Abstract. The 2016 M_w 7.8 Kaikōura Earthquake (South Island, New Zealand) caused widespread complex ground deformation including significant coastal uplift of rocky shorelines. This coastal deformation is used here to develop a new methodology, in which the upper living limits of intertidal marine biota have been calibrated against tide-gauge records to quantitatively constrain pre-deformation biota living-position relative to sea level. This living-position is then applied to measure coseismic uplift at three other locations along the Kaikōura coast. We then assess how coseismic uplift derived using this calibrated biological method compares to that measured using other methods [Light Detection and Ranging (LiDAR) and strong motion data], as well as non-calibrated biological methods at the same localities. Data show that where biological data is collected by RTK-GNSS in sheltered locations, this new tide-gauge calibration method estimates tectonic uplift with an accuracy of +/- ≤0.07 m in the vicinity of the tide-gauge, and an overall mean accuracy of +/- 0.10 m or 10% compared to differential LiDAR methods for all locations. Sites exposed to high wave wash, or data collected by tape-measure, are more likely to show higher uplift results. Tectonic uplift estimates derived using predictive tidal charts produce overall higher uplift estimates in comparison to tide-gauge calibrated and instrumental methods, with mean uplift results 0.21 m or 20% higher than LiDAR results. This low-tech methodology can, however, produce uplift results that are broadly consistent with instrumental methodologies and may be applied with confidence in remote locations where LiDAR or local tide-gauge measurements are not available.

1 Introduction

Vertical displacement has been measured globally using inter-tidal marine biota on rocky coastlines which often provide important constraints for incremental uplift during large-magnitude earthquakes and cumulative geological uplift (e.g. Alaska: Plafker, 1965; California: Carver et al., 1994; Mexico: Bodin and Klinger, 1986; Ramirez Herrera and Orozco 2002; Costa Rica: Plafker and Ward 1992; Chile: Fitzroy, 1839; Castilla, 1988; Castilla et al., 2010; Farias, 2010; Vargas et al., 2011; Melnick et al., 2012; Argentina: Ortlieb et al., 1996; Eastern Mediterranean: Pirazzoli et al., 1982; Stiros et al., 1992; Laborel and Laborel-Dugeun, 1994; Mouslopoulou et al., 2015a; Japan: Pirazzoli et al., 1985 and New Zealand: Mouslopoulou et al., 2019). Biological data was the basis for the first written records of coastal uplift following earthquakes along the Chilean coast (Graham, 1824; Fitzroy, 1839; Wesson, 2017) and continue to provide important constraints for elastic rebound and coseismic slip processes together with the locations, depth and dip of causal faults (e.g., Melnick et al., 2012; Wesson et al., 2015; Mouslopoulou et al., 2015b; 2019).

Biological indicators such as lithophagid borings and stranded bioconstructions of corals, coralline algae and barnacles, along with brown algae, gastropods, bivalves, and additional intertidal species with locally reliable tidal elevation zones, have been used to estimate eustatic sea-level changes and rock uplift (or subsidence) due to tectonic processes (Laborel and Laborel-Dugeun, 1994). Quantifying earthquake uplift from such biological datasets has been achieved using a variety of techniques, from simple measuring devices, such as tape measures, to laser survey methods and Global Navigation Satellite System (GNSS) techniques. While some studies (e.g., Melnick et al., 2012; Jaramillo et al., 2017) have successfully compared the reliability of the conventionally acquired biological uplift records against Real Time Kinematics (RTK) GNSS measurements, none have attempted to numerically and independently quantify the living-position of each biological marker. Jaramillo et al. (2017) compare pre- and post-deformation intertidal biota, but most studies, including this one, rely on post-deformation data only. Clark et al. (2017) and Mouslopoulou et al., (2019) use a variety of methods to record deformation immediately following the 2016 Kaikōura Earthquake, however, their marine-biota measurements have not previously been calibrated. Moreover, none of the above studies have systematically compared the manually collected tape-measurement estimates of coseismic uplift with instrumental earthquake-uplift datasets at individual localities to quantitatively assess the potential uncertainty inherent in the various techniques.

In this paper we use uplift produced by the November 14th, 2016 7.8M_w Kaikōura Earthquake (South Island, New Zealand) to develop a methodology for calibrating coastal vertical deformation utilising the displacement of biological marker horizons near a local tide gauge site. This calibrated information can then be applied to estimating coastal uplift or

subsidence at other sites in the Kaikōura region. Capitalising on the long-term, continuous, high-precision tide-gauge readings at Kaikōura Peninsula, biological markers within the intertidal zone uplifted during the earthquake are here utilised to: a) develop a new methodology with which to independently calculate (and thus calibrate) the upper living-position of individual intertidal (algal) taxa (organisms which are widely used to measure coseismic vertical displacement), and; b) compare, at each of three localities, the conventional biologically constrained hand-held measurements of coseismic uplift to values derived using various real-time remote sensing and other instrumental techniques, such as RTK-GNSS, LiDAR and strong-motion seismometers. Results may have application to inform future studies of the reliability of biological uplift measurements along rocky shores arising from large earthquakes at mid-latitudes (particularly in the Southern hemisphere) and with moderate tidal ranges (e.g., ~2 m), especially where instrumental technologies, such as differential LiDAR, are not available.

2 Geological and biological setting

2.1 The 2016 Kaikōura Earthquake

The 2016 M_w 7.8 Kaikōura Earthquake ruptured across the southern end of the Hikurangi subduction margin in northeastern South Island of New Zealand (Mouslopoulou et al., 2019). Northeast of the Kaikōura Earthquake surface rupture, the plate boundary is dominated by oblique subduction of the Pacific Plate beneath the Australian Plate at rates of 40-47 mm/yr (De Mets et al., 1994) (Fig. 1, inset). At the southern termination of the subduction, relative plate motion is transferred onto the transcurrent Alpine Fault via strike-slip on the Marlborough Fault System (MFS) (Pondard and Barnes, 2010; Wallace et al., 2012). The MFS generally strikes parallel to the relative plate motion vector and these active faults mainly accommodate right-lateral strike-slip with the amount of fault-related uplift increasing towards the coast. Offshore and east of the surface rupture, plate boundary deformation manifests itself as an accretionary prism complex. The accretionary complex and eastern MFS are underlain by the Pacific plate which, based on the presence of a Wadati-Benioff Zone, extends to a depth of at least 200 km beneath the northern South Island (Eberhart-Phillips and Bannister, 2010). The subducting slab is at a depth of ~20-30 km beneath the surface fault traces at Kaikōura (Nicol et al., 2018) and ruptured in response to slip triggered by these surface-breaking faults during the earthquake (Mouslopoulou et al., 2019).

The Kaikōura Earthquake is the largest (M_w=7.8) historic earthquake to have ruptured within the southern termination of the Hikurangi subduction margin (Mouslopoulou et al., 2019). The earthquake involved a complex network of at least 21 strike-slip, thrust and oblique-slip upper-plate faults that ruptured the ground surface and straddle the coastline of the northeast South Island (Hamling et al., 2017; Litchfield et al. 2018). The event's complexity is reflected in the moment tensor of the main shock which features only 65 to 75% double couple percentage (GEOFON http://geofon.gfz-potsdam.de accessed March 20, 2017) and is characterized by an oblique mechanism, with components of thrusting and right-lateral slip. Fault

ruptures generally propagated northwards from the epicentre for about 200 km, with a focal depth of the main shock at 15 km (Hamling et al., 2017; Kaiser et al., 2017; Cesca et al., 2017). The resulting surface ruptures vary in strike from east-west to north-northwest with faults having east-northeast strike being primarily right-lateral strike-slip and more northerly striking faults accommodating strike-slip and reverse displacement (Nicol et al., 2018). The earthquake ruptured three faults (Hundalee, Papatea and Kekerengu faults) that cross the coastline and locally produced differential uplift of the rocky shorelines. Vertical displacement of -0.5 to +8 m occurred along >100 km of coastline with the highest values in the hanging wall of the reverse sinistral Papatea Fault north of Kaikōura (Litchfield et al. 2018; Mouslopoulou et al., 2019). The coastal section examined in this paper is crossed by the Hundalee Fault (Fig. 1; see also Figure 1c in Mouslopoulou et al., 2019) which accommodated a component of reverse displacement and uplift of the coast up to ~2 m. In addition to the mapped surface faults, the spatial extent of coastal uplift and the widespread occurrence of tsunamis (which propagated distances of up to ~250 km from Kaikōura south; Power et al., 2017) and the significant afterslip on the plate-interface, suggest that faulting at the ground surface was accompanied by slip on the subduction interface and an offshore thrust fault that splays from the plate-interface to extend within the accretionary prism complex (e.g., Cesca et al., 2017; Mouslopoulou et al., 2019).

2.2 Physical and Biological Setting

The northern Canterbury coastline is predominantly exposed to wave action, strikes northeast-southwest, and is broken only by the promontory of the Kaikōura Peninsula (Fig. 1). Hinterland topography is steep and the coastal strip is narrow, comprising mainly greywacke bedrock beneath bouldery shorelines interrupted by bays with gravel-dominated beaches. Prevailing winds from the northeast (summer months) and southwest (winter months) maintain year round exposure and the coastline supports a biota adapted to this high energy setting. The region is in a cool temperate oceanographic setting with semi-diurnal tides with a daily tidal variation of ~2 m. These factors influence the living-positions of intertidal biota.

The intertidal biota in this cool temperate setting is dominated by seaweeds, typically the large brown algae *Durvillaea antarctica* (bull-kelp), *D. willana, Carpophyllum maschalocarpum* (Fig. 2a), and *Hormosira banksii,* coralline algae (Fig. 2b), barnacles, limpets, chitons and mobile invertebrates (Marsden, 1985). Attached invertebrates, such as mussels and oysters, are present but not common on this stretch of coast. On the Kaikōura Peninsula species diversity is high, with up to 78 species present in a single intertidal transect (Marsden, 1985). The vertical distribution of species on these rocky shores is controlled by exposure to wave action as well as interspecies competition (Goldstien pers. comm., 2017). The rocky shores around Kaikōura support three major biozones that approximately correspond to tidal height: a) an upper belt of littorinid gastropods (e.g., *Littorina unifasciata* and *L. cincta*) and barnacles (e.g., *Epopella plicata*); b) a mid-tidal region dominated by grazing molluscs (e.g., *Cellana denticulata, Melagraphia aethiops* and *Turbo smaragdus*); and c) a lower zone of brown algae (e.g., *Durvillaea antarctica* and *Carpophyllum maschalocarpum*) (Marsden, 1985). When the shoreline was inspected,

about two and a half months after earthquake uplift, many mobile taxa were absent in the uplifted intertidal zone and living or dead remains of stranded encrusting or attached taxa, such as barnacles, coralline algae and brown algae, dominated the shoreline. The green alga *Ulva* is normally present in limited amounts (Marsden, 1985), however, following the Kaikōura Earthquake and shoreline disturbance, growth of this alga was prolific and it subsequently covered much of the post-earthquake intertidal zone in the study area (Fig. 2b-d). This proliferation was accompanied by the death and bleaching of stranded coralline red algae forming a distinctive white crust on rocky surfaces (Figs. 2b & d), which were often visible at kilometre-scale distances; at that time, this was the most obvious visual indicator of uplift along the coastline.

In this study the brown algae *Durvillaea* and *Carpophyllum* are utilised to measure coastal uplift. *Durvillaea* is restricted to the southern hemisphere and occurs on rocky coastlines throughout New Zealand, while *Carpophyllum* is endemic (Adams, 1994). Around the Kaikōura Peninsula and north Canterbury coast, holdfasts of *Durvillaea antarctica* (bull-kelp) and *D. willana* (Fig. 2a), are anchored by a fleshy non-calcified holdfast to coralline encrusted rocky surfaces in the lower inter-tidal zone (Adams, 1994; Nelson, 2013) and holdfasts extend sub-tidally by 1-2 m. Individual plants have fronds 3-5 m in length that typically drape down from the inter-tidal zone to depths of ~5 m (Adams, 1994; Nelson, 2013). On sites exposed to higher wave action, holdfasts of *Durvillaea* may appear higher in the intertidal zone due to increased wave wash (Marsden, 1985), however, in sheltered areas and sites where waves are baffled holdfasts may be sub-aerially exposed at spring low tides, but not at neap low tides (Goldstien pers. comm., 2017). By contrast, *Carpophyllum* is only present in the low intertidal zone where it forms a distinct band close to low water (Nelson, 2013) (label *C* in Fig. 2c), and is not normally emergent at low spring tides (Goldstien pers. comm., 2017). Although both *Carpophyllum* and *Durvillaea* may be present on open coasts (Fig. 2a), *Durvillaea* dominates in exposed sites and *Carpophyllum* is more abundant at relatively sheltered locations. Dead stranded, and living representatives of one or both of these brown algae were present at all the rocky coastal sites visited in this study, making *Carpophyllum* and *Durvillaea* an excellent combination of biozone markers for measuring coseismic uplift.

The reproductive season for *Durvillaea* is during the winter months peaking in August and harvesting studies have shown slow resettlement when fronds are removed in September through February (Hay and South, 1979). The intertidal zone on the Kaikōura coast is undergoing recovery from the November 2016 earthquake and stabilised intertidal zones are not yet re-established. In temperate climate settings this may take several years, as shown by Castilla and Oliva (1990) following the 1985 Chile earthquake.

3 Methods

155   To measure coseismic uplift due to the Kaikōura Earthquake, independent methods utilising marine biological sea-level indicators, tidal gauge measurements, remote sensing techniques (RTK-GNSS and LiDAR) and strong motion recordings are used. The characteristics of each dataset collected and the methodology used to derive tectonic uplift are presented below. All uplift data are available in the Supplementary Material.

160   ### 3.1 Kaikōura Tide Gauge

New Zealand has 15 tide-gauges which record tidal variation, tsunami events, eustatic sea-level changes and vertical displacements of the coast. The Kaikōura Tide Gauge (Fig. 1) measures sea-level relative to two Druck PTX1830 sensors (KAIT 40 and 41 each referenced to different datums) located at the end of the wharf at Kaikōura (WGS-84 -42.41288°, 173.70277°; NZTM 1657824, 5304141). In this study, data from the KAIT 41 sensor
165   (http://apps.linz.govt.nz/ftp/sea_level_data/KAIT/) are used exclusively to maintain internal consistency, although results would be the same had KAIT 40 been used. The instrument is fixed to bedrock beneath the wharf, referenced to nearby benchmarks, including one on the wharf itself (LINZ geodetic code EEFL) and records sea-level at one minute intervals. The data are recorded in UTC time and the water-levels represent water surface elevation above the base of the tide-gauge in metres. The tide-gauge was established in late May 2010 and operated continuously through the period of the November 14th
170   Kaikōura Earthquake recording tectonic uplift at the site. KAIT 41 Tide Gauge data assembled for this study spanned the period from December 1st, 2015 to February 7th, 2017 and indicate that tidal range varies between a spring tide average of c. 2 m and c. 1.25 m during neap tides (Table 1). Spring low-tides before the Kaikōura Earthquake registered c. 2.05 m on the gauge while spring high-tides were c. 4.05 m. After the earthquake, low-water spring tide measured c. 1.1 m and high-water spring c. 3.1 m. Neap tides measured c. 2.5 m (low) and c. 3.7 m (high) before the earthquake and c. 1.5 m (low) and c. 2.75
175   m (high) after the earthquake (Table 1).

To determine the absolute uplift value from the tide-gauge data (U_{TG}; see Suppl. File S1) we used the following methodology: A) Subtracted the high-spring and high-neap tide readings before the earthquake from those after the earthquake; B) Averaged high-tide and low-tide readings from several tidal cycles (3 day period) before and after the
180   earthquake; C) aligned pre-earthquake tidal data with post-earthquake data and incrementally adjusting them until achieving a best fit; D) compared the average water elevation from a pre-earthquake month to the same month's data after the earthquake (e.g. December 2015 against December 2016); and E) calculated the difference in average waterline elevations for an extended period (44 days) before and after the earthquake (Oct. 30th to Dec. 27th). The average uplift (U_{TG}) estimated from the above steps (Tables 1 & 2) is subsequently used to independently estimate the pre-earthquake upper range of the

species used in this study (see Sect. 3.2). It has also acted as a reference point against which all other instrumental and hand-held measurements are compared.

Some limitations on calculating vertical displacement from tide-gauge records arise from the specific circumstances associated with the record around the November 14th, 2016 M_w 7.8 Kaikōura Earthquake. This event struck during a period of sharply increasing tidal change due to high spring tides (related to lunar perigee and approaching solar perihelion) that culminated a few days after the earthquake. In addition, the earthquake generated a significant tsunami (Power et al., 2017), the effects of which persist in the tide-gauge record for at least 12 hours after the earthquake. Further, a day after the earthquake, Kaikōura was subjected to a southerly storm with powerful swells and these are also apparent in the tide-gauge data. These factors result in some blurring in the precision of uplift deriving from the difference between pre-earthquake and post-earthquake data.

Uplift values calculated from tide gauge data were compared with those derived from LiDAR differencing data (see Section 3.4.1). Biological data from this site (see Section 3.2) were used to calibrate the elevation of the upper extent of brown algal holdfasts relative to sea level (in this case, MLWS).

3.2 Biological Data Collection

Biological data collected comprised the location and elevation of approximately 400 stranded algal holdfasts during a ten-day period, approximately two and a half months after the Kaikōura Earthquake (Suppl. File S2). Decay of attached and uplifted biota was well-advanced and, in most cases, uplifted remnants of marine algae, our primary target species, were restricted to holdfast stumps of *Durvillaea* or *Carpophyllum* with brittle fronds attached (Figs. 2b-d). Despite the decay of algae, the position of the remaining stumps clearly reflected pre-earthquake algae distribution evidenced by a lack of rock "scarring" where removed stumps might also remove other intertidal biota and often expose fresh rock surfaces. The biological data presented in this paper were collected from close to the Kaikōura Tide Gauge on the northern side of the peninsula, Kaikōura Harbour on the south side, and from two localities along the south Kaikōura coastline, Paia Point and Omihi Point (Fig. 1).

At all localities uplift was apparent from the exposure and subsequent degradation of intertidal biota with algal holdfasts exposed above the waterline, and measurements were collected on rising or falling mid- and low-tides. Holdfasts were preferentially measured on rock faces sheltered from, but retaining connection to, the open sea, to minimise error introduction by the potentially higher tidal position of *Durvillaea* in wave-washed sites. Each site was visually assessed to establish the upper extent of holdfasts, and the upper holdfasts were measured (as they represent specimens closest to the

pre-earthquake upper limit for each species). In sites with boulders rather than bedrock exposure, only boulders that showed a portion of their surface to have been clearly within the pre-earthquake mid- or upper-tidal zone (evidenced by bare or barnacle encrusted surfaces) and had clearly remained undisturbed by strong ground shaking and subsequent storm wave
220   exposure were selected for measurement, therefore ensuring the upper limit of holdfasts were represented.

Two different methods were used to measure the vertically displaced biota. The primary method of collection of field data was by Real Time Kinematic Global Navigation Satellite System (RTK GNSS). At each site the water-level was measured in the most sheltered area available to minimise wave effects, and the time the measurement was collected was recorded.
225   Following measurement of the waterline, up to twenty holdfasts (either or both *Carpophyllum* and *Durvillaea*) were measured within close proximity. Where additional holdfasts were available at each site water-level was re-measured and further sets of up to twenty holdfasts measured. This RTK collection method did not require the waterline measurement site and the holdfasts to be immediately adjacent to each other. Additional biological data were collected using a second method, direct tape-measurement of the height of holdfasts above water-level. Tape measurements were collected between the
230   waterline (measured between wavelet peaks and troughs) and the upper algal holdfasts on rock surfaces. Sheltered faces were again preferentially measured, although the requirement to have stranded holdfasts immediately adjacent to a measurable waterline meant that sites exposed to wave-wash were more commonly used to achieve approximately twenty measurements. Each reading for both methods (RTK or tape) was annotated with the alga species measured and relative site exposure (exposed or sheltered) and time of measurement was recorded.

235

3.3 Biological Data Processing

These field measurements of holdfast heights were then processed to determine coseismic uplift, taking into account the time of data measurement within the tidal cycle and the pre-earthquake living position of algal holdfasts. Three different methods were used for calculating tectonic uplift from the vertical offsets of the biological horizons. These were: a) tide-gauge
240   calibration, b) NIWA tide-forecaster measurement and, c) LINZ tide-prediction charts. The first method utilised data from the Kaikōura Tide Gauge and differs significantly from the two tide-prediction methods by calibration to real-time water-level records of the Kaikōura Tide Gauge. The NIWA forecaster and LINZ tidal chart methods are included, however, to simulate locations where real-time tide-gauges are not available. All data and calculations are presented in the Supplementary File S2.

245

3.3.1 Deriving an upper living-position correction using the Kaikōura Tide Gauge ($X_{C/D/G}$)

This new method determines an upper living-position for each species using the measured elevations of the stranded

8

holdfasts and then relating them to the pre-earthquake tidal cycle (Fig 3) by subtracting uplift recorded by the tide-gauge. This enables the elevation of the holdfasts, which are being used to determine surface uplift, to be referenced to a pre-earthquake datum, in this case the base of the tidal cycle mean low water spring (MLWS). The Kaikōura Tide Gauge provides a record of the pre- and post-earthquake MLWS. First the height of the stranded holdfast is determined by adding the waterline height measured in the tide gauge (H) and the observed height of the holdfast above the waterline in sheltered locations (OM). The offset of MLWS pre- and post-earthquake in the tide-gauge calculated as uplift is subtracted, along with the height of MLWS in the tide gauge. This leaves a residual height that reflects the pre-earthquake elevation of holdfasts of each species with respect to MLWS.

The upper holdfast living-position is described here by the correction $X_{C/D}$, which is treated as a constant for *Carpophyllum* (X_C), *Durvillaea* (X_D) or a combination of both (X_G), respectively. $X_{C/D/G}$ were determined by the Eq. (1):

$$X_{C/D/G} = (H_{TG} + OM_{C/D/G}) - U_{TG} - MLWS \hspace{3cm} (1)$$

where H_{TG} is the waterline height at the tide-gauge at the time of data collection (which can be accessed from http://www.linz.govt.nz/ and which was averaged here over 10 min intervals to mitigate local fluctuations); $OM_{C/D/G}$ is the observed height above the waterline for each stranded holdfast (determined by subtracting RTK waterline height measurement from each RTK holdfast measurement per site, or directly using tape-measurements; the subscripts C/D/G correspond to measurements for the different holdfasts); MLWS is the average tide-gauge reading for mean low water-spring tide (1.1 m for KAIT 41; see Table 1); U_{TG} is this uplift calculated at the tide-gauge by the method described in Sect. 3.1.

As *Carpophyllum* and *Durvillaea* occupy slightly different upper living positions in the inter-tidal zone, $X_{C/D}$ was calculated separately for each species. A general correction X_G, using both *Carpophyllum* and *Durvillaea* holdfasts was also determined, to be applied at sites where holdfast species were not known or determined, or insufficient numbers of each were available and data were pooled by necessity. To calculate the correction, data were pooled by species irrespective of site. The method described here uses the upper extent of intertidal algae as marker horizons, as at Kaikōura these are readily available attached biota. However, biozone boundaries for any attached inter-tidal organism with a restricted tidal range could be used to calculate this correction factor.

3.3.2 Deriving tectonic uplift using the Kaikōura Tide Gauge method ($U_{B(TG)}$)

Once the $X_{C/D/G}$ correction was derived as described above, coseismic uplift was calculated from biological data pooled by site in the location studied, using Eq. (2):

280 $U_{B(TG)} = ((H_{TG} + OM_{C/D/G})-MLWS)-X_{C/D/G}$ (2)

where $U_{B(TG)}$ is the uplift calculated from biological data, at the Kaikōura Tide Gauge.

3.3.3 Deriving tectonic uplift using the NIWA Tide Forecaster ($U_{B(NIWA)}$)

In order to calculate uplift from sites distant to the tide-gauge RTK biological data was used in conjunction with tidal charts
285 (https://www.niwa.co.nz/services/online-services/tide-forecaster) that provide tidal predictions for sites between formal chart
stations and attempt to account for local variation. For this calculation, Eq. (3) is used:

$U_{B(NIWA)} = (H_{NIWA} + OM_{C/D/G})-X_{C/D\_NIWA}$,   (3)

290 where $OM_{C/D/G}$ is the observed elevation of the holdfasts relative to locally measured sea level, H_{NIWA} is the predicted tide
height from NIWA charts at the survey time, and X_{C/D_NIWA} is a correction value (NIWA Forecaster calibrated correction),
estimated to reflect the relative height of *Carpophyllum* and *Durvillaea* within the tidal cycle (Fig. 4). This value for X is
independent of tidal-gauge data as used above and relies on assessment of qualitative biological data only. As described in
Sect. 2.2, *Carpophyllum* in sheltered areas with connection to the sea will not usually be exposed at low spring tide (LST)
295 (Goldstien pers. comm., 2017). Tidal prediction charts over one year were qualitatively assessed and a mean low spring tide
height of 0.1 m (X_{C_NIWA}) estimated for the upper limit of *Carpophyllum* and used as the correction value for this species in
data processing. Likewise *Durvillaea* will be regularly exposed at low spring tides but usually not exposed at low neap tide
(Goldstien pers. comm. 2017). A correction (X_{D_NIWA}) of 0.25 m was estimated, representing a height between spring and
neap low tides, relevant to the Kaikōura region. These values for X_{C/D_NIWA} assume the upper holdfast elevation of
300 *Carpophyllum* and *Durvillaea* are consistent between sheltered and exposed areas.

The value H_{NIWA} was determined using the predicted tide heights and times from the NIWA Tide Forecaster website. The
NIWA Tide Forecaster provides tide height at user designated locations, that may be between the fixed LINZ locations in
order to accommodate the passage of tidal highs and lows between fixed points. H_{NIWA} was calculated using the following
305 Eq. (4) from http://www.linz.govt.nz/

$H_{NIWA} = h1 + (h2 - h1) [(cosA + 1)/2]$ (4)

Where $A= \pi([(t - t1)/(t2 - t1)] + 1)$ radians and t1 and h1 denote the time and height of the tide (high or low) immediately
310 preceding time t, and t2 and h2 denote the time and height of the tide (high or low) immediately following time t. Only time t
is measured, t1 and t2 and h1 and h2 are derived from predictive tide charts.

3.3.4 Process to derive tectonic uplift using the LINZ tide prediction charts ($U_{B(LINZ)}$)

Land Information New Zealand (LINZ) tide charts available at http://www.linz.govt.nz/ provide fixed tide prediction charts
315 for New Zealand primary and secondary ports and were also used to derive H_{LINZ}, using Eq. (3), and LINZ calibration correction values of 0.2 m for X_{C_LINZ} and 0.4 m for X_{D_LINZ} estimated as above from these charts. H_{LINZ} was again determined by Eq. (4) defined above, and only RTK data was processed this way.

3.3.5 Sources of error

320 Data points collected by RTK GNSS were accurate to $\pm$ 5 cm, and this applies to both the waterline measurement at each site, and each holdfast measurement. Both of these measurements were used to derive OM, with a total error of $\pm$ 10 cm. Manually-collected biological data rely on the accuracy of the waterline measurement taken. While sheltered microsites were selected for these measurements, they were placed at an estimated median water-level between wavelets. This error is more pronounced when measuring waterline heights at more exposed sites. Additionally the time at which the measurement was
325 taken may have occurred when water-level was at either a positive or negative fluctuation from tidal prediction charts or Tide Gauge readings for sites south of Kaikōura. The total error is difficult to quantify, however, assessment of the Kaikōura Tide Gauge data show water-level fluctuations of less than +/- 0.1 m. Averaging tide-gauge data over 10 minutes helped mitigate the error resulting from the tide gauge itself, however, the error introduced by sea-level fluctuations away from the tide-gauge remained.

330

Durvillaea lives along open coasts, however at very exposed sites pre-earthquake holdfasts would have sat higher than average in response to increased wave wash and run-up. This potential error is difficult to quantify as deviation from average heights will be linked to wave heights and run-up at individual sites that may be modified following uplift. For this reason, the most exposed sites were avoided (where possible) and data were collected from sheltered locations.

335

3.4 Differential LiDAR and strong motion uplift estimates

3.4.1 Differential LiDAR (U_{LiDAR})

Differential LiDAR has been developed along the coastal south Kaikōura region using pre- (DEM_Kaikōura_2012_1m) and post-earthquake (NZVD2016 and DEM_NZTA_1m) surveys of road and railway routes using a common geodetic datum for
340 each survey. To minimise the impact of gravity-induced slope failures and horizontal tectonic displacement on sloping ground during the earthquake, the difference of the altitude of 1x1 pixels along the post-earthquake centreline of roads was

11

used. Specifically, for the Omihi Point and Paia Point study localities (see Fig. 1) the nearby State Highway-1 was used, while for the Kaikōura Tide Gauge study-site, a section of the coastal road near the wharf that houses the gauge was used. The road sections that acted as a reference level have low relief (e.g., <10 cm relief) and are wider than the horizontal
345 displacements recorded during the earthquake; thus, neither lateral tectonic displacement nor gravitational processes should significantly impact on the differential LiDAR measurements. Collectively, a total of 510 differential LiDAR points were collected and analysed (148 at the Kaikōura Tide Gauge, 152 points at Paia Point and 210 points at Omihi Point) (Suppl. File S3). These data were used to produce mean uplift estimates of at each site with 2σ uncertainties of ±0.06-0.18 m (Table 6). Differential LiDAR data was not available immediately adjacent to Kaikōura Harbour, on the south side of the peninsula.

350

3.4.2 Strong motion (U_{SM}).

A further independent instrumental uplift measurement was achieved by calculating the static vertical displacement recorded by the nearby strong-motion site KIKS (Fig. 1). The KIKS station is located 2.2 km south of the Kaikōura Tide Gauge (lat./long. -42.426°N/173.682°E; NZTM: 1656161, 5302714; see Fig. 1) and operated by GeoNET. The Kinemetrics FBA-
355 ES-T-BASALT 2420 sensor is located at 8 m elevation on the concrete floor of a single storey building at Kaikōura Harbour. Ground acceleration is recorded with a period of 0.005 s and data can be downloaded online from ftp://ftp.geonet.org.nz/strong/processed/.

Static displacement was calculated from the vertical component of the instrument following the method of Wang et al.
360 (2011) and using their software package *smbloc*, which applies an empirical baseline correction to remove linear pre- and post-event trends in the data. Static displacement derived with this method after large earthquakes has been shown to be robust (e.g. Schurr et al., 2012). Here, the resulting vertical displacement for the KIKS strong-motion station is 0.87±0.06 m (Table 6 & Suppl. File S4 for further details on data processing).

4 Results and comparison of methods

365 ### 4.1 Kaikōura Tide Gauge locality

Tide gauge data indicate that the Kaikōura Tide Gauge was coseismically uplifted by 0.96 ± 0.02 m (U_{TG}) (Table 1 and 2) (see sect. 3.1) and represents a key reference point for this study. In addition to providing an independent estimate of uplift, the tide gauge data have been used to calculate the upper living-position correction factor $X_{C/D/G}$ from all stranded biological holdfast data collected proximal to the Tide Gauge (Eq. 1) (Table 3; Fig. 5).

370

12

The calculated corrections $X_{C/D}$ (Table 3) were applied to biological measurements collected proximal to the Kaikōura Tide Gauge (Fig. 5) and compared with uplift of the Kaikōura Tide Gauge (calculated in section 3.1). RTK-GNSS survey data of *Durvillaea* and *Carpophyllum* for sheltered and exposed holdfasts produce tectonic uplift values of 0.71 m to 1.13 m, with a mean of 0.97 m ± 0.08 m (Table 4, Fig. 5). Similarly, for all tape-measure data collected proximal to the tide gauge, tectonic

375　uplift estimates range between 0.87 m and 1.35 m, with a mean of 1.05 ± 0.11 (Table 4, Fig. 5). The resulting analysis suggests *Carpophyllum* at sheltered sites recorded using RTK-GNSS and tape measure produce uplift estimates that are, within the uncertainties given, indistinguishable from uplift recorded by the tide-gauge (0.96 m) and differential LiDAR (0.92 cm) (Fig. 5). By contrast, estimates of uplift using *Durvillaea* are always higher than tide-gauge and differential LiDAR values. Tape-measurements of *Durvillaea* produced the highest biological uplift estimates with exposed *Durvillaea*

380　recording a mean uplift of 1.21 m, which is 0.25-0.29 m above the tide-gauge and differential LiDAR values (Table 4, Fig. 5). These data suggest that *Durvillaea* should be regarded as providing maximum uplift estimates, supporting previous work in suggesting that *Durvillaea* at exposed sites should be used with caution (e.g., Clark et al., 2017).

The same biological data collected near the Kaikōura Tide Gauge was then grouped by data collection location (sets of

385　approximately twenty data points) rather than holdfast type, and uplift estimates produced results of 0.99 m ± 0.07 m, 0.923 m ± 0.10 m and 0.98 m ± 0.07 m, while tape measures resulted in uplift estimates of 1.00 m ± 0.07 m, 1.12 m ± 0.11 m and 1.19 m ± 0.08 m, respectively (Fig. 6a, Table 5). In addition to directly measuring water-levels at the tide-gauge, the NIWA Forecaster and LINZ tide-charts were used to calculate uplift in an effort to test the utility of tide-charts at remote locations where tide gauge and instrument data may not be available. These comparisons are illustrated in Table 5 and Figure 6. At the

390　tide-gauge site, the LINZ Tide Chart produced, for *Carpohyllum,* uplift results 0.11-0.12 m greater than the tide-gauge method, while NIWA Forecaster chart produced uplift estimates of 0.04-0.05 m greater than the tide-gauge mean (Table 5). As was the case for the tide gauge calibration method, *Durvillaea* produced the greatest uplift at the tide gauge using the tide chart method, with average uplift values of 1.18 m and 1.24 m. In summary, uplift estimates calculated from *Carpophyllum* holdfasts processed using the NIWA Forecaster tide charts (rather than LINZ charts), are the most similar to direct uplift of

395　the tide-gauge itself, to the tide-gauge biological results and to LiDAR (plus 0-0.25 m), promoting their use in circumstances where a tide gauge is unavailable. LINZ tide chart methods produced results within 0.32 m of other methods.

4.2 Kaikōura Harbour, Paia Point and Omihi Point

To further test the utility of the Kaikōura calibration method, and the other methods under consideration, algae uplift data were also processed from the Kaikōura Harbour, Paia Point and Omihi Point sites. Data from these locations are not as

400　detailed as those collected at the tide-gauge study-site itself, with the distinction between *Carpophyllum* and *Durvillaea* or sheltered and exposed not always available.

At Paia Point, uplift estimates from all data collection and processing methods range from 1.12 m to 1.36 m, with a mean uplift of 1.24 m ± 0.16 m (Table 5; Fig. 6). While the biological uplift results are internally consistent, on average they are

405 about 0.2 m higher than the differential LiDAR average uplift at this site, which is 1.05 m ±0.07 m (Table 6; Fig. 7). This higher estimate for biological data cannot be attributed to differences in species of algae or measurement technique, however, shoreline exposure to wave action cannot be excluded as a factor. The role of shoreline exposure may only be resolved once the uplifted shoreline is recolonised with new *Carpophyllum* and *Durvillaea*. Algal uplift measurements collected at Omihi Point (Fig. 1), and processed using the tide-gauge calibration correction $X_{C/D}$ are within 0.07 m from one

410 another and to uplift recorded by differential LiDAR (Tables 5 & 6, Fig. 6). RTK measurements from Omihi Point processed using the NIWA Forecaster and LINZ tide charts methods are 0.08 m and 0.23 m respectively above tide-gauge calibrated estimates. In summary, there is no systematic difference in the uplift estimates at Paia and Omihi Points between the different measurement techniques (RTK-GPS vs tape-measure), species of algae (*Carpophyllum* or *Durvillaea*) or tide charts (NIWA Forecaster or LINZ tide chart) (Fig. 6).

415

At the Kaikōura Harbour site, where the KIKS seismic station is located (Fig. 1), uplift estimates from biological data, processed with the tide-gauge calibrated upper living-position methodology are 0.74 m ± 0.12 m, 0.85 m ± 0.12 m for NIWA calibrated methods and 0.98 m ± 0.12 m for LINZ methods. These results bracket the uplift result recorded by the strong motion data of 0.87 m ±0.06 m (Fig. 6). Differential LiDAR was not available adjacent to Kaikōura Harbour for comparison

420 with biological measurements

Comparison of results for all biological methods, independent of location, shows a consistent correlation (Fig. 8). No single method stands out as producing persistently divergent results from other methods, although all biological methods produce uplift estimates that are higher than LiDAR results. The tide gauge calibrated method has yielded results most consistent to

425 LiDAR. At all sites uplift estimated using the tide gauge calibration method give results within 0.0 to +0.21 m (or 0.35 to 21%) higher than LiDAR results, with a mean of +0.11 m (10%). Further, at all sites and over all biological methods, uplifts estimates are 0.0 to +0.31 m (or < 34%) higher than associated LiDAR results, with a mean of + 0.17 m.

5 Discussion

The distribution of kelp within the intertidal zone at Kaikōura is well defined with respect to qualitative upper, mid and low

430 intertidal zones (Marsden, 1985). Nevertheless, because the width of the intertidal zone varies with site exposure, topography, wave-wash and competition between different organisms, an attempt to quantify this uncertainty is made by calibrating coseismically uplifted intertidal brown algae (*Durvillaea* and *Carpophyllum*) in the immediate vicinity of the

Kaikōura Tide Gauge, aiming to establish a quantitative correction value for the upper living-position of the kelp holdfasts with respect to MLWS (Figs. 3 and 5).

435

Using Eq. (1) (see Sect. 3.2) at the Kaikōura Tide Gauge, an upper living-position correction of X_C of 0.26 ± 0.09 m above MLWS is derived for sheltered *Carpophyllum maschalocarpum*. For *Durvillaea* in sheltered sites, the upper living-position correction X_D is 0.38 ±0.09 m above MLWS. These values were subsequently used to estimate tectonic uplift at sites located up to 15 km from the tide-gauge and produced uplift measurements which were in good agreement with uplift calculated at

440 the same localities by differential LiDAR (Figs. 6 and 7). Thus, it appears that this method of estimating correction values may be important as it provides, for the first time, an independent quantitative method for estimating the preferred upper living-position for intertidal biota with respect to MLWS. This method may be applied elsewhere to other intertidal biota in the vicinity of a tide-gauge. *Carpophyllum* is endemic to New Zealand while *Durvillaea* is widespread in the southern hemisphere. The derived corrections are specific to these taxa in the Kaikōura region which is characterised by a moderate

445 tidal range. If these values are applied elsewhere, the uncertainty would be equal to the maximum correction value of 0.38 m. The three biological post-processing methods used to obtain uplift, all yield results which are, within uncertainties, similar to one another, meaning that any of these methods could be applied depending on the available tidal data at the site of interest. Analysis of all data suggest that hand-held measurements most often overestimate uplift compared to results from RTK-GPS survey data.

450

In the vicinity of the Kaikōura Tide Gauge, biological results using the tide-gauge correction are most similar to non-biological methods. With increasing distance from the tide-gauge, this new method provides reliable results; nevertheless, other biological methods were comparable. Progression of daily tides is even and fluctuations from the expected tidal progression may occur over several minute intervals due to natural unevenness in the ocean surface caused by wind,

455 barometric pressure and local topography (eg. Garrison, 2010). While the influence of this natural fluctuation for biological data collected proximal to the tide-gauge is well mitigated by use of real-time tide gauge water-level (H), away from the Kaikōura Tide Gauge this real time fluctuation is less able to be mitigated. Therefore, the NIWA and LINZ tidal chart calculations for H, and associated corrections may give equally accurate uplift estimates. Overall, the NIWA method produces results more consistent with non-biological methods than does the LINZ method. Despite this, data collected by

460 RTK and processed using predictive charts, such as LINZ, may be used to calculate uplift estimates, and could be used with confidence in remote locations, or locations where other methods are not available.

This study has shown that instrumental and biological methods can produce comparable results; yet, in order to reduce uncertainty in the biological methods, the biota should have a living-position relative to an appropriate sea-level datum that

465 is calibrated against real-time tide-gauge data. To this end, our study has provided a new calibration method to derive a

correction for this upper living-position that can be applied globally where tide-gauge records are available. In circumstances where tide-gauge records are unavailable, the usage of predictive charts to process biological data may still be appropriate, accepting that uncertainties may be higher. The use of strongly anchored taxa such as algae may allow for data to be gathered either immediately or a period of time after deformation. The timeframe over which data could be recovered post deformation will depend on local conditions, seasons and anchoring strength of taxa utilised.

6 Conclusions

Tectonic deformation determined from uplifted intertidal biozone indicators produce results comparable with tectonic uplift recorded by the Kaikōura tide-gauge, remote-sense datasets (LiDAR and RTK-GPS) and strong-motion seismic data. Calibrating measured intertidal biological data to real-time tide gauge records gives results within an average 0.11 m of those derived from direct uplift of the tide-gauge, and localised differential LiDAR values. Uplift results from biological data, calibrated using predictive tidal charts, are as reliable as other biological and non-biological methods when distant to real-time tide-gauges, and are appropriate for use where differential LiDAR or other real-time remote-sensing datasets are not available. Results from this study indicate that *Carpophyllum,* an alga with a tightly defined upper intertidal limit, is the most reliable predictor of uplift at sheltered sites. *Durvillea*, an alga with a less well-defined upper intertidal limit, is less reliable, especially when measured at exposed sites. Biological data collected by RTK-GNSS gives the strongest overall comparison to non-biological methods of estimating uplift. Data collected by tape-measure may be reliable where sheltered sites are available but are likely to provide higher apparent uplift results in exposed locations, where intertidal biozone boundaries are blurred and elevated by wave fetch and exposure on sections of a rocky coastline.

Author's contributions

All authors contributed to the research idea, data-collection during fieldwork and their subsequent analysis. The first draft of the manuscript was written by C.R. with the contribution of all co-authors. The final manuscript resulted from close collaboration of all co-authors.

Note distinctive white zone of dead coralline algae.

Figure 3: Schematic diagram illustrating uplift and stranding of holdfasts at the Kaikōura Tide Gauge. It also illustrates schematically the method for calculating uplift from the upper limit of holdfasts ($X_{C/D/G}$; Eq. 1) using Mean Low-Water Spring (MLWS) values within the tide-gauge data. MLWN = Mean Low-Water Neap, MHWN = Mean High-Water Neap, MHWS = Mean High-Water Spring, H_{TG} = tide height as measured in tide gauge, U_{TG} = uplift as measured by tide gauge offset data pre- and post-deformation, OM = observed measurement (holdfast), X = offset of holdfasts from MLWS. Inset: Results for X as calculated for kelp at the Kaikoura Tide Gauge. Mean values are shown by a solid-circle while tails represent maxima and minima values. See Sect. 3.2.1 for details.

Figure 4: Schematic diagram illustrating uplift and stranding of holdfasts used to calculate offset of holdfasts ($X_{NIWA/LINZ}$) from Mean Low-Water Spring (MLWS) independent from tide gauge data. MLWN = Mean Low-Water Neap. Here MLWS is determined from LINZ and NIWA predictive charts, and the position of holdfasts with respect to MLWS and MLWN is determined from local knowledge of kelp distribution (Goldstien pers. comm. 2017).

Figure 5: Uplift at the Kaikoura Tide Gauge calculated from the upper living-positions of various kelp holdfasts and exposure sites plotted against the offset recorded, at the same locality, using the tide-gauge and differential LiDAR. Holdfast data are presented as *mean* and *standard deviation* while the tide-gauge and LiDAR data are presented as *mean* only. Black

numbers beside the datapoints indicate the mean values while 'n' values at the top represent the number of measurements per category.

Figure 6: (a) Tectonic uplift in metres measured at the Kaikōura Tide Gauge, Kaikōura Harbour, Paia Point and Omihi Point from biological data processed using the tide-gauge correction, and NIWA and LINZ predictive tide-chart correction methods (see Sect. 3.2). These values are compared to uplift recorded by the Tide Gauge and differential LiDAR (where available). (b) Percentage of uplift-deviation of the biological methods with respect to the LiDAR measurements. Horizontal axis not to scale.

Figure 7: Locality, digital elevation imagery and differential LiDAR data for Paia Point (see Fig. 1 for location). (a) Aerial photo from Google Earth imagery of Paia Point, State Highway-1 and uplift collection points. Blue line = portion of SH1 from which differential LiDAR uplift calculated, red circles: RTK-GPS collected kelp data-points, yellow circles: tape-measure collected kelp data-points. (b) Digital Elevation Model developed from post-earthquake LiDAR data. Blue line and colour-coded circles as per (a). (c) Plot of uplift of points at 1 m intervals along the blue line on SH1 in (a) and (b) derived from differential LiDAR.

Figure 8: Cross plots of data collection and processing methods. (a) RTK and tape-measure uplift data processed using the tide-gauge correction method. (b) RTK uplift data, processed using the tide-gauge correction method, plotted against differential LiDAR uplift data. (c) Tape-measure uplift data, processed using tide-gauge correction method, plotted against differential LiDAR uplift data. (d) RTK uplift data, processed using the tide-gauge correction method, plotted against the NIWA Forecaster tide chart correction method.

Table 1: Calculation of uplift at the Kaikōura Tide Gauge (KAIT) using tide-gauge readings for high and low spring-tides and high and low neap-tides (see Sect. 3.1).
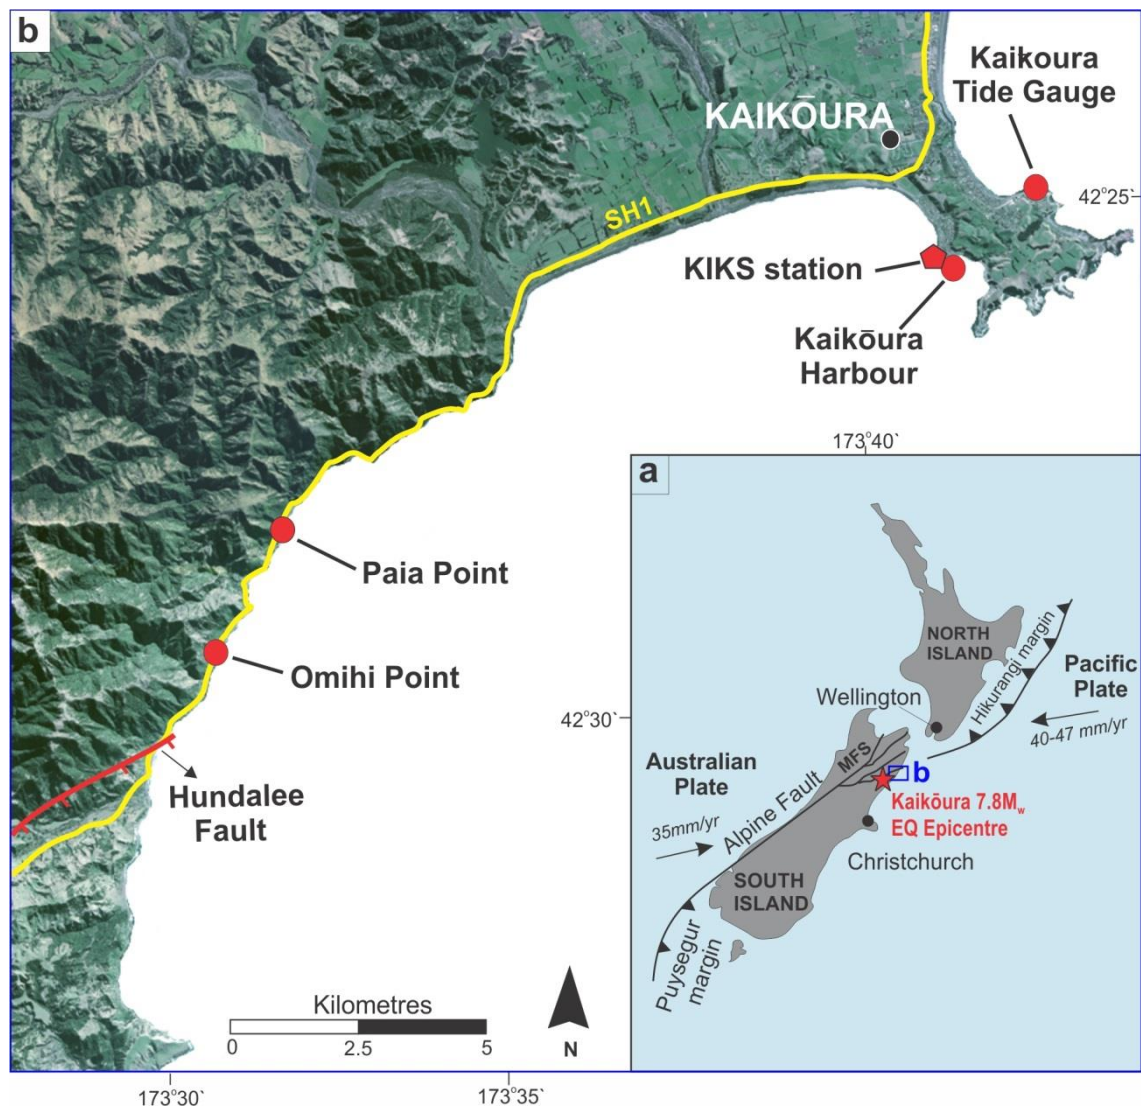

Table 2: Absolute uplift values calculated from the Kaikōura Tide Gauge data using methods B-E. Method B: Comparison of average high-tide and low-tide readings from several tidal cycles (3-day period) before and after the earthquake; Method C: Aligning pre-earthquake tidal data with post-earthquake data and incrementally adjusting them until a best fit; Method D: comparing the average water-elevation from a pre-earthquake month to the same month's data after the earthquake (December 2015 against December 2016); Method E: Calculating the difference in average waterline elevations for an extended period (44 days) before and after the earthquake (Nov 14th to Dec 27th). As Method A here we refer the methodology established in Sect. 3.1 and presented in Table 1.

Table 3: Results for calculation of the upper living-position $X_{C/D/G}$ relative to MLWS for holdfasts at the Kaikōura Tide Gauge. Note, that only holdfasts of *Carpophyllum* and *Durvillaea* in sheltered locations were used to calculate this elevation.
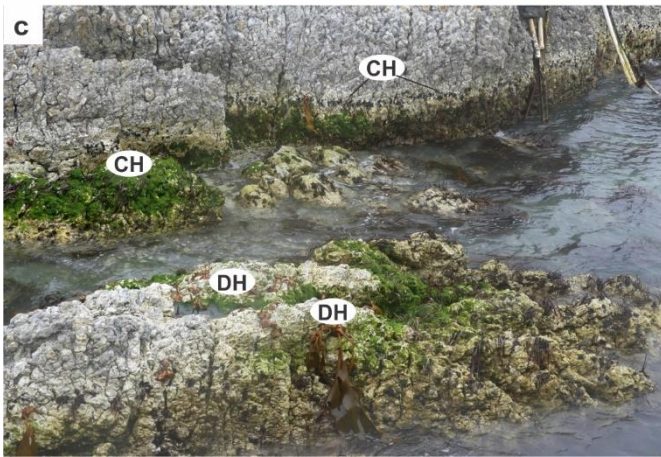

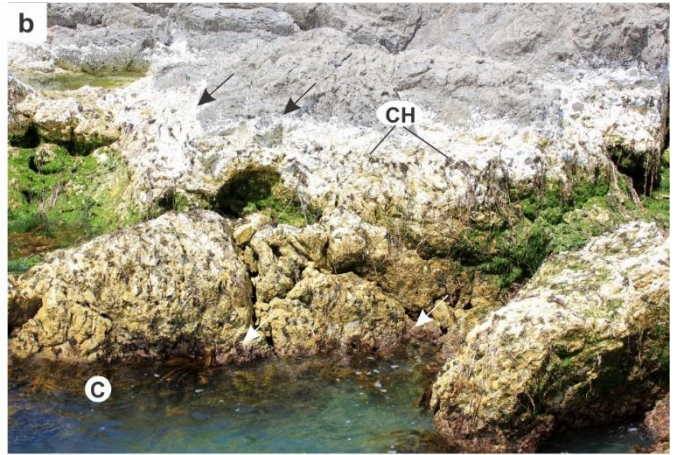

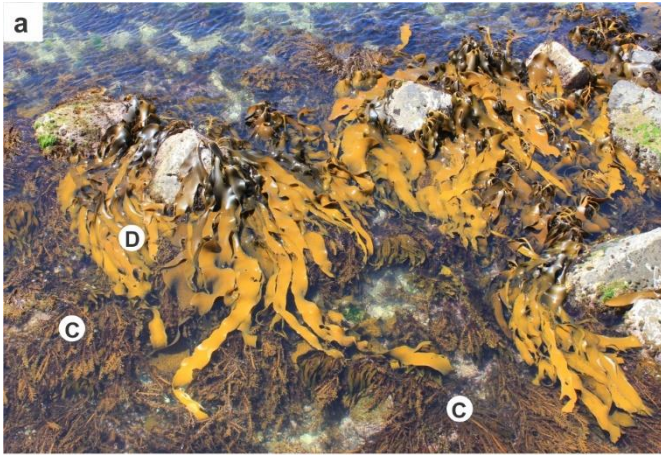

Table 4: Comparison of uplift results for data collected by RTK and tape-measure at the tide-gauge and including a comparison of kelp types in both sheltered and exposed locations. Results are presented by holdfast species and exposure ranking, independently of the collection site.

Table 5: Comparison of mean uplift values derived using RTK for the various methodologies (e.g., tide-gauge calibration method, NIWA Forecaster method, LINZ Tide Chart method). As the source data remain the identical for each method, the standard deviation reflects error derived from the RTK measurements. Data is presented by site at each location; where a site was collected using both *Carpophyllum* and *Durvillaea,* the holdfast type is recorded as "mixed".

Table 6: Uplift calculated from differential LiDAR and strong-motion uplift estimated from the KIKS station.
