate meteoric ¹⁰Be contamination (Brown et al., 1991). We then spiked the purified quartz samples with 0.3 mg of the Centre de Recherches Pétrographiques et Géochimiques (CRPG) ⁹Be carrier solution (concentration of 2020 ± 83 ppm, corresponding to ~2.25 × 10⁹ atoms ⁹Be). The spiked quartz samples were then completely dissolved in 48 % HF; beryllium was separated using anion and cation exchange columns and pH-sensitive precipitations before being oxidized to BeO, mixed with Nb powder and loaded into targets for measurement of ¹⁰Be/⁹Be ratios using the ASTER accelerator mass spectrometer at Centre Européen de Recherche et d'Enseignement des Géosciences de l'Environment (CEREGE).

All measured ¹⁰Be/⁹Be ratios were calibrated using the CEREGE STD11 in-house normalization, which is similar to the KNSTD07 normalization and assumes a ¹⁰Be/⁹Be ratio of (2.79 ± 0.03) × 10⁻¹¹ for the SRM4325 standard material (Braucher et al., 2015). Five and three chemical blanks were processed and measured during the 2016 and 2017 analytical sessions, respectively; the 2016 and 2017 blanks yielded ¹⁰Be/⁹Be ratios of (2.05 ± 0.38) × 10⁻¹⁵ and (1.99 ± 0.43) × 10⁻¹⁵, respectively.

3.2 Calculation of denudation rates

In situ cosmogenic ¹⁰Be is produced by cosmic rays in minerals such as quartz within the uppermost layer of Earth's surface (Lal and Peters, 1967). The ¹⁰Be concentration in quartz depends directly on the time spent near the surface and, thus, on the denudation rate (Lal, 1991). Therefore, the average denudation rate at the basin scale can be derived from the ¹⁰Be concentrations measured in detrital quartz exported by fluvial sediments and sampled at the outlet of the studied basin (Brown et al., 1995). Assuming that denudation is steady-state and the ¹⁰Be decay constant is negligible (von Blanckenburg, 2005), the spatially averaged denudation rate of a basin is inversely proportional to the ¹⁰Be concentration in sediments (Brown et al., 1995; Granger et al., 1996). The basin-averaged denudation rate can thus be calculated as:

$$\bar{\varepsilon} = \sum_{i,x} \frac{\overline{P_i} \, \Lambda_i}{\rho \, \bar{c}}, \tag{1}$$

where i refers to the different ¹⁰Be production pathways and associated particles (n for neutron, μs for slow muons and μf for fast muons). $\overline{P_i}$ are the mean basin-wide ¹⁰Be production rates, computed from the arithmetic mean of spallogenic and muogenic production using specific scalings for each production pathway as a function of elevation and latitude: $P_n = 4.11 \pm 0.19$ atoms g⁻¹ yr⁻¹, $P_{\mu s} = 0.011 \pm 0.001$ atoms g⁻¹ yr⁻¹ and $P_{\mu f} = 0.039 \pm 0.004$ atoms g⁻¹ yr⁻¹ (Braucher et al., 2011; Martin et al., 2017). Λ_i are the attenuation lengths for each particle: $\Lambda_n = 160$ g cm⁻², $\Lambda_{\mu s} = 1500$ g cm⁻² and $\Lambda_{\mu f} = 4320$ g cm⁻²

(Braucher et al., 2011). Finally, ρ is the mean density of the eroded material (2.7 g cm^{-3}) and $\bar{C}$ is the ^{10}Be concentration measured in the fluvial sediments collected at the basin outlet.

We calculated basin-averaged ^{10}Be production rates for each production pathway and each studied subbasin using the Basinga GIS tool (Charreau et al., 2019), based on the Lal–Stone time-dependent scaling model (Lal, 1991; Nishiizumi et al., 1989; Stone, 2000), and using up-to-date worldwide production rates computed by the Cosmic Ray Exposure program online calculator (https://crep.otelo.univ-lorraine.fr/; Martin et al., 2017). We accounted for basin topography using a cell-by-cell approach based on the 5 m resolution digital elevation model "RGE ALTI" produced by the French Institut National de l'Information Géographique et Forestière. Denudation rates were corrected for paleomagnetic variations that occurred during the integration time and topographic shielding (Charreau et al., 2019). Topographic shielding factors were calculated using the ArcGIS toolbox of Codilean (2006), which computes both self-shielding and shading. Quartz-free areas were excluded from the basin-averaged production rate calculations based on 1:50 000 and 1:250 000 scale French Geological Survey geological maps (Bigot et al., 1967; Campredon et al., 1980; Faure-Muret et al., 1954, 1957; Gèze et al., 1969; Ginsburg et al., 1980; Kergkhove and Montjuvent, 1977; Kergkhove and Roux, 1976; Kergkhove and Thouvenot, 2010; Roure et al., 1976). Quartz-bearing zones comprise 730 km^2, corresponding to 26 % of the total surface area of the Var basin. We calculated denudation rates for each of the Var's subbasins using the measured ^{10}Be concentrations and Eq. (1) (Table 1). We also calculated effective denudation rates and ^{10}Be concentrations in the downstream part of three basins by correcting for the contribution of upstream nested subbasins (Table 2, Fig. S1) (see Granger et al., 1996 and Portenga et al., 2015 for methods).

3.3 Results

The raw ^{10}Be concentrations of the sediment samples are reported in Supplementary Data. Blank-corrected ^{10}Be concentrations are reported in Table 1 and summarized in Figure 2 for the 2016 sampling. We obtained twenty ^{10}Be measurements from the eleven samples collected in 2016; concentrations were measured in both the 50–100 and 100–250 µm grain size fractions for all samples except VAR-16-4 and TIN-16-2, which did not yield sufficient amounts of quartz in the 50–100 µm fraction. We obtained five ^{10}Be measurements from the four samples collected in 2017; both grain size fractions were measured for VAR-17-2, only the 50–100 µm fraction was measured for VAR-17-5B and only the 100–250 µm fraction was measured for VES-17-1 and TIN-17-2. Measurement blanks accounted for, on average, 11 ± 7 % of the measured ^{10}Be/^{9}Be ratios. Native ^{9}Be amounts have been measured in three samples (VAR-16-5B 100–250 µm, TIN-16-2 100–250 µm and VES-16-1 100–250 µm). All three samples have been found to have negligible amounts of native ^{9}Be, accounting for at most 0.3 % of the ^{9}Be carrier added to each sample. Most samples had similar ^{10}Be concentrations within uncertainties for the 50–100 and 100–250 µm grain size fractions (Table 1 and Fig. 2). VES-16-1 and VES-16-2 are two exceptions because they yielded different ^{10}Be concentrations in each size fraction: for both samples, the 50–100 µm fraction had higher ^{10}Be concentrations than the 100–250 µm fraction. Importantly, the most distal samples collected at the outlet of the Var River (VAR-16-5A and VAR-16-5B) had undistinguishable ^{10}Be concentrations in both size fractions, ranging from $(4.02 \pm 0.78) \times 10^4$ atoms g^{-1} to $(4.40 \pm 0.64) \times 10^4$ atoms g^{-1}. We also note a decrease of the variability of the ^{10}Be concentration from upstream to downstream (Fig 2.). Sediments resampled in 2017 (VAR-17-2, VAR-17-5B, VES-17-1 and TIN-17-2) had concentrations similar within uncertainties to the 2016 samples (Table 1); only the 50–100 µm fraction of VAR-17-2 had a significantly lower ^{10}Be concentration compared to the same size fraction of the 2016 sample.

Calculated denudation rates for 2016 ranged from 0.10 ± 0.01 mm yr^{-1} (Coulomp River, COU-16-1, 100–250 µm) to 0.57 ± 0.09 mm yr^{-1} (Vésubie River, VES-16-1, 100–250 µm) (Fig. 3). The averaged denudation rates calculated at the outlet of the

Var basin were 0.24 ± 0.03 and 0.25 ± 0.04 mm yr^{-1} for the 100–250 and 50–100 μm fractions, respectively. For the 2017 samples, denudation rates ranged from 0.17 ± 0.05 mm yr^{-1} (Var River, VAR-17-2, 100–250 μm) to 0.52 ± 0.06 mm yr^{-1} (Vésubie River, VES-17-1, 100–250 μm), and the average denudation rate at the Var outlet was 0.27 ± 0.04 mm yr^{-1} for the 50–100 μm fraction.

The integration time of the ^{10}Be signal deduced from each sample varied from 1 kyr (Vésubie River, VES-16-1, 100–250 μm) to 6 kyr (Coulomp River, COU-16-1, 100–250 μm) (Table 1).

4 Discussion

4.1 Comparison of ^{10}Be-derived denudation rates with the modern sediment flux

To validate the use of ^{10}Be-derived denudation rates obtained from fine-grained sediments, we compare the denudation rates obtained at the outlet of the Var River (samples VAR-16-5A and VAR-16-5B) to previous results for the Var basin. Both the denudation rates derived from the 100–250 μm (0.24 ± 0.03 mm yr^{-1}) and 50–100 μm fractions (0.25 ± 0.04 mm yr^{-1}) at the Var outlet are in remarkable agreement with the denudation rate of 0.22 mm yr^{-1} calculated by Bonneau et al. (2017) based on modern Var River sediment fluxes estimated by Mulder et al. (1996). This demonstrates that fine-grained sediments can accurately preserve and transport the ^{10}Be-derived denudation signal across the Var basin. Furthermore, because the ^{10}Be-derived denudation rate was calculated solely for quartz-bearing rocks whereas the sediment flux-based estimate includes all lithologies, the agreement between the two methods suggests that quartz-bearing rocks are eroded at the same rate as other rock types in the basin. Given different lithologies may have different erodabilities, this observation might be questionable. Thomas et al. (2017) measured ^{36}Cl derived denudation rates in carbonates rocks located about 100 km from the Var basin. They obtained denudation values ranging between 0.10 mm yr^{-1} and 0.20 mm yr^{-1}, comparable to those of the quartz bearing rock of the lower Var catchments, which have similar climatic and geomorphologic settings. We note that the integration time of the ^{10}Be signal at the outlet (VAR-16-5A and VAR-16-5B) is between 2.3 and 2.6 kyr (Table 1), whereas the modern sediment flux was estimated over a 20 year period (between 1974 and 1994; Mulder et al., 1996). The agreement of the two methods thus suggests that denudation rates in the Var basin have been stable over the last 2.6 kyr.

4.2 Comparison with previously published ^{10}Be studies across the Alps

In this subsection, we compare the Var basin denudation rates with other studies reporting ^{10}Be-derived denudation rates in similar environments of the Alps. It is notably important to verify that the variability of the ^{10}Be signal carried by fine-grained sediments follows the same trend as larger grain sizes. Multiples studies have explored the relationship between denudation and landscape parameters such as topography and climate at a global scale (e.g. Portenga and Bierman, 2011) and at the scale of the Alps (Delunel et al., 2010; Dixon et al., 2016; Molliex et al., 2016; Norton et al., 2011; Wittmann et al., 2007). The two most frequent parameters used in correlation with denudation rates are the average slope (Dixon et al., 2016; Portenga and Bierman, 2011; Wittmann et al., 2007) and average elevation of the basin (Delunel et al., 2010; Molliex et al., 2016; Wittmann et al., 2007). Figure 4 compares the ^{10}Be-derived denudation rates of each subbasin with its mean slope and elevation. ~~We calculated subbasin effective denudation rates by excluding nested upstream subbasins for three subbasins (VAR-16-2, TIN-16-1 and VES-16-2) following the method of Portenga et al. (2015) (Table 2) to account for the local parameters of each subbasin.~~ Furthermore, Figure 4 compares our data from the Var basin with previously published ^{10}Be-derived denudation rates across the Alps, as available in the OCTOPUS Database (Codilean et al., 2018). We selected 133 basins with drainage areas comparable to the Var basin and its subbasins, i.e. ranging from 10 to 10 000 km^2 (Fig. 4). Alpine denudation rates range from 0.01 ± 0.01 mm yr^{-1} (Buechi et al., 2014) to 2.83 ± 0.93 mm yr^{-1} (Norton et al., 2010) for grain sizes ranging from 63 to 1000 μm, consistent with the overall variability of denudation rates across the Var basin

(Fig. 4). It is worth noting that the Octopus database takes into account all lithologies when calculating morphometric values (such as mean elevation and mean slopes as shown in Fig. 4); whereas in this study all metrics have been calculated on quartz bearing surfaces only.

5   In Figure 4, we classified [10]Be-derived denudation rates for the Alps into three granulometric groups: ~~<250, 250–500~~ <125, 125–500 and >500 μm, and we note several key observations. First, the ~~maximum~~ minimum grain size analyzed does not seem to induce a strong control on the [10]Be-derived denudation rates at the scale of the Alpine belt. Second, the mean slope of the basin does not exert a linear control on denudation rates because the highest denudation rates are not observed on the steepest slopes (Fig 4. a); denudation rates on average slopes of 23–32° are characterized by the highest average values, but

10   are highly variable. In the Var basin, denudation rates increase nonlinearly with subbasin slope, as observed in mountainous basins elsewhere (Binnie et al., 2007; Dixon et al., 2016; Montgomery and Brandon, 2002; Roering et al., 2001; Wittmann et al., 2007). This nonlinear relationship has been interpreted as the result of a change from diffusive to non-diffusive transport dynamics above a given slope angle, variously reported to be between 22° and 30° (Binnie et al., 2007; Montgomery and Brandon, 2002; Roering et al., 2001). This slope threshold is about 30° in the Var basin. On average slopes of 16–30°,

15   denudation rates in the Var basin are rather restricted, from 0.10 ± 0.01 mm yr^{-1} (COU-16-1, 100–250 μm) to 0.22 ± 0.04 mm yr^{-1} (VAR-16-2, 100–250 μm). Denudation rates increase on the steepest average slopes (>30°), with values ranging from 0.20 ± 0.04 mm yr^{-1} (VES-16-2, 50–100 μm) to 0.83 ± 0.28 mm yr^{-1} (TIN-16-1, 100–250 μm) (Table 2; Fig. S1). ~~The hillslope transport model of Montgomery and Brandon (2002), based on the model of Roering et al. (1999), can explain the nonlinear relationship between average slope and denudation rate observed in our data (Fig. 4a).~~ We explain the nonlinear

20   relationship between average slope and denudation rate observed in our data using the hillslope transport model of Montgomery and Brandon (2002), based on the model of Roering et al. (1999), (Fig. 4a). In this model we assume a chemical weathering rate of 0.023 mm yr^{-1} for the Var (the mean value between spring and winter from Donnini et al., 2016), a critical slope of 33° (similar to Ouimet et al., 2009) and diffusivities (K) of 0.001 m yr^{-1} and 0.008 m yr^{-1}, which are within the range of global values complied by Hurst et al. (2013). Third, it has been shown that elevation exerts a positive

25   control on denudation rates across the Alps (Fig. 4b), either due to frost cracking (Delunel et al., 2010), the impact of U-shaped glacial morphologies (Molliex et al., 2016) or greater uplift rates in higher regions (Wittmann et al., 2007). In the Var basin, the relationship between elevation and denudation appears rather weak, notably because the Tinée subbasin (sample TIN-16-1, 100–250 μm) presents the highest denudation rate (0.83 ± 0.28 mm yr^{-1}) although situated at a relatively low elevation (1486 m). The high denudation rate in this area is most likely the result of the steep average slope (~32°) (Table 2;

30   Fig. 4; Fig. S1). In the Alps, slope and elevation display a nearly linear relationship for slopes lower than ~20°, but the two variables are much more scattered for slopes steeper than 25° (Fig. 4c).

Overall, the [10]Be-derived denudation rates we obtained from fine-grained sediments (50–250 μm) in the Var basin are in the range of previously reported rates in the Alps. Our rates are also similar to those inferred from a wide range of grain sizes

35   (63–1000 μm) at various slopes and elevations. This result suggests that denudation rates derived from [10]Be concentrations in fine-grained sediments (50–250 μm) properly record denudation in this region, with slope being the dominant control on denudation rates. This conclusion is further supported by the similar [10]Be concentrations of the 50–100 and 100–250 μm size fractions throughout the basin, the notable exception being the steep upstream Vésubie subbasin (VES-16-1, Fig. 5), discussed in Sect. 4.3.

40   **4.3 Impact of grain size on [10]Be concentrations**

In the Var basin, we observe no systematic impact of grain size on the [10]Be concentration (Fig. 2). All but two samples have similar [10]Be concentrations for the 50–100 and 100–250 μm size fractions. In the Vésubie subbasin, the [10]Be concentrations

of the two size fractions did not overlap within uncertainties (Table 1; Fig. 5). To understand this discrepancy, following previous studies (van Dongen et al., 2019; Lukens et al., 2016; Riebe et al., 2015) we investigated the potential controls of topographic and climatic parameters on the ^{10}Be concentrations of the sediments (Fig 5). For basins with nested upstream subbasins (VAR-16-2 and VES-16-2), we calculated subbasin ^{10}Be concentrations by removing the contribution of their

5 upstream subbasins (COU-16-1 and VES-16-1, respectively; Table 2, Fig. S1) following the method of Portenga et al. (2015). It is thus apparent that above 2000 m elevation in the upper Vésubie (VES-16-1), sediments of the 50–100 μm size fraction have significantly higher ^{10}Be concentrations than those in the 100–250 μm fraction, whereas the two fractions have relatively similar concentrations in the downstream subbasin (VES-16-2; Fig. 5a). Because mean annual temperature is a function of elevation, it is tempting to propose that the main control on this discrepancy is climatic (Fig. 5b). A plausible

10 temperature-altitude control could be related to frost cracking, an erosion mechanism enhanced by cold conditions. ~~Indeed, in the nearby Ecrins Pelvoux massif (~120 km north of the Var basin), Delunel et al. (2010) found a positive correlation between elevation and ^{10}Be-derived denudation rates.~~ It has been previously shown that frost cracking, an erosion mechanism enhanced by cold conditions, can be the principal driver of ^{10}Be-derived denudation rates in the nearby Ecrins Pelvoux massif (~120 km North of the Var basin) (Delunel et al. 2010). However, more data are required from different

15 settings to thoughtfully document the influence of a potential frost cracking impact on a grain size dependent erosion rate.

An alternative possibility is that the slope of the subbasin affects the contributions of different grain sizes to the observed ^{10}Be concentration (Fig. 5c). Steeper areas are characterized by a larger contribution of sediments from deep-seated landslides, which are typically coarser sediments (Attal et al., 2015) with lower ^{10}Be concentrations (Puchol et al., 2014).

20 The mixing of landslide-derived material with finer hillslope surficial sediments will thus produce sediments with different ^{10}Be concentrations in the fine and coarse fractions (Fig. 5c), which is in line with the global compilation by van Dongen et al., (2019) where average basin slope has been found to be the primary driver of grain-size-dependent ^{10}Be concentrations. Additional data are necessary to distinguish between the effects of climate and landslides in generating the observed discrepancy between the 50–100 and 100–250 μm fractions in the upper Vésubie subbasin. However, we stress that this

25 grain size effect is limited to the Vésubie upstream subbasin and is not observed in larger subbasins below 2000 m elevation. Importantly, we observe no effect of grain size on the measured ^{10}Be concentrations at the outlet of the Var basin (Fig. 2).

4.4 Sediment mixing

To determine if the ^{10}Be concentrations measured at the river outlet are representative of the entire basin, it is critical to assess whether the sediments are well mixed throughout the basin (Bierman and Steig, 1996; Binnie et al., 2006). This is of

30 increased importance in the Var basin due to the heterogeneous distribution of quartz-bearing rocks. Because the basin-averaged denudation rate integrates surfaces of variable denudation rates, the average rate will not reflect the correct repartition of source areas if sediment mixing is inefficient, leading to erroneous denudation rates. Therefore, we here investigate the efficiency of sediment mixing by calculating the expected ^{10}Be concentration of sediments downstream of a particular junction, $C_{\text{calculated}}$, as the ^{10}Be concentration of sediments from each tributary weighted by the sedimentary fluxes

35 upstream of the junction (Binnie et al., 2006; Clapp et al., 2002; Matmon et al., 2003; Neilson et al., 2017; Savi et al., 2014):

$$C_{\text{calculated}} = \frac{C_1 \times A_1 \times \varepsilon_1 + C_2 \times A_2 \times \varepsilon_2}{A_1 \times \varepsilon_1 + A_2 \times \varepsilon_2},$$

(2)

where subscripts 1 and 2 denote the two upstream subbasins, C_1 and C_2 are the ^{10}Be concentrations of their respective sediments measured upstream of the junction, ε_1 and ε_2 are their denudation rates, and A_1 and A_2 are the surface areas

40 comprising quartz-bearing rocks in each subbasin. If sediment mixing is efficient, the calculated concentrations will be similar to that measured downstream of the junction.

We calculated mixed concentrations at the Var-Tinée (VAR-16-3, junction I), Var-Vésubie (VAR-16-4, junction II) and Var-Estéron junctions (VAR-16-5A/B, junction III) (Fig 6.). We used the [10]Be concentrations measured in both size fractions for junction I, but only those of the 100–250 μm fractions (the only available data) in junctions II and III. At junction I, the calculated [10]Be concentrations for both grain sizes are in agreement with the measured [10]Be concentrations. Similarly, at junction II, the expected and measured [10]Be concentrations are compatible within uncertainties. At junction III, the difference between the measured and expected [10]Be concentrations is greater, though they are compatible within uncertainties (C_{measured} = 4.07 ± 0.74 atoms g^{-1} vs $C_{\mathrm{calculated}}$ = 3.55 ± 0.50 atoms g^{-1}). This discrepancy may be due to the 16 km distance between the Var-Estéron junction, where the mixed [10]Be concentration is computed, and the downstream sampling location, VAR-16-5A/B. Indeed, between these two points, the basin is developed over quartz-rich Pliocene conglomerates (Fig. 1) whose contribution may slightly modify the observed [10]Be concentrations. Finally, the presence of sedimentary dams in this area does not strongly affect the observed [10]Be concentrations of the sediments. Consequently, the fluvial dynamic of the Var basin efficiently mixes the sedimentary material transported by each major tributary. This confirms that the overall decrease of [10]Be concentrations from upstream to downstream (Fig. 2) is due to the efficient mixing of sediments across the basin. This behavior has previously been observed in other basins with much larger floodplains such as the Po (Wittmann et al., 2016) or the Ganga (Lupker et al., 2012).

4.5 Interannual variability of [10]Be concentrations

As in most mountainous areas, the discharge regimes of the Var River and its upstream tributaries (Tinée and Vésubie) are characterized by erratic and torrential behavior (Anthony and Julian, 1999). Therefore, it is important to assess whether extreme rainfall events, which are frequent in the study area (Anthony and Julian, 1999) and generate floods with high sedimentary loads (Mulder et al., 1996), affect the observed [10]Be concentrations. In November 2016, heavy rainfall induced multiple high discharge events in the Tinée, Vésubie and upstream Var (Fig. 7b). Consequently, the discharge at the outlet of the Var increased to over 200 m^3 s^{-1} seven days before sampling. Conversely, 2017 was characterized by more moderate rainfall and the discharge at the Var outlet was around 10 m^3 s^{-1} during sampling. Despite these differences, the [10]Be concentrations measured in 2016 and 2017 are in agreement (Fig. 7a), with the exception of the finer sediments (50–100 μm) in the upstream Var, which yielded statistically different [10]Be concentrations in 2016 and 2017 (samples VAR-16-2 and VAR-17-2). This difference may have resulted from a stochastic event (e.g. landslide) that locally modified the [10]Be concentrations. Such perturbations are rarely buffered in such a small subbasin (the VAR-2 subbasin has a quartz-bearing surface area of only 83.3 km^2) (Niemi et al., 2005; Yanites et al., 2009). However, upstream valleys (i.e. the Tinée and Vésubie) are the most subject to such events (Anthony and Julian, 1999), but do not show any interannual variations. Most importantly, the fine sediment (50–100 μm) samples at the Var outlet (VAR-16-5B and VAR-17-5B) were remarkably similar between the two years (Table 1, Fig. 7a). This scale effect on the [10]Be signal buffering - larger watershed reducing the temporal stochasticity - has already been observed in other settings (e.g. Lupker et al., 2012). Thus, despite highly variable discharge and the occurrence of stochastic events, the integrated [10]Be concentrations of sediments exported by the entire Var basin are not affected by a detectable interannual variability.

5 Conclusions

We documented ~~modern~~ millennial denudation rates in the Var basin (southern French Alps) using [10]Be concentrations measured in quartz grains in the 50–100 and 100–250 μm size fractions of detrital river sediments. [10]Be-derived denudation rates range from 0.10 ± 0.01 mm yr^{-1} to 0.57 ± 0.09 mm yr^{-1} within the basin and the average denudation rate obtained at the Var outlet is 0.24 ± 0.04 mm yr^{-1}, in remarkable agreement with the denudation rate of 0.22 mm yr^{-1} determined based on

the Var River sediment flux (Bonneau et al., 2017). The spatial variability of denudation rates within the Var basin is on the same order of magnitude as other [10]Be studies across the Alps. The dominant control on denudation rates in the Var basin appears to be the average slope of the subbasin, consistent with ~~previous~~ published studies. The [10]Be concentrations of the two analyzed size fractions were different only in the upper and steeper parts of the basin, but were similar at the Var outlet. By comparing the expected and measured [10]Be concentrations at three tributary junctions, we demonstrated that sediment mixing is efficient throughout the basin. We investigated the interannual variability of [10]Be concentrations in sediments under different discharge regimes during wet and dry years (2016 and 2017, respectively); we observed local variations, but concentrations at the outlet were similar each year. Our results demonstrate that fine-grained sediments (50–250 µm) may return denudation rates similar to those of coarser sediments typically used in [10]Be studies (250 µm to 1 mm) and are thus potential suitable targets for future [10]Be applications, such as studies of paleo-denudation rates using offshore sediments. However, marine sedimentary dynamics such as long-shore transport, mixing, density flows and sea level changes, might alter the validity of this statement. Hence, an additional test will be to analyze [10]Be concentrations in both fine and coarse sand subaliquots of marine core samples.

6 Data availability

A raw data table including all samples is available in supplement.

7 Authors contributions

AM, PHB and JC designed the study. AM, PHB, JC and CP collected the samples for analysis. AM prepared the samples for [10]Be analysis and the ASTER Team measured the [10]Be/[9]Be ratios using the French Service National AMS ASTER. AM, PHB, JC and SM analyzed the data. AM wrote the initial manuscript, ~~all authors~~ PHB, JC, CP and SM commented and contributed to the final version.

8 Competing interests

Authors declare that they have no conflict of interest.

9 Acknowledgements

ASTER Team is Georges Aumaître, Didier L. Bourlès and Karim Keddadouche. This research was funded by the ANR JC EroMed project (N° ANR-17-CE01-0011-01; Principal Investigator P.-H. Blard). This work is part of the PhD thesis of Apolline Mariotti, whose scholarship was jointly supported by the CNRS and the Région Grand Est. Fruitful discussions with Samuel Toucanne, Stephan Jorry, Lucille Bonneau and Vincent Godard benefited the design of the study and interpretation of the results. We are grateful to Emmanuel Davy and Abdellah Zitouni for their help with quartz separation at CRPG, and to Laëticia Léanni and Régis Braucher for their expertise in [10]Be wet chemistry at LN2C/CEREGE. Robert Dennen is acknowledged for proofreading and improving the overall readability of the manuscript. We also thank Hella Wittmann and an anonymous reviewer for their constructive reviews that improved the quality of the manuscript.

Figure 1: Geological setting of the Var basin and its subbasins. Geological data are from the French Geological Survey (see text for references). White lines delimit the sampled subbasins, colored squares represent sampling points and red hashed areas indicate the presence of quartz-bearing rocks. Hydrological station data are from the HYDRO database (www.hydro.eaufrance.fr): I, Villneuve d'Entraunes station; II, Nice, Pont Napoléon station; III, Saint Sauveur sur Tinée station; and IV, Utelle station. Hydrological dams are: A, Isloa 2000 dam; B, Lac Fous dam; C, Lac Long dam; and D, Lac Boréon dam. Weather stations are from Météo France: 1, Nice; and 2, Guillaumes. The outset maps indicates the location of the Var basin in the southern French Alps.
Figure 2: [10]Be concentrations in quartz from river sands of the Var basin plotted against the distance to the estuary (km). Data are available in Table 1. Symbol shape reflects the analyzed grain size and colors indicate the subbasin. The dashed line corresponds to the mean concentration of all samples, excluding the four outlet samples. Error bars represent 1 sigma uncertainties.

2016 ^{10}Be-derived denudation rates (mm yr^{-1})

0.10 - 0.20	0.20- 0.30	0.30 - 0.40	0.40 - 0.50	0.50 - 0.60
Figure 3: Spatial variations of ^{10}Be-derived denudation rates for the 2016 Var samples (data reported in Table 1). White polygons denote the absence of data. Denudation rates were derived from the (a) 100–250 μm and (b) 50–100 μm grain size fractions.
Figure 4: [10]Be derived denudation rates in the Var basin and elsewhere in the Alps plotted against (a) mean basin slope and (b) mean basin elevation. The relationship between mean elevation and slope is plotted in (c). For the Var basin, all parameters were calculated for quartz-bearing surfaces only using a 5 m resolution DEM from the Institut National de l'Information Géographique et Forestière (http://professionnels.ign.fr/donnees). For the COU-16-1, EST-16-1, TIN-16-2 and VES-16-1 subbasins, we used denudation rates from Table 1. For the VAR-16-2, TIN-16-1 and VES-16-2 subbasins, we used subbasin [10]Be denudation rates (Table 2) ~~to exclude their nested upstream subbasins (COU-16-1, TIN-16-2 and VES-16-1, respectively)~~. We used the OCTOPUS database (Codilean et al., 2018) to acquire data from the Alps (Buechi et al., 2014; Chittenden et al., 2014; Delunel et al., 2010; Dixon et al., 2016; Glotzbach et al., 2013; Grischott et al., 2016; Molliex et al., 2016; Norton et al., 2008, 2010, 2011; Savi et al., 2014; Wittmann et al., 2007, 2016). ~~The nonlinear denudation model is from Montgomery and Brandon (2002) using a chemical weathering rate of 0.023 mm yr⁻¹ for the Var (the mean value between spring and winter from Donnini et al., 2016), a critical slope of 33° (similar to Ouimet et al., 2009) and diffusivities (K) of 0.001 m yr⁻¹ and 0.008 m yr⁻¹, which are within the range of global values complied by Hurst et al. (2013).~~

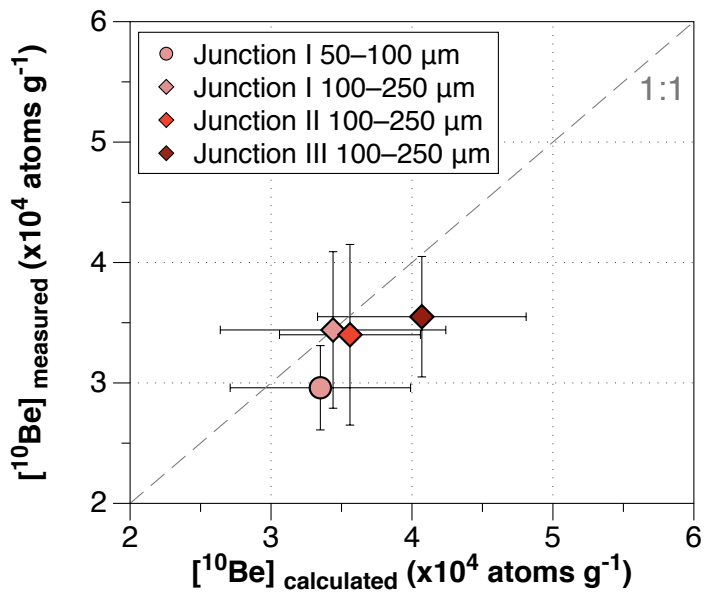
Figure 5: Differences in ^{10}Be concentrations of the 50–100 and 100–250 μm size fractions as a function of (a) elevation, (b) mean annual temperature and (c) average subbasin slope. Mean elevation and temperature were calculated for quartz-bearing surfaces only using a 5 m resolution DEM from the Institut National de l'Information Géographique et Forestière (http://professionnels.ign.fr/donnees). Temperature data are from the WorldClim database (http://worldclim.org/version2; Fick and Hijmans, 2017). Subbasin concentrations (Table 2) are used for VES-16-2 and VAR-16-2 to exclude their nested upstream subbasins (VES-16-1 and COU-16-1, respectively).


Figure 6: [10]Be concentrations of sediments at three river junctions calculated using Eq. (2) plotted against those measured in sediments downstream of the tributary junctions (Table 1). Junction I is the Var-Tinée junction, measured at VAR-16-3; Junction II is the Var-Vésubie junction, measured at VAR-16-4; and Junction III is the Var-Estéron junction, measured at VAR-16-5A/B. For Junction III, the measured concentration is the average of the concentrations in the 100–250 µm size fractions at VAR-16-5A and VAR-16-5B.
Figure 7: Interannual variability of sediment ^{10}Be concentrations. (a) Concentrations in sediments sampled in 2016 (x axis) are plotted against sediments of the same size fraction sampled in the same locations in 2017 (y axis). Most samples are in agreement with the 1:1 line, indicating little interannual variation. Only the 50–100 µm fraction at VAR-2 does not show the same trend. (b) Daily discharge data (log scale) from four hydrological stations in the Var basin (see Fig. 1): Var upstream (station I, Villneuve d'Entraunes), Vésubie (station IV, Utelle), Tinée (station III, Saint Sauveur sur Tinée) and Var downstream (station II, Nice, Pont Napoléon). Discharge data are freely accessible at www.hydro.eaufrance.fr.

Table 1: ^{10}Be-derived denudation rates in the Var basin in 2016 and 2017. Reported ^{10}Be concentrations have been corrected for analytical blanks (Raw data available in Supplementary materials). ^{10}Be/^{9}Be ratios were calibrated using the CEREGE STD11 in-house normalization (Braucher et al., 2015). Neutron production rates include paleomagnetic modulations over the integration time. Denudation rates were calculated with neutron, fast muon and slow muon attenuation lengths 160 g cm^{-2}, 4320 g cm^{-2} and 1500 g cm^{-2}, respectively (Braucher et al., 2011), and assuming a rock density of 2.7 g cm^{-3}. Integration time represents the time required to remove 60 cm of bedrock.

Table 2: Subbasin [10]Be concentrations and denudation rates in the Var basin in 2016. These effective denudation rates were calculated by excluding nested upstream subbasins following the method of Portenga et al. (2015). Denudation rates were calculated with neutron, fast muon and slow muon attenuation lengths of 160 g cm⁻², 4320 g cm⁻² and 1500 g cm⁻², respectively (Braucher et al., 2011), and assuming a rock density of 2.7 g cm⁻³. Integration time represents the time required to remove 60 cm of bedrock.
