

Author responses to the comments of the reviewers.

We first of all thank the reviewers for their effort and critical evaluation of our manuscript. We appreciated the constructive nature of the comments and tried our best to address them in the revised version of the manuscript.

5 Both reviewers found that the overall presentation of our study could be improved by making it shorter and focusing on specific aspects of the study. Reviewer 1 suggested to focus on the algorithm and metrics and presenting the numerical experiments in a separate paper. We think that is a great suggestion and thus we divided our study into two separate manuscripts. In part 1 we present the new algorithm and metrics, and apply it to the Big Tujunga to demonstrate capabilities and limits. In part 2 we present the landscape evolution experiments and our analysis of the response of the drainage divide network to perturbations. We think this separation helps focusing on the two aspects of the study. Although the two manuscripts together are even longer than the original submission, the individual manuscripts now have standard lengths and we think that the thread of each is much easier to follow.

15 In the following we provide all of the referee's comments, followed by our response where applicable. Because the reviewer's comments are related to the original submission, which is now presented in two separate papers, we provide our responses in blue font when related to part 1 of the revised version, and in red font, when related to part 2 of the revised version.

Reviewer #1

Referee report on "Identification and ordering of drainage divides in digital elevation models" by Scherler & Schwanghart

20 The manuscript submitted by Scherler & Schwanghart proposes a new way to calculate and characterize drainage basin boundaries and shows how the new metrics can be used to identify sections of the divide, which are vulnerable to topographic changes.

The paper presents a valuable contribution to geomorphology especially as the tools are made freely available in a easily usable framework (topotoolbox), which is accessible also for IT-skilled geomorphologists.

25 While the technical part of the manuscript is well presented and the algorithms clearly described, the analysis section lacks a central theme. Instead of getting to a point which shows how landscape perturbations affect the geometry or better topology of drainage divides the authors rush in a rather descriptive way through a series figures (Fig 11-21) most with multiple sub-panels.

30 Given that the title focuses on "algorithm and metrics" with the analysis only being an "application showcase", I do not see this as a critical part for the paper. However the authors may consider shortening this part and focusing on only one perturbation scheme (maybe the rotating one which shows the most striking responses) which exemplifies their metrics without trying to make a geomorphological claim.

A more thorough analysis of different perturbations and their impact on drainage divide networks may be presented in a separate paper.

35 We thank the reviewer for her/his critical assessment of our study and the suggestions how to improve its presentation. We like the idea of focusing on the algorithm and metrics part and moving the impact of perturbations to a separate paper very much and therefore adopted it as outlined above.

Below a few minor comments and questions/suggestions:

40 For the efficient calculation of watersheds, as well as their susceptibility to perturbations by topographic changes, I would like to draw the author's attention to a series of papers which may not be on the general "radar" of the geomorphology / hydrology audience:

Fehr, E., et al. "New efficient methods for calculating watersheds." Journal of Statistical Mechanics: Theory and Experiment 2009.09 (2009): P09007.

45 Impact of Perturbations on Watersheds E. Fehr, D. Kadau, J. S. Andrade, Jr., and H. J. Herrmann Phys. Rev. Lett. 106, 048501

Scaling relations for watersheds E. Fehr, D. Kadau, N. A. M. Araujo, J. S. Andrade, Jr., and H. J. Herrmann Phys. Rev. E 84, 036116

We thank the reviewer for pointing out these interesting articles. They were indeed not on our radar. We added two citations to the manuscript.

50 Usually, when making a topographic analysis stream networks are defined by a flow accumulation threshold. The authors define a parameter which describes the distance from the divide to the closest stream. Such a parameter would, however, depend on the specific choice of the flow accumulation threshold and could vary between 0 and the system size. The authors should add a formal definition of their stream networks and clarify how they addressed this point.

55 Although we stated the flow accumulation threshold in the beginning of section 4.1, we missed to do so in the case of the numerical experiments. To avoid any confusion, we now provide the flow accumulation threshold (0.1 km² for the natural example and 0.2 km² for the numerical experiments) that we used to define the stream network in the method sections 3.2 and 2.2.

The following comments/questions are using Figures as reference, but should also be addressed in the corresponding parts of the main manuscript.

60 Figure 1: Wouldn't it make sense to put (a) and (b) into a single (bigger) figure such that the reader directly can associate the divide network with the corresponding stream network?

Yes, makes sense. Changed as suggested.

Figure 3: Would it be possible to reduce the complexity of the figure without scarifying the main message. If I read the figure correctly, the right hand half contains already all necessary information.

65 Yes, possible. Changed as suggested.

Fig 7: The 3d figures are small hard to understand.

70 a. Initialize: I would suggest the authors to put an arrow "time" from the initial to the final (steady state condition). (this may also be presented simply in plain top view) c. Labeling the (rotating) circle and 12h initial position and showing how this marker moves through time (3 snapshots) may be easier to understand than the small 3d visualization d. and e. I had first difficulties to understand these graphics as they show the LEM surface and the "lithology" underneath, which changes the

erodibility as the landscape erodes through this heterogeneous bottom. Here the authors may improve they description explicitly mentioning (depth) and the fact that the topography erodes through these formation creating a variable erodibility over time.

75 another option would be to combine c. d. e. as small panels in Fig. 11 and showing there 2 time snapshots in the evolution of the topography.

These are all great suggestions. Thanks! To improve the readability of this figure, we added a downward pointing arrow that indicates time as suggested and explained in the figure caption in more detail what is shown: *“The starting condition of each model is shown at the top of each rock column. During the experiments, the entire rock column is eroded and deeper lying regions are exhumed.”*

80 Fig 13: While the "Initialize" plot shows a significant change over the course of 10Myr, the changes in the plots of the perturbed systems seems almost insignificant, especially when compared to the changes of the "Reference" topography offer the course 10Myr-20Myr. Note, if I am correct, the "Reference" solution should have reached steady state and therefore should show no changes at all. In order to present how the disturbance changes affect the divides it would make more sense to compare the disturbed system to the reference system at the same time, thus $t=15\text{Myr}$ and 20Myr and show the difference
85 between the two. Alternatively one could also evaluate the time evolution of the different perturbed cases relative to the evolution of the "Reference" solution.

We agree with the reviewer that the changes in the perturbed models are small compared to the initialize model. In the reference model, relatively small changes were still ongoing for quite some time, although standard topographic metrics, such as mean elevation, mean slope, etc. have reached steady state. We realized that referring to a simulation as reference
90 when there were still changes going on is confusing and we thus decided to run our models again. This time however, we extended the initialize simulation to a duration of 30 Myr, after which no more changes in the topography or drainage divide network occurred. The reference simulation is thus free of any divide migration.

When comparing the perturbed models with the reference model, we still prefer to show the entire time series. When focusing on one particular year, then only the particular difference between the drainage divide networks during that year
95 becomes visible, but not the range of differences observed during the models. In fact, it's really the temporal variation in the network that makes the difference and that requires showing not just one year.

Note also that we changed the y-axis scale from cumulative divide length to divide length, in response to a comment from Reviewer 2 regarding this figure. This change improves the conspicuity of the differences between the reference and the perturbed models.

100 Fig 17: Fig 17b consists of a main (invariant) cluster (black dashed line) corresponding to the general topographic shape of the landscape. It would be interested to see where (in the landscape) the deviations from this behavior are located.

That's a great suggestion. We tried to incorporate it by marking those junctions that correspond to the points lying outside of the invariant cluster in a new panel. We tested adding such markers to the existing panels, but quickly realized that the figure gets overcrowded this way. We therefore decided to add another panel in which we show the junctions, their elevation, and
105 the markers that indicate which junctions lie outside the range of values observed in the Reference model.

Fig 21: The scatter plots in this figure are difficult to interpret, especially because color is an additional variable. e.g. do yellow points mask blue markers underneath? It may be favorable to divide the color scale in 3 or 4 categories and bin the results in x,y for each category. Additionally the authors should quantify between the different measured quantities using e.g. a simple linear regression model.

110 Yes, we can see the point. It is true that yellow points mask blue points underneath and we have been discussing amongst us
for quite some time how to best present the pattern. Categories would only help when combining them with an additional
layer of information, like bins, as suggested, but that would further increase the complexity of the figure, especially if added
to each axis of each of the panels. To help the reader understand the figure, we instead added a note to the caption, where we
115 point out that the data points have been sorted to show the highest divide distance above data points with lower divide
distance, and that data points with lower divide distance occur beneath those with higher divide distance. We hope that this
explanation avoids confusion or the impression we would try to obscure something.

We furthermore added a new figure to the revised version, in which we quantified the correlation between the different
metrics and erosion rate differences using a linear regression model, as suggested by the reviewer. In this figure, we show
120 how the coefficient of determination (R^2 value), differs between the models, the metrics and also depends on the divide
distance. We think this is a very useful figure that avoids some of the limitations we were facing with the other figure that
shows merely the scatter plots.

I hope that the above comments & suggestions help the author to improve the manuscript and strengthen their arguments.

They surely did – thank you very much!

Reviewer #2

The authors present an algorithm to automatically extract the drainage divide networks from digital elevation models as well
as ordering schemes to classify the different divides with respect to each other. The application of the algorithm to a field
example (San Gabriel Mountains) and different numerical landscapes is shown, exploring the relationship between different
135 geometric and topographic metrics attributed to divides with respect to their mobility.

I believe that the tool presented in this manuscript (and already implanted in Topotoolbox) is valuable to explore landscapes
more systematically, offering the potential of developing new approaches to characterize landscape stability and to retrieve
information about the history and drivers of landscape evolution.

140 I also believe that Esurf is the perfect outlet for this contribution, but before I can recommend the manuscript for publication,
I would like to point out some comments/concerns for the authors to consider in order to clarify certain parts of the
manuscript, as well as to highlight the main points of this contribution.

We thank the reviewer for her/his assessment of our study and the suggestions how to improve its presentation.

1 General Comment

145 The authors have carried out an extensive analysis of divide drainage networks from a field case (Big Tujunga catchment)
and several numerically simulated landscapes (including their temporal evolution) by exploring different (topologic,
geometric and topographic) metrics. The manuscript contains 21 figures (with 120+ panels! – some of them quite complex).
I think the number of figures is excessive, particularly because the presence of many of them (and their description) are not
that insightful/necessary to make the main points on the paper, which are currently diluted. I would strongly suggest that the

150 authors transfer to the Supplementary Material most of the panels, keeping only the ones that are key to the message, and
expanding in their description and insight gained from this analysis. I believe the manuscript will substantially benefit from
an effort in this direction, improving its readability and impact.

155 We thank the reviewer for the open criticism. The main message we take out from the above paragraph is similar to what
reviewer one also commented. In its present form the paper does not manage to convey the main points because it branches
into too many directions. Instead of moving figure panels to the supplementary material, we better like the idea of splitting
the paper into two parts; one that focuses on the algorithm and the metrics, and one that analyses the response of the drainage
network to perturbations. See our initial statements at the beginning of this document. For the paper that focuses on the
numerical experiments (part 2), we prefer to retain the different models and present their results next to each other in
different panels. We find that this way of presenting the results facilitates comparing the results of the different numerical
simulations.

160

2 Comments:

- 165 • Line 76: It is stated that divide networks even contain cycles. Do cycles correspond to enclosed (internally drained)
basins? In the rest of the manuscript, it is said that these networks are represented as tree-like networks, i.e. no
cycles, (e.g. line 116) and that enclosed basins are not considered in the analysis. Is the algorithm and ordering
scheme applicable for the cases the network contains cycles?

Ouch! First question and already touched the most sensitive part of the algorithm! Yes, by cycles we referred to
internally drained basins, and no, they don't reflect a true tree network. Yes, we did not consider internally drained
basins in our analysis, and no, the ordering scheme is not applicable for that case.

170 But more formally: as stated in line 162 (page 6) of the original submission, our algorithm does not handle internally
drained basins well and in all of our examples they don't show up. The problem simply is that the sorting procedure fails
when the divide of an internally drained basin is encountered. Nevertheless, we are working on a solution that allows
bypassing internally drained basins in order to reach divides beyond them, where the condition is met again, but this
proves more challenging than anticipated.

175 To make the reader aware of this limitation, we modified section 2 and we expanded the final paragraph of section 3.1,
in which we describe the divide algorithm: *“As aforementioned, our divide algorithm currently does not handle
internally drained basins. Whereas the divides of internally drained basins are easy to identify, they are not easily
sorted in a meaningful manner. In fact, the distance to a common stream location (A) is undefined for a divide of an
internally drained basin. At the moment, the sorting procedure (Figure 4) stops at such divides, because the divide
segments cannot be assigned a direction. In consequence, also parts of the divide network that potentially lie beyond an
internally-drained basin, and for which the distance to a common stream location is defined, cannot be reached
anymore. While we are working on a solution to this issue, our algorithm is currently best applied to acyclic drainage
divide networks.”*

185

- A new ordering scheme is introduced (Topo) and it is mostly adopted for the analysis reported in the manuscript. However, I missed a more detailed comparison between the different schemes in terms of characterizing the divide network.

We have modified the entire text in several places, which also affected the presentation and discussion of the ordering schemes in sections 3.1, 4.1, and 5.1. We hope that this level of detail is sufficient.

- There are some metrics used or introduced in the manuscript, which although might seem intuitive, are not properly defined, and they can lead to misunderstandings. I would encourage the authors to properly define each of the metrics, particularly those that are central to the manuscript. As an example, I have struggled in imagining what is the definition of divide distance (which is used in almost every figure on the paper). The first time that it is mentioned in the manuscript is in line 129-131, where it is stated: *“We thus propose to order the nodes and edges of the divide network, by their maximum down-divide distance from divide endpoints, measured either in map units or in the number of divide segments. From now on, we call the distance measured in map units along the divide network the divide distance (dd).”* What does *down-divide distance* mean? Only paths where elevation is strictly decreasing are considered? Please provide a clear definition of the different metrics utilized (consider including an illustration if needed – e.g. Fig 4 is quite helpful)

That’s a very good point! We agree that down-divide distance is a term not easily understood. It does not refer to elevation, but is related to assigning directions to the divide segments and measuring distance along these directions. We modified section 2 in several places to provide a clear definition of all terms that we introduce. Specifically, we explain in much more detail how we can go from a drainage divide (section 2.1) to a divide network (section 2.2). First, we point out that divides have no terrain property that allows to easily assign directions to the divide network: *“In contrast, drainage divides have no inherent direction, and there exists no terrain property, like elevation, that could be used to assign a direction to them.”* We then explain how directions can be assigned based on the tree-like network topology: *“Instead, we suggest that directions can be derived from the tree-like structure of drainage divide networks. Analogous to a parcel of water that travels down a river from its source to its mouth, we propose to start at the leaves of the tree, which we call the endpoints of the divide network (Figure 2), and incrementally move down the branches (Figure 4). Note that the term “move down” does not refer to elevation, but to the hierarchy of the divide network. Where two or more drainage divides meet, they form a junction. We call individual parts of drainage divides that link endpoints and junctions, junctions and junctions, or endpoints and endpoints, the drainage-divide segments, and we refer to the ends of divide segments as segment termini to avoid confusion with endpoints. At junctions with more than one unsorted divide segment, the sorting process pauses because it is not obvious in which direction the sorting shall continue. However, in the absence of cycles (internally drained basins), each junction will reach a point in the sorting loop when there is only one unsorted divide segment left so that the sorting can continue (Figure 4). This condition assures that the divide segments are correctly sorted in a tree-like manner, but it fails when encountering a cycle. As we will show later, the average branch length A scales linearly with the maximum distance from an endpoint along the sorted divide network, as well as the maximum number of divide segments (or junctions), both of which are more easily computed. We thus propose to order the nodes and edges of the divide network, by their maximum distance from divide endpoints, measured either in map units or in the number of divide segments. From now on, we call the distance measured in map units along the directed divide network the divide distance (dd).”* To illustrate our points, we call out to the former Figure 5, which now appears before the former Figure 3.

- Section 3, particularly section 3.1 and Appendix 7.1, are the central contribution in the paper. However, I find the description of the algorithm not very clear, particularly the second step (lines 140-143) and Figure 3, which I am unable to follow. There are terms that are not defined, e.g. how do you define (the number of) segment termini?

230

Agreed. We added a definition of segment terminus to section 2 and labelled a divide segment in Figure 2. We also modified section 3.1 and explained our algorithm in more detail. We support this explanation with a figure that shows the workflow of our approach and hope that the different steps of the algorithm are now easier to understand.

- Line 181 – Since the metrics are computed for each divide edge, isn't \bar{X} just twice the value of X^- ? In that case, I guess there is no need to keep both.

Yes, it's true that the sum of a metric is twice the mean of that metric, but we don't think there is need to get rid of either the sum sign and replace it with two times the mean or to replace the mean sign with the sum divided by two.

235

- Equation 7. Not clear. Should d and d_d function of x within the integral?

Thanks for spotting this error. The equation was actually incorrect. We checked our procedure and replaced it with the following equation: $C_J = \frac{dx}{d_{d,max}} \sum_{i=1}^n \frac{d_i}{d_{d,i}}$, and also changed the accompanying text: "We define C_J to correspond to the sum of the ratios of the Euclidean distance, d , and the divide distance, d_d , integrated over of all divide edges, n , within a specified maximum divide distance, $d_{d,max}$, times the ratio of the cell size, dx , and $d_{d,max}$."

240

- Line 240-241: "In contrast, the ordering rules of the Strahler and Shreve scheme (see Eq. 1 and Eq. 2) may yield unequal orders during the sorting, so that the divide orders of the last divide segments may be different by more than one." I can see how this can happen for the Shreve scheme but under what circumstances would that occur using the Strahler scheme?

245

Under the same circumstance. The Strahler scheme requires two joining segments of equal order for the continuing segment to increase in order. If only one has a higher order, the order does not increase. In the Big Tujunga catchment, the part north of the main stem river has greater area and thus larger tributaries and longer divides that climb up to higher orders compared to the southern part. The Strahler orders along the northern drainage divide of the entire Big Tujunga catchment thus increase more rapidly to higher Strahler orders and eventually reach a higher Strahler order than they do along the southern divide (see figure below). This explanation is the same that we gave in the text for why the Shreve order increases more rapidly and we thus modified the text to make it clear that this explanation applies for the Strahler scheme, too.

250

Figure caption: Drainage divide network of the Big Tujunga catchment. Divide orders derived from Strahler ordering scheme: Green = 1, purple = 2, yellow = 3, red = 4, blue =5.

- 255
- Line254–Why the analysis is limited to $\omega < 55$. Is it because for $\omega > 55$ Λ is not defined?

Yes, exactly. The extent of the DEM is not large enough for defining Λ at $\omega > 55$. As stated in the text (section 2) that would be one of the weaknesses of using Λ , and the reason why we refer to the divide distance instead. We added an explanation to the text: “*Although the maximum order for which Λ can be determined (because of the size of our DEM) is limited to $\omega \leq 55$...*”

- 260
- Lines 262-263 / Fig 13: I don’t think that using the cumulative divide length is the most effective way to determine what are the orders changing the most (why not to use $\text{length}(\omega)$) since by construction the curve shown in Fig 3 will be robust to changes for values corresponding to small ω in comparison with large ω . I would be also interesting to see a similar curve when the analysis is done using the Strahler scheme, which I believe is more robust in terms of assigned orders (particularly to high order segments), to verify that indeed high order segments are the most affected. (Also lines 364-365)
- 265

Great point. We changed the y-axis, which now shows the divide length for a given divide order. When using the Strahler ordering scheme, there are only very few different divide orders. Changes in the network structure are thus more difficult to observe, because they could occur within one divide order, whereas they are represented by different divide orders in the Topo ordering scheme. In any case, we think that the new models, specifically the Reference model, which shows no more changes, and the way we now present the divide length by order, provide good support for the observation that mostly the distributions of high order segments are affected by perturbations.

- 270
- Lines285-290: There are some statements about dependencies between variables. Are those just inferred from visual inspection?

Yes, they are inferred from visual inspection of Figure 15 (now Figure 8 in the revised version). We think that statistical tests to determine whether the values observed for different divide distances are truly distinct is not required for the argument. We note however that the dependencies of some metrics on divide distance that we describe are much clearer in the new models, specifically the Reference model, in which nothing happens, and where the sentences are related to. The dependencies of the other metrics (cross-divide differences in topographic metrics) are further studied in figures 11 and 12.

275

- 280
- Line 314-315: resembling instead of mimicking?

Changed to “resembling”.

- Lines 332-333: “*Furthermore, the junction connectivity along the eastern edge is relatively low, despite being high up in the divide network (Figure 20a).*” Very qualitative statement and not that obvious from visual inspection, could you further quantify this point?

285

Good point. We deleted this statement.

- Line 355: topology instead of geometry?

Changed to “topology”.

- Figure 4. The green and red tones are not that easy to distinguish (at least in a printed copy).

We increased the size of the data points. Hopefully that helps.

290

- Figure 18: I wonder whether the higher variability observed for the first 5 km is partially due to the higher density of points in that range. Does the same observation hold when distance percentiles are used on the x-axis (instead of the linear axis)?

295

That's a good point. We added a statement that acknowledges the larger number of observations for lower divide distances: "*It should be noted that divide edges at low divide distances are much more abundant compared to those at higher distances, or equivalently, at higher divide orders (Figure 7)*". Regarding the x-axis scaling: Each divide node has a divide distance that increases when moving up in the divide network structure. Because the divide distance is defined to be the maximum distance from an endpoint along the directed divide network, there exist jumps in divide distance. When referring to the entire divide network for computing distance percentile, the picture does not change, only the labeling of the x-axis. When referring to individual divide segments, for example, the whole figure gets very messy, as both short and long divide segments, anywhere within the network will plot on top of each other. However, the greater scatter for lower divide orders/distances is a stable observation that is also a common observation in the numerical experiments in part 2.

300

- Fig 20: The layout/background used in panel a makes it difficult to delineate the actual catchment and compare with Fig 19a for example.

305

We removed this figure in the revise version.

Drainage divide networks, Part 1: Identification and ordering of drainage divides in digital elevation models

Abstract.

We propose a novel way to measure and analyse networks of drainage divides from digital elevation models. We developed
10 an algorithm that extracts drainage divides, based on the drainage basin boundaries defined by a stream network. In contrast
to streams, there is no straightforward approach to order and classify divides, although it is intuitive that some divides are more
important than others. A meaningful way of ordering divides. ~~We thus propose a divide network metric that orders divides
based on~~ is the average distance one would have to travel down on either side of a divide to reach a common stream location.
However, bBecause measuring these distances is computationally ~~very~~ expensive and prone to edge effects, we instead sort
15 divide segments ~~based on in a their~~ tree-like network structure, starting from endpoints at river ~~junctions~~ confluences. The
sorted nature of the network allows assigning distances to points along the divides, which can be shown to scale with the
average distance ~~downstream~~ downslope to the common stream location. Furthermore, because divide segments tend to have
characteristic lengths, an ordering scheme in which divide orders increase by one at junctions, mimics these distances.
We applied our new algorithm to ~~a natural landscape~~ the Big Tujunga catchment in the San Gabriel Mountains of southern
20 California and studied the morphology of the drainage divide network. ~~Our results show that topographic metrics, like the
downstream flow distance to a stream and the hillslope relief attain characteristic values that depend on the drainage area
threshold used to derive the stream network. Portions along the divide network that have lower than average relief or are closer
than average to streams are often distinctly asymmetric in shape, suggesting that these divides are unstable. Our new and
automated approach thus helps to objectively extract and analyse divide networks from digital elevation models.~~

25

1 Introduction

Drainage divides are fundamental elements of the Earth's surface. They define the boundaries of drainage basins and thus form barriers for the transport of solutes and solids by rivers. It has long been recognized that drainage divides are not static through time, but that they are mobile and migrate laterally (e.g., Gilbert, 1877). The lateral migration of divides is a consequence of spatial gradients in erosion, climate and in surface rock uplift (positive or negative) as well as stream captures. These ~~The latter~~ frequently accompany tectonic deformation due to shearing, stretching, and rotating stream networks (Bonnet, 2009; Castellort et al., 2012; Goren et al., 2015; Forte et al., 2015; Guerit et al., 2018), but recent studies have shown that even in tectonically inactive landscapes, drainage divides may migrate over prolonged periods of time (Beeson et al., 2017). Such behaviour is consistent with the notion that small and local perturbations can trigger nonlocal responses with potentially large effects on drainage form and area (Fehr et al., 2011; O'Hara et al., 2019). At regional scales, mobile divides can lead to ~~important~~ profound changes in drainage configurations and subsequent alterations of base-level and sediment dispersal to sedimentary basins. For example, Cenozoic building of the Eastern Tibetan Plateau margin has been proposed to account for major reorganization of large East Asian river systems and associated changes in sediment delivery to marginal basins (Clark et al., 2004; Clift et al., 2006). Moreover, changes in drainage area that are associated with migrating divides affect river incision rates (Willett et al., 2014), and thus the topographic development of landscapes, which potentially confounds their interpretation in the context of climatic and tectonic changes (Yang et al., 2015). The lateral migration of divides is a consequence of spatial gradients in surface uplift (positive or negative) as well as stream captures, which frequently accompany tectonic deformation due to shearing, stretching, and rotating stream networks (Bonnet, 2009; Castellort et al., 2012; Willett et al., 2014; Goren et al., 2015).

~~Whether based on the geometry of hillslopes or river channels, previous~~ Recent studies ~~on~~ of the causes and effects of mobile drainage divides generally focused on relative topographic differences ~~in either one~~ across several specific, manually selected drainage divides (e.g., Willett et al., 2014; Goren et al., 2015; Whipple et al., 2017; Buscher et al., 2017; Beeson et al., 2017; Gallen, 2018; Guerit et al., 2018; Forte and Whipple, 2018). Even if appropriate in these studies, such a procedure introduces unwanted subjectivity, both in the selection of divides and how any across-divide comparison is done. This choice of procedure may be attributed to the fact that, so far, no straightforward approach exists to reliably extract the drainage divide network from a digital elevation model (DEM). Functions that classify topographic ridges (the common shape of drainage divides) based on local surface characteristics and a threshold value (e.g., Little and Shi, 2001; Koka et al., 2011) are prone to misclassifications. The grey-weighted skeletonization method by Ranwez and Soille (2002) (homotopic thinning) requires the determination of topographic anchors (e.g., regional maxima), which makes it sensitive to DEM errors. The approach by Lindsay and Seibert (2013), who identified pixels belonging to drainage divides based on confluent flow paths from adjacent DEM pixels and a threshold value, is computationally expensive and sensitive to edge effects that depend on DEM size. Furthermore, drainage divides that coincide with pixel centres are inconsistent with the commonly used D8 flow routing algorithm (O'Callaghan and Mark, 1984), in which each pixel belongs to a specific drainage basin. A probabilistic approach,

60 based on multiple flow directions exists (Schwanghart and Heckmann, 2012), but computation is expensive and thus restricted to a few drainage basin outlets. Finally, all of these approaches merely yield a classified grid, but no information about the tree-like network structure of drainage divides, which requires ordering of the divide pixels into a network (Figure 1).

Although divide networks might be thought of as mirrors of stream networks, there exist fundamental differences between the two. Starting at channel heads, i.e., the tips of stream networks, streams always flow downhill and the upstream area
65 monotonically increases. Stream networks are therefore directed networks that have a tree-like structure, and a natural order, which has been quantified in different ways (e.g., Horton, 1945; Strahler, 1954; Shreve, 1966). Divide networks, however, are neither directed nor rooted, and they may even contain cycles. They do not obey any monotonic trends in elevation, or other topographic properties that could be easily measured. As a consequence, their ordering is less straightforward. Nevertheless, it is intuitive that some divides (e.g., a continental divide) should have a different order than others. In addition, the structure
70 of divide networks could be important in their susceptibility to drainage captures. For example, higher-order divides may record perturbations longer, as they are farther away from the base level and thus cannot adjust as quickly as lower-order divides. Furthermore, where higher-order divides are close to higher-order streams, drainage-capture events would result in profound changes in drainage area and thus a greater impact on stream discharge and power (e.g., Willett et al., 2014).

In this study, we propose to measure and analyse networks of drainage divides to address questions like: How is the geometry
75 of a divide network related to that of a stream network? Do similar scaling relationships apply? And: Can the divide network be used to infer catchment/drainage dynamics? Empirically driven answers to these questions require tools to study drainage divides, most efficiently from DEMs. We present our study in two separate papers. In the following, part 1, we ~~first~~ present a new approach that allows identification and ordering of drainage divides in a DEM. We investigate ways of ordering drainage divide networks and analyse basic statistical as well as topographic properties with a natural example from the Big Tujunga
80 catchment in the San Gabriel Mountains in Southern California. ~~We San Gabriel Mountains and analyse the drainage divide network for signs of drainage divide mobility.~~ In part 2 of this study (Scherler and Schwanghart, submitted), we present the results from numerical experiments with a landscape evolution model that we conducted to examine the response of drainage divide networks to perturbations.

2 Theoretical considerations

85 2.1 **Drainage divides in digital elevation models**

Drainage divides are the boundaries between adjacent drainage basins and thus their determination is based on the definition of drainage basins. In a gridded DEM, drainage basins are generally defined through the use of flow direction algorithms. The D8 flow direction algorithm (O'Callaghan and Mark, 1984) assigns flow from each pixel in a DEM to one of its eight neighbours in the direction of the steepest descent. As a result, each pixel is associated with a distinct upstream, or uphill,
90 drainage basin. In contrast, multiple flow direction algorithms, such as the D_{∞} flow direction algorithm (Tarboton, 1997), split the flow from one pixel to several others, which results in some pixels contributing to more than one drainage basin

(Schwanghart and Heckmann, 2012). In the following, we only consider drainage basins derived from the D8 flow direction algorithm. ~~In gridded DEMs, flowpaths derived from this algorithm run along the pixel centers of pixels in gridded DEMs (Armitage, 2019), and there is exists the possibility that two flowpaths run parallel to each other in neighboring pixels.~~ As a result consequence, drainage basin boundaries, and thus divides, ~~must be~~ located in between DEM pixels, and have infinitesimal width (Fehr et al., 2009). Another important consequence is that divides will have only two possible orientations that are parallel to pixel boundaries. Our definition of divides is different from one, in which divides are linked to the highest points (pixels) on interfluves (Haralick, 1983). In the case of multiple flow directions, for example, a meaningful position of a drainage divide would be the place within a pixel that partitions the pixel area according to the flow contributions to adjacent drainage basins.

For a given point in a channel network, its drainage basin is uniquely defined to be the upstream area of that point. The drainage divide of that basin, however, does not intersect the channel itself. We thus define drainage divides as lines (or graphs) that mark the margin of drainage basins and that do not cross rivers (Figure 2). ~~When derived from a DEM, these graphs consist of nodes and edges: nodes are located on pixel corners and edges follow pixel boundaries. A meaningful property of divide nodes and edges is that they should not coincide with nodes or edges of the drainage network.~~ When applying the D8 flow routing algorithm to a gridded DEM, with square elevation cells, however, this requirement poses a problem, due to the different pixel connectivity of divides and rivers. Whereas divide nodes can be connected to only four cardinal neighbours, river nodes can be connected to eight different neighbours. In consequence, divide nodes may exist that coincide with diagonal edges of drainage networks (Figure 2). In a gridded DEM this issue could be resolved with a D4 flow direction algorithm; or, more generally, this issue could be avoided if flow is only allowed orthogonal to cell boundaries. In our approach, we nonetheless adopt the D8 flow direction algorithm and allow for spatial congruence of streams and divides. In practice, such issues mainly arise near confluences (Figure 2).

2.2 Drainage divide networks

~~Just like~~ Analogous to streams, drainage divides are typically organized into tree-like networks (Figure 1), although cycles that correspond to internally-drained basins may exist. ~~Because of the directed flow of water, stream networks can be regarded as directed graphs that~~ start at channel heads (the leaves of the tree) and end at an outlet or a river mouth (the root of the tree). ~~Flow directions in stream networks can be easily derived from node elevations (e.g., O'Callaghan and Mark, 1984) and the hierarchy of streams can be related to their upstream area, for example. In contrast, drainage divides have no inherent direction, and there exists no terrain property, like elevation, that could be used to assign a direction to them. A start (and end) at stream confluences and follow the boundaries between adjacent drainage basins. We refer to these points as endpoints of the divide network (Figure 2). Where two or more drainage divides meet, they form a junction. We call individual parts of drainage divides that link endpoints and junctions, junctions and junctions, or endpoints and endpoints, the drainage-divide segments. In stream networks, flow is directed and leads to natural sorting of stream nodes by elevation and the hierarchy of stream segments can be easily described by their upstream area, for example. In contrast to streams, however, there exists~~

125 ~~no obvious metric for ordering and classifying divides. We propose that a~~ meaningful metric for ordering divides ~~is~~ may be
the average *branch length* (Lindsay and Seibert, 2013), i.e., the average distance A [m] one would have to travel down on
either side of a divide to reach a common stream location (Figure 3). ~~However, m~~Measuring this distance requires that the
common stream location and the entire path leading to it be contained in the DEM. Because this may not be true for a significant
part of the divide network in a DEM and because measuring this distance is computationally expensive (Lindsay and Seibert,
130 2013), it is not very practical. ~~However,~~
Instead, we suggest that directions can be derived from the tree-like structure of drainage divide networks. Analogous to a
parcel of water that travels down a river from its source to its mouth, we propose to start at the leaves of the tree, which we
call the *endpoints* of the divide network (Figure 2), and incrementally move down the branches (Figure 4). Note that the term
“move down” does not refer to elevation, but to the hierarchy of the divide network. Where two or more drainage divides meet,
135 they form a *junction*. We call individual parts of drainage divides that link endpoints and junctions, junctions and junctions, or
endpoints and endpoints, the drainage-divide *segments*, and we refer to the ends of divide segments as *segment termini* to avoid
confusion with endpoints. At junctions with more than one unsorted divide segment, the sorting process pauses because it is
not obvious in which direction the sorting shall continue. However, in the absence of cycles (internally drained basins), each
junction will reach a point in the sorting loop when there is only one unsorted divide segment left so that the sorting can
140 continue (Figure 4). This condition assures that the divide segments are correctly sorted in a tree-like manner, but it fails when
encountering a cycle. ~~a~~As we will show later, ~~this distance the average branch length A~~ scales linearly with the maximum
distance from an endpoint along the sorted divide network, as well as the maximum number of divide segments (or junctions),
both of which are more easily computed. We thus propose to order the nodes and edges of the divide network, by their
maximum ~~down divide~~ distance from divide endpoints, measured either in map units or in the number of divide segments.
145 From now on, we call the distance measured in map units along the directed divide network the divide distance (d_d).

3 Materials and Methods

3.1 Divide algorithm

We implemented the above-described way of extracting and ordering drainage divides from a DEM in the TopoToolbox v2
(Schwanghart and Scherler, 2014), a MATLAB-based software for topographic analysis. Figure 5 shows the workflow of our
150 approach, which consists of the following steps:

- (1) For a given DEM, we first defined a stream network, based on the D8 flow direction algorithm and a ~~minimum~~
upstream-threshold drainage area (Figure 5a,b). The lower the threshold, the more detail will have the stream
and divide networks be. We then applied the following steps.
- (2) We ~~defined-extract~~ drainage divides, based on drainage basin boundaries that we obtained for upstream
155 drainage areas at tributary junctions and drainage outlets (Figure 5c). Initially, each drainage basin boundary is
composed of one divide segment that connects two endpoints, and junctions do not yet exist. These divide

segments do not cross any rivers but their nodes may coincide with stream edges (Figure 2). We removed redundant divide segments in the collection of divides, which arise from nested and adjoining drainage basins. As a result, we are left with a set of unique divide segments, which, however, may be continuous across junctions or terminate where they should be continuous (Figure 6).

~~(2) We removed redundant divide segments in the collection of divides, which arise from nested and adjoining drainage basins. As a result, we are left with a set of unique divide segments, which, however, may be continuous across junctions or terminate where they should be continuous (Figure 5).~~

(3) We next organized the collection of divide segments into a drainage divide network (Figure 5d). This is the core of the algorithm, in which we effectively identify endpoints and junctions, merge broken divide segments, and split divide segments at junctions (Figure 6). Our algorithm distinguishes between junctions, endpoints, and broken divide segments, by computing for each node of the divide network based on the number of edges linked to it, the number of segment termini linked to it, and the existence and direction of a diagonal flow direction at the terminal nodes of divide segments (Appendix 7.1). For example, most nodes with two edges and two segment termini correspond to a broken segment and need to be merged, unless they coincide with a stream and merging them would make the resulting divide cross that stream (Figure 6). See Appendix 7.1 for more details.

(4) Finally, we sorted the drainage divide segments of within the network (Figure 5e). ~~We~~ The algorithm iteratively identifies segments that are connected to endpoints and removes them from the list of unsorted divide segments until no divide segments ~~we~~ are left (Figure 5Figure 4). This step assigns a direction to each divide segment and transforms the divide network into a directed acyclic graph. For the sorted divide network, we then compute the divide distance, i.e., the maximum distance from an endpoint along the sorted divide network (Figure 5f).

After the sorting, we also computed maximum distances along the divide network and assigned orders to divide segments, based on the ordering of stream networks, first introduced by Horton (1945). We adopted both Strahler's (1954) and Shreve's (1966) rules of stream ordering, and added a third rule that we call *Topo*. All ordering schemes start with a value of one at endpoints and progressively update divide orders at junctions based on the following rules:

$$\text{Strahler: } \omega_k = \max(\min\{\omega_i\} + 1; \omega_i) \quad \text{Eq. 1}$$

$$\text{Shreve: } \omega_k = \sum_{i=1}^n \omega_i \quad \text{Eq. 2}$$

$$\text{Topo: } \omega_k = \max(\omega_i) + 1 \quad \text{Eq. 3,}$$

where ω_i are the divide orders of the n joining divide segments and ω_k is the divide order of the following divide segment. In the *Strahler* ordering scheme, the order increases by one if the joining divide segments have the same order, otherwise it remains at their maximum order. In the *Shreve* ordering scheme, the resulting divide order is the sum of those of the joining divide segments; and in the *Topo* ordering scheme, divide orders increase by one at each junction. Junctions typically link

three different divide segments, but up to four can occur (Figure 6). Based on the *Strahler* ordering scheme, the bifurcation ratio R_b , can be derived from (Horton, 1945):

$$R_b = \frac{N_\omega}{N_{\omega-1}} \quad \text{Eq. 4,}$$

where N_ω is the number of divide segments of order ω .

190 ~~As already aforementioned, our divide algorithm currently does not handle internally drained basins very well. Whereas the divides of internally drained basins are easy to identify, they are not easily sorted in a meaningful manner. In their case fact, our proposed metric of ordering drainage divides, based on the distance to a common stream location (L), is undefined for a divide of an internally drained basin. At the moment, such divides are simply left unsorted and are flagged as belonging to an internally drained basin. the sorting procedure (Figure 4) stops at such divides, because the divide segments cannot be assigned a direction. In consequence, also parts of the divide network that potentially lie beyond an internally-drained basin, and for which the distance to a common stream location is defined, cannot be reached anymore. While we are working on a solution to this issue, our algorithm is currently best applied to acyclic drainage divide networks.~~

3.2 Topographic data and analysis

We investigated basic characteristics of drainage divide networks using a 30-m resolution DEM from the 1-arc second Shuttle Radar Topography Mission data set (Farr et al., 2007). We focused on the catchment of the Big Tujunga River in the San Gabriel Mountains, USA. The catchment is a good example of a transient landscape with active drainage basin reorganization and landscape rejuvenation as the river incises into a relict pre-uplift landscape (DiBiase et al. 20142015). We pre-processed the DEM by carving through local sinks (Soille et al. 2003) to avoid artificial internally drained basins, and we obtained a stream network based on a minimum upstream area of 0.1 km². We note that this threshold is likely well within the zone of debris flow instead of fluvial incision (Stock and Dietrich, 2003); but for the purpose of our analysis, this is irrelevant.

We analysed the divide network, its planform geometry, and its relation to both on its planform geometry and on the topography that it is related to. Planform geometry is studied using statistical analysis of the number and length of divide segments of different orders. Topographic analyses are based on metrics that we determined for the entire DEM and that ~~were~~ subsequently associated, or mapped, to divide edges and entire divide segments. As topographic metrics, we focus on hillslope relief (HR) and horizontal flow distance to the stream network (FD). HR was defined to be the elevation difference between a point on the divide and the point on the river that it flows to. To quantify the morphologic asymmetry of a divide, we propose to use the across-divide difference in hillslope relief (ΔHR), normalized by the across-divide sum in hillslope relief ($\sum HR$), and call its absolute value the divide asymmetry index (DAI); We also computed χ values on either side of a divide, using a reference area A_θ of 1 m², a reference concavity θ_{ref} of 0.45, and setting the base level x_b to 0 at the edge of the model domain (e.g., Perron and Royden, 2013):

$$DAI = \left| \frac{\Delta HR}{\sum HR} \right| \quad \text{Eq. 5.}$$

The *DAI* ranges between 0 for entirely symmetric divides and 1 for the most asymmetric divides. Note that this index is based only on values of hillslope relief (*HR*). Theoretically, a divide with equal amounts of *HR* on either side of a divide, but contrasts in flow distance (*FD*) and thus slope angle, would yield a *DAI* of zero. However, due to the definition of streams by a minimum drainage area, this hardly ever occurs. In addition, such cases can be identified by cross-divide differences in *FD*.

4 Results

4.1 Basic divide statistics

We applied our divide algorithm to the Big Tujunga catchment, based on a stream network that we derived from a minimum upstream area of 0.1 km², and the resulting divide network for different ordering schemes and the associated frequencies of exceedance of divide orders are shown in Figure 7. Because the *Shreve* and *Topo* ordering schemes yield larger ranges in divide orders, their visualization allows for greater differentiation compared to the *Strahler* ordering scheme. Differences in the visual appearance of the divide network due to the ordering scheme are also apparent at the root node, i.e., the junction that is encountered last in the ordering process (black arrows in Figure 7). In the *Topo* ordering scheme, divide orders increase by one during each sorting cycle, so that the last divide segments will have orders that are different by not more than one. In contrast, the ordering rules of the *Strahler* and *Shreve* scheme (see Eq. 1 and Eq. 2) may yield unequal orders during the sorting, so that the divide orders of the last divide segments may be different by more than one. In the Big Tujunga catchment, the basin area and thus the number of divide segments is larger north of the Big Tujunga River, compared to south of it. In consequence, both *Strahler* and *Shreve* divide orders increase more rapidly along the northern perimeter compared to the southern, and the junction encountered last during the sorting process (at the root of the tree) opposes divide segments of different with orders of 7 and 6 for *Strahler*, and 1463 and 772 for *Shreve*, in the north and south, respectively (Figure 7). For the *Strahler* ordering scheme, the frequency of exceedance distribution of divide segments decreases exponentially with divide order (ω), which is consistent with Horton's law of stream numbers (Horton, 1945), and corresponds to a bifurcation ratio of $R_b = 3.89 \pm 0.30$ (standard error). The bifurcation ratio of the associated stream network is 5.39 ± 0.87 .

We computed divide segment lengths for different drainage area thresholds (A_{min}) and show the associated empirical distribution functions in Figure 8a. Divide segment lengths are not normally distributed, but can be reasonably fitted with a gamma distribution. However, the fitted gamma distributions predict systematically higher probabilities for shorter divide segments and lower probabilities for longer divide segments compared to the actual data. For the different drainage area thresholds that we tested, the shape parameter of the fitted gamma distribution (k) attains values that range between 0.87 and 1.75. In general, the average length of all divide segments is positively correlated increases with the drainage area threshold minimum upstream area used for deriving the stream network, simply because both the stream and the divide network extend to finer branches. For a drainage area threshold the value that we used (of 0.1 km²), the average length across all divide orders

is 442 ± 323 m ($\pm 1\sigma$), compared to an expected value ($= k\theta$) of ~ 442 from the fitted gamma distribution. The average length for different divide orders tends to be slightly lower at $\omega < \sim 40$ (based on the *Topo* ordering scheme), compared to $\omega \geq \sim 40$ (Figure 8b).

250 We quantified the ~~proposed divide metric, the~~ average *branch length*, i.e., the average distance one would have to travel down on either side of a divide to reach a common stream location (A), for 100 randomly chosen divide edges per divide order in the *Topo* ordering scheme. Although the maximum order, for which A can be determined ~~in~~ (because of the size of our DEM), is limited to $\omega \leq 55$, results demonstrate that A (in km) increases linearly with $0.36 \times$ divide order (ω), and $1.11 \times$ ~~maximum~~ divide distance (d_o , ~~in km~~) (Figure 9). The linear scaling of these two relationships is a consequence of the similarity of segment
255 lengths for different divide orders (Figure 8b). Whereas the *Topo* ordering scheme can be approximated by dividing the divide distance by the expected divide segment length, this does not hold true for the *Strahler* and *Shreve* ordering schemes, which yield relationships between A and divide order that are non-linear (not shown).

4.2 Anomalous Drainage divide networks morphology ~~in~~ of the Big Tujung catchment

We next studied the morphology of the drainage divide network from the Big Tujung catchment. Because the divide
260 morphology consists of parts that lie within the catchment as well as parts that lie outside of it, we analysed the entire drainage divide network from the DEM as shown in Figure 5. Although the drainage divide network is truncated along the DEM edges, the following analysis is insensitive to this issue. Figure 10 shows the drainage divide morphology of the Big Tujung catchment, based on a stream network that was derived from a drainage area threshold of 1 km². Topographic metrics are shown for each divide edge (cf., Figure 1). Whereas across-divide mean flow distance (\overline{FD}) varies between 0 and ~ 3000 m,
265 mean hillslope relief (\overline{HR}) varies between 0 and ~ 800 m. It is notable that the biggest range in values occurs at divide distances < 10 km, whereas divides at higher distances appear to hover around characteristic values that are controlled by the drainage area threshold used to derive the stream network (Figure 10e). It should be noted that divide edges at low divide distances are much more abundant compared to those at higher distances, or equivalently, at higher divide orders (Figure 7). At increasingly higher drainage area thresholds however, the frequency of divides at low order and distance decreases more rapidly compared
270 to the frequency of high orders and distances. The average ($\pm 1\sigma$) \overline{FD} and \overline{HR} values for a drainage area threshold of 1 km² are 1325 ± 350 m and 341 ± 129 m, respectively. The empirically determined average \overline{FD} for all tested drainage area thresholds are consistent with Hack's law (Hack, 1957), which relates the length L of the longest stream in a catchment to its drainage area A , according to $L = k_a A^h$. Values of k_a and h are ~ 1.6 and ~ 0.5 , respectively – similar to values observed elsewhere (Hack, 1957). Combining \overline{HR} and \overline{FD} yields average slope values that vary between $\sim 20^\circ$ and $\sim 8^\circ$, for drainage area thresholds
275 between 0.1 km² and 10 km². The mean slope value of the entire DEM is $\sim 21.5^\circ$, which suggests that the lower drainage area threshold better confines the divides to hillslopes as compared to lower-sloping channels.

~~With~~ Based on the information observation of how the characteristic values of different divide metrics \overline{FD} and \overline{HR} recorded landscape disturbances in the numerical experiments, we sought to identify returned to the Big Tujung catchment to assess

280 ~~whether parts of the divide network that have anomalously low relief or are anomalously close to a stream shows signs of~~
~~disturbances. Instead of mean values, we turned towards across-divide minimum values of flow distance (FD_{min}) and hillslope~~
~~relief (HR_{min}), as these would be more sensitive to deviations on either side of a divide. In addition, we compared these values~~
~~with the divide asymmetry index (DAI), as we expected that anomalous divides may also be topographically asymmetric (e.g.,~~
~~Whipple et al., 2017). Figure 11 is similar to **Error! Reference source not found.** and shows how minimum hillslope relief~~
~~(HR_{min}), minimum flow distance (FD_{min}), and the divide asymmetry index (DAI) vary with distance along the divide network~~
285 ~~of the Big Tujung catchment. As in the simulations, we observe the largest range of HR_{min} and FD_{min} values, as well as some~~
~~of the most asymmetric divides at low divide distances (<5 km), whereas most of the divides at higher distances cluster around~~
 ~~HR_{min} values of 200-500 m and FD_{min} values of 800-1800 m. Notable deviations from average values (cf., Figure 10) occur at~~
~~~22-25 km, ~41-45 km, and >54 km divide distance, and are typically associated with asymmetric divides (Figure 11). Highly~~  
~~asymmetric divides are furthermore found at low divide distances (<5 km) and typically coincide with low values of  $HR$ ,~~  
290 ~~whereas  $FD$  could be high or low. The systematic decrease in  $FD$  and  $HR$ , concurrent with an increase in the  $DAI$  at higher~~  
~~divide distances prompted us to enquire the geographic position of these divides and how they compare to the surrounding~~  
~~landscape. We thus imposed thresholds to identify Figure 12a shows the geographic position of anomalously low ( $HR_{min}$  <200~~  
~~m) and asymmetric divides ( $DAI$  > 0.5), which are less than 1000 m from a stream ( $FD_{min}$  < 1000m) (Figure 12). Beheaded~~  
~~streams as well as sharp-crested and shortened hillslopes identified in high-resolution satellite imagery (Figure 12b-e) support~~  
295 ~~the impression that these divides are mobile and migrating in the direction of lower  $HR$  and sometimes shorter  $FD$ , and Figure~~  
~~12b-e give impressions of how they appear in Google Earth. Most of these divides can be seen to border regions of contrasting~~  
~~local relief (Figure 12a), and many cluster along the eastern edge of the catchment. The predicted migration direction indicated~~  
~~in Figure 12a is derived from the orientation of the divide segments and their mean  $DAI$  magnitude. If correct, most of the~~  
~~divide migration of divides along the southern and eastern edge of the catchment, from higher to lower relief, is mostly inwards,~~  
300 ~~would result in causing area loss for the Big Tujung catchment. Furthermore, the junction connectivity along the eastern edge~~  
~~is relatively low, despite being high up in the divide network (Figure 12a). While the overall trend is that divides at greater~~  
~~divide distance ( $d_d$ ) are higher in elevation and have higher junction connectivity (Figure 12b), in the Big Tujung catchment,~~  
~~the highest junction connectivity is associated to a divide segment in the southwestern part of the catchment (Figure 12a),~~  
~~which is also high in elevation and local relief (Figure 11a).~~

## 305 5 Discussion

### 5.1 Extraction and ordering of drainage divide networks

Our new approach allows routinely extracting drainage divide ~~networks~~ from any DEM without internally drained basins. We have shown that the maximum divide distance  $d_d$ , calculated as the maximum distance along the (directed) divide network from an endpoint, is a meaningful metric for ordering drainage divide networks, as it scales linearly with the average branch  
310 length  $A$ , i.e., the average distance one would have to travel down on either side of a divide to reach a common stream location

(Figure 9). In contrast to the average branch length, however, the divide distance is more easily and rapidly calculated and is less prone to edge effects that inhibit the ordering of divides (cf., Lindsay and Seibert, 2013). However, whenever a drainage basin intersects the edge of a DEM, it's truncation will likely produce a spurious drainage divide. Furthermore, calculated divide distances are most likely lower than they would be for a larger DEM, similar to the reduction of upstream area along a stream network. Truncated drainage basin boundaries should therefore be avoided, or discarded from analyses that rely on correct divide distances.

The proposed sorting procedure (Figure 4) recovers the tree-like structure of the divide network and allows the derivation of divide orders, analogous to the well-known stream orders. Because divide segments have similar mean lengths across all divide orders (Figure 8), divide orders derived with the *Topo* ordering scheme can serve a similar purpose as divide distance. Shreve (1969) studied link lengths in stream networks and concluded that their distribution is better described with a gamma distribution compared to an exponential or log-normal distribution. Results from the Big Tujunga catchment support this conclusion with respect to divide segment lengths, although systematic deviations can be observed (Figure 8a). It needs to be tested with more observations whether these deviations are inherent to drainage divide networks in general, or whether they could hold clues about the dynamic state of a landscape.

An advantage of characterizing the divide network by distance instead of orders is that the divide distance is invariant with respect to the chosen drainage area threshold, whereas divide orders are not, because they depend on the total number of divide segments and junctions. Further differences are apparent at the root node, which may oppose divide segments with orders that differ by more than one (Figure 7). In the case of the Big Tujunga catchment, Strahler orders are not that different across the root node, but in a different landscape that could well be the case. This issue is more prevalent in the case of Shreve ordering, but it is avoided with the Topo ordering scheme. Furthermore, the non-uniform distribution of divide segment lengths (Figure 8) influences how similar or dissimilar divide distances of the meeting divide segments are at the root node. If the average divide segment length of trees that meet at the root node are different, divide distances will make a jump, even if divide orders are similar. In the Big Tujunga catchment, the divide distance jump at the root node is 5400 m.

Alternatively, divide orders derived with the Strahler ordering scheme, can be used to investigate how the divide network conforms to Horton's (1945) laws of network composition. In the Big Tujunga catchment, for example, the bifurcation ratio of the divide network ( $R_b \sim 3.9$ ) is lower than that of the stream network ( $R_b \sim 5.4$ ). This may in part be due to the fact that we analysed only a part of the divide network; divide segments that originate from the main catchment boundary and extend outwards are not included in the statistics. Including those in the calculation yield  $R_b \sim 4.6$  for the divide network, still lower than the bifurcation ratio of the stream network. Nevertheless, We obtained similar bifurcation ratios for the divide ( $R_b \sim 3.74 \pm 0.48$ ) and stream ( $R_b \sim 4.53 \pm 0.18$ ) networks in the Reference model of the numerical simulations, when taking only the four largest, similar sized stream networks into account. The above these bifurcation ratios are similar to published bifurcation ratios of different natural stream networks (e.g., Tarboton et al., 1988), supporting the expected similarity of the stream and divide network geometry/topology. However, more observations from different landscapes are needed to assess systematic differences in and commonalities between divide and stream networks.

## 5.2 Drainage divide mobility in the Big Tujunga catchment

Based on the observation of characteristic values of minimum hillslope relief (300-500 m) and minimum flow distance (1000-1800 m), we identified drainage divides in the Big Tujunga catchment that are anomalously low, close to a stream, and asymmetric (Figure 11, Figure 12). These geometric properties suggest the existence of windgaps, hillslope undercutting by rivers, and spatial anomalies in erosion rates, which are diagnostic for past or ongoing mobility of drainage divides that they are mobile. Anomalous drainage divides are particularly frequent along the eastern edge of the catchment, where an area of low hillslope angles and local relief (Figure 12), the so-called Chilao Flats, is bordering a steep catchment to the south and east of it. This high-elevation low-relief area is thought to represent a relict peneplain surface that has been uplifted during growth of the San Gabriel Mountains, and is currently destroyed by headward incision of rivers (Spotila et al., 2002; DiBiase et al., ~~2014~~2015). Cosmogenic <sup>10</sup>Be-derived erosion rates confirm lower erosion rates in the Chilao Flats area compared to the surrounding steeper catchments (DiBiase et al., 2010), which ought to drive divide migration and drainage area loss in the headwaters of the Big Tujunga catchment, consistent with our results. ~~The inference of mobile divides is further supported by the scarcity of divide junction peaks (cf., Spotila, 2012) and low values of junction connectivity (C<sub>j</sub>) (Error! Reference source not found.).~~

We identified another stretch of anomalous divides along the southern margin of the Big Tujunga catchment (Figure 12a, d), part of which is coincident with the trace of the San Gabriel Fault, which follows the orientation of the valley (Morton and Miller, 2006). Reduced relief in a ~1-km wide zone around this fault is also observed farther to the east, along the West Fork of the San Gabriel River (Scherler et al., 2016), suggesting weaker rocks closer to the fault (e.g., Roy et al., 2015). Other anomalous divides in this area, as well as along the northern margin of the Big Tujunga catchment, show signs of mobility by one-side shortened hillslopes and beheaded valleys (Figure 12b, d). We thus suggest that most, if not all of the anomalous divides we identified based on hillslope relief, flow distance, and divide asymmetry, are in fact unstable and migrating with time. Because most of the peripheral divides indicate drainage area loss of the Big Tujunga catchment, these area changes ought to result in changes in stream power (Willett et al., 2014), which complicate the interpretation of stream profile knickpoints in a tectonic framework (DiBiase et al., ~~2014~~2015).

## 370 6 Conclusions

In this study, we presented an approach to objectively extract and analyse drainage divides from DEMs. We argued that divides can be ordered in a meaningful way based on the average distance one would have to travel down on either side of a divide to reach a common stream location, and we have shown that this distance can be well approximated by the maximum along-divide distance from endpoints of the divide network, which we termed the divide distance. We have also shown that the tree-like structure of divide networks lends itself for topological analysis similar to stream networks, and we introduced an ordering

scheme (*Topo*), in which divide orders increase by one at divide junctions. Because divide segments tend to have characteristic lengths, the *Topo* ordering scheme mimics the divide distance. Topographic analysis of the drainage divide network of the Big Tujunga catchment yielded characteristic values of flow distance and hillslope relief that can be shown to depend on the drainage area threshold, with which the stream network was derived. Based on these characteristic values and a minimum divide distance of ~5 km, below which we observed large scatter, we identified divides that have anomalously low hillslope relief, are close to rivers, and are asymmetric in shape. We interpret these divides to be mobile and indicating beheaded valleys or future capture events.

## 7 Appendix

### 7.1 Classification of divide network nodes

Once the drainage divides are defined, based on the outline of drainage basins, and redundant divide segments are removed, they compose a network  $D = (V,E)$  which is defined by a set of vertices  $V$  (or nodes) and a set of edges  $E$ , each of which is associated with two distinct vertices. However,  $D$  may contain some divide segments that do not end at junctions or that terminate at nodes that are neither junctions nor endpoints. To create the divide network, we have to identify divide endpoints and junctions, as well as divide segments that need to be merged or parted. We achieve this by computing for each node  $x_i$  the number of edges (1 to 4) and divide-segment termini (0 to 4) that exist in  $D$ , and identifying whether the node coincides with a stream edge (0/1) (**Table A1**). Based on these criteria, we classify nodes to be endpoints (EP), junctions (J), or broken segments (BS). In the case of nodes with three edges, three segment termini, and the presence of a stream edge, we also check which of these edges, if connected, would cross a stream, to distinguish the EP from the BS. After this classification, we are able to merge broken segments, split segments at junctions, and thus update  $D$ , which now contains all the divide segments that compose the drainage divide network.

## 8 Code availability

The divide algorithm developed in this study has been implemented in the TopoToolbox v2 (Schwanghart and Scherler, 2014). The codes will be made available with the next TopoToolbox release, and shall be accessible through <https://github.com/wschwanghart/topotoolbox>.

## 9 Competing interests

The authors declare that they have no conflict of interest.

## 10 Acknowledgements

D. Scherler acknowledges funding through grant SCHE 1676/4-1 from the Deutsche Forschungsgemeinschaft (DFG).

**Figure 1:** Big Tujunga catchment, San Gabriel Mountains, United States. (a) Stream network (blue), and (b) drainage divide network (red), both draped over hillshade image. Drainage divide network obtained with the approach developed in this study. Thickness of the stream and divide lines is related to upstream area and divide order, respectively. The map projection is UTM zone 11.

**Figure 2:** Definition of drainage divides in a digital elevation model. Note the point where a drainage divide (red) coincides with a river channel (blue). See text for details.

**Figure 3:** Ordering of divides based on the average distance to a common stream location. *A*. Numbered circles are places on drainage divides, and blue lines indicate the flow path to their common stream location (red circle). The resulting order of the drainage divide places is  $1 < 2 < 3$ .

550

**Figure 4:** Iterative sorting and ordering of the divide network. The divide network is assembled starting with divide segments that contain endpoints (green) and which are then removed from the collection of divide segments. Former junctions (red) that have only one segment remaining, become endpoints and the iteration continues until no more endpoints exist.

**Figure 5:** Workflow of identifying and ordering drainage divides in digital elevation models. (a) Digital elevation model of the Big Tjunga catchment, San Gabriel Mountains, California. (b) Drainage network based on a minimum upstream area of 1000 pixels (0.81 km<sup>2</sup>). (c) Drainage divides of all drainage basins upstream of confluences in b. (d) Drainage divide network with endpoints (red) and junctions (green). (e) Sorted drainage divide network. Line thickness indicates divide order from low (thin) to high (thick). (f) Drainage divide network color-coded by divide distance; (blue = low, yellow = high). Note that only divides at a distance >1 km are shown.

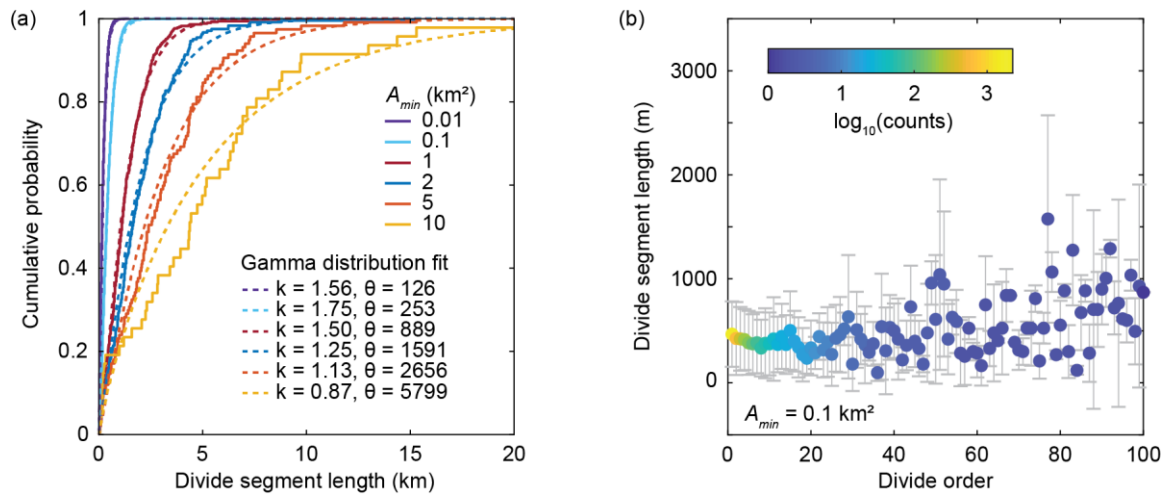

**Figure 6:** Transformation of a collection of drainage divide segments (a) into a drainage divide network with endpoints and junctions (b). Black lines are drainage divides, blue lines are streams, and flow directions are shown as light gray lines. Note that we used a minimum upstream area of only 10 pixels to define the stream network for illustration purposes.

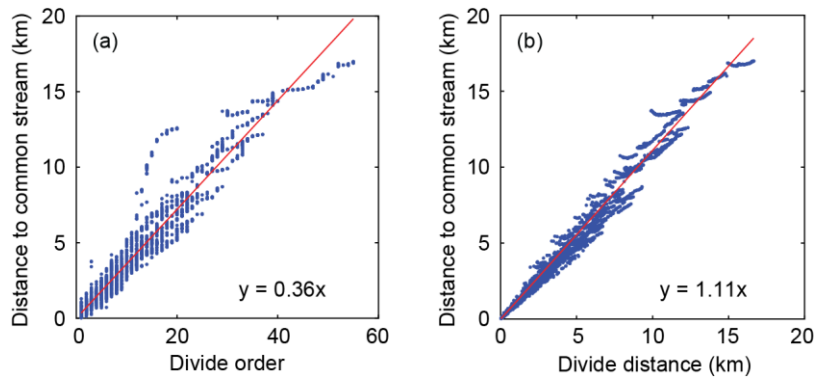

570 **Figure 7:** Divide network of the Big Tujunga catchment in the western San Gabriel Mountains, California, USA. Left column shows the divide network, with line thickness indicating the divide order. Arrow marks the last divide segment encountered in the sorting process, or, equivalently, the root of the tree-like network. Right column shows the frequency-number of exceedance of divide orders by divide segments as a function of divide order.

## **Abstract.**

10 ~~Drainage divides are organized into tree-like networks that may record information about drainage divide mobility. However, opinions~~ ~~views~~ diverge about how to best assess divide mobility. Here, we apply a new approach of automatically extracting and ordering drainage divide networks from digital elevation models ~~and~~ to results from landscape evolution model experiments. ~~We compared landscapes perturbed by strike-slip faulting and spatiotemporal variations in erodibility to a reference model~~ to assess which ~~topographic metrics (hillslope relief, flow distance, and  $\gamma$ ) parameters of divides and divide networks~~ are diagnostic of divide mobility. Results show that stable drainage divides strive to attain ~~a~~ constant values of hillslope relief as well as flow distance ~~from to~~ the nearest stream, provided a distance of  $> \sim 5$  km from ~~endpoints~~ river confluences, where divides end. Disruptions of such pattern can be related to mobile divides that are lower than stable divides, closer to streams, and often asymmetric in shape. In general, we observe that drainage divides high up in the network, i.e., at great distances ~~from endpoints~~ river confluences, are more ~~vulnerable~~ susceptible to disruptions than divides closer to ~~endpoints~~ these confluences of the network and are thus more likely to record disturbance for a longer time period. We ~~compared different topographic metrics to assess drainage divide mobility and~~ found that across-divide differences in hillslope relief proved more useful for assessing divide migration than other tested metrics. However, even stable drainage divide networks exhibit across-divide differences of any of the studied topographic metrics. Finally, we propose a new metric to quantify the connectivity of divide junctions.

## 1 Introduction

Divide migration is a time-dependent process that is difficult to quantify. While the effects of regional-scale drainage captures may be preserved within sedimentary archives (e.g., Clift et al., 2006), this is unlikely for smaller scale drainage captures or gradual divide migration. In such cases, most studies are relying on topographic indicators. Mobile divides are typically inferred from post-drainage capture evidence: distorted drainage structures, low divides (wind gaps), or high tributary junction angles (e.g., Clark et al., 2004) (Figure 14). However, divide mobility may also be expressed in the topography without major drainage captures or flow reversals, but as a result from more gradual migration of divides. Willett et al. (2014) inferred drainage divide mobility from across-divide differences of  $\chi$  values, a proxy for steady-state river channel elevation (Perron and Royden, 2013). They argue that changes in drainage area within mountain ranges, e.g., due to tectonic strain of the crust (Yang et al., 2015), may commonly lead to relative differences in incision rate and the formation of low-relief landscapes that are bordered by migrating divides. Whipple et al. (2017a,b) however argued that the time scale of such changes is too short to profoundly affect mountainous landscapes. Instead, they argue that transient low-relief landscapes, such as those in Southeastern Tibet, are more likely to be formed by regional changes in rock uplift rate and upstream propagation of knickpoints between the adjusted and unadjusted parts of landscapes. They also cast doubt on the ease of comparing across-divide differences in drainage network geometry (i.e.,  $\chi$  values) where the common base level is far and where opposing rivers may incise into areas of different rock types, different rock uplift rates, or different climates. Whipple et al. (2017a,b) instead proposed that the shape of drainage divides themselves hold clues about their mobility (Figure 14). Amongst the topographic parameters that they tested are across-divide differences in channel elevation at a reference drainage area, mean headwater hillslope gradient, and mean headwater local relief.

In summary, several different metrics have been proposed that may allow quantification of divide mobility in both natural and modelled landscapes. Forte et al. (2018) compared the performance of these metrics with a landscape evolution model in which they induced divide mobility, and concluded that across-divide differences in relief or gradient better depict divide motion than  $\chi$ . In their analysis however, they focused on divide motion that is perpendicular to the regional drainage direction and averaged divide migration rates as well as topographic metrics across the entire width of the model domain, so that each time step is associated with single values for divide migration rate, erosion rate difference, and the tested topographic metrics. In the following part 1 of this study (Scherler and Schwanghart, submitted), we first-presented a new approach that allows for the automatic identification and ordering of drainage divide networkss in a DEM. Here, we present experiments with a numerical landscape evolution model that we conducted to investigate how drainage divide networks respond to different perturbations, including fault activity and differences in erodibility. In contrast to previous studies that examined the response of drainage divides to perturbations, we studied the entire drainage divide network in an objective manner and examined how different portions of the divide network respond to perturbations. In addition, we tested the utility of a new metric that quantifies the connectivity of drainage divide junctions.

~~We then present experiments with a numerical landscape evolution model that we conducted to investigate how drainage divide networks respond to external perturbations.~~

## 60 2 Materials and Methods

### 2.1 Landscape evolution model

We studied the response of divide networks to stream captures and divide migration, using the TopoToolbox Landscape Evolution Model (TTLEM; Campforts et al., 2017). In our experiments, we modelled the topographic evolution of a 20 km × 20 km square block (50-m node spacing), subject to uniform rock uplift, stream power-based fluvial incision (e.g., Howard and Kerby, 1983; Whipple and Tucker, 1999), as well as hillslope diffusion (e.g., Culling, 1963):

$$\frac{dz}{dt} = U - K_r A^m S^n - \nabla \mathbf{q}_s \quad \text{Eq. 1,}$$

where  $z$  is elevation (L),  $t$  is time (T),  $U$  is rock uplift rate (L T<sup>-1</sup>),  $A$  is upstream area (L<sup>2</sup>),  $S$  is local channel slope (L L<sup>-1</sup>),  $K_r$  is a parameter of the efficiency of river incision (T<sup>-1</sup>) ( $K_r = 1 \times 10^{-5}$  yr<sup>-1</sup>), and  $m$  and  $n$  are dimensionless constants with values of 0.5 and 1, respectively. The last term on the right-hand side depicts elevation change due to the divergence in diffusive hillslope transport  $\mathbf{q}_s$  (L<sup>3</sup> L<sup>-1</sup> T<sup>-1</sup>), which we consider to be a linear function of hillslope gradient:  $\mathbf{q}_s = -D \nabla z$ , where  $D$  is the diffusivity (L<sup>2</sup> T<sup>-1</sup>) of soil creep ( $D = 2 \times 10^{-3}$  m<sup>2</sup> yr<sup>-1</sup>). All four edges of the block were fixed in elevation ( $z = 0$  m), which forced rivers to flow outwards. The uplift rate ( $U = 1$  mm yr<sup>-1</sup>) was constant in all models. Our choice of parameter values was guided by the study of Whipple et al. (2017b), who tested a wide range of rock uplift and erosional efficiency parameters and found almost no difference of divide mobility in models with and without hillslope diffusion and for  $n$  values of 1 and 2.

We started from a flat surface with imposed random noise and ran the experiment for ~~3~~40 Myr, until the topography reached ~~a nearly~~ steady state. The result of this model, which we termed ‘Initialize’, provided the starting point for four other models that we ~~again~~ ran for 10 Myr (Figure 2). The model ‘Reference’ included no further changes. In the model ‘Rotating’, we included a circular (10-km diameter) left-lateral strike slip fault that was active throughout the experiment. Strike-slip faults are well known for enforcing drainage captures and thus divide mobility (e.g., Castellort et al., 2012; Duval and Tucker, 2015). Although the rotating block has, to our knowledge, no real-world equivalent, this model setup represents a convenient way of ~~simulating~~ extended periods of strike-slip faulting, as the fault does not intersect the model boundary (cf., Braun and Sambridge, 1997). The fault slip rate was fixed at 4 mm/yr, which corresponds to an angular velocity of  $8 \times 10^{-7}$  rad/yr, resulting in  $\sim 460^\circ$  of total rotation during the model run. We note that the rotating movement requires interpolation and thus leads to numerical diffusion of elevations within the rotating disc. However, the resulting change in total volume by interpolation is  $< 0.03\%$  of the volume uplifted during the same time and therefore small. The model ‘Inclined’ included 1-km thick and 5-km spaced layers of 50-% reduced erosional efficiency of rivers ( $K_r$ ), dipping  $30^\circ$  towards northwest. The ‘Inclined’ model is ~~representative~~ for a landscape, in which rivers incise into tilted sedimentary rocks of non-uniform rock strength, similar to

what has been studied by Forte and Whipple (2018). During the experiment, the combination of surface lowering and inclination resulted in the strong-resistant layers to regularly sweep from southeast to northwest across the simulated landscape. The model ‘Spheres’ included 30 randomly assembled spheres of 3 km diameter with 75-% reduced erosional efficiency of rivers ( $K_r$ ). This experiment may represent incision of a region that is characterized by country rocks with more-resistant magmatic intrusions. The expected behaviour of this model is similar to the landscape response to localized perturbations studied by O’Hara et al. (2018).

## 2.2 Topographic analysis

We analysed the modelled topography and the associated drainage divide network. For each modelled topography and at each time step (dt = 40,000 years), we first computed flow directions and flow accumulation, and subsequently identified the stream network using a drainage area threshold of 0.2 km<sup>2</sup>. We next derived the drainage divide network on the basis of the stream network and using the algorithm proposed in Scherler and Schwanghart (submitted). We calculated divide distances as well as divide orders based on the *Topo* ordering scheme (cf., Scherler and Schwanghart, submitted). As topographic metrics, we included elevation ( $z$ ), as well as hillslope relief ( $HR$ ) and horizontal flow distance to the stream network ( $FD$ ).  $HR$  was measured as the elevation difference between a point on the divide and the nearest river location as measured by the distance along local flow directions-point on the river that it flows to. We also computed  $\chi$  values on either side of a divide, using a reference area  $A_0$  of 1 m<sup>2</sup>, a reference concavity  $\theta_{ref}$  of 0.45, and setting the base level  $x_b$  to 0 at the edge of the model domain (e.g., Perron and Royden, 2013):

$$\chi = \int_{x_b}^x \left( \frac{A_0}{A(x')} \right)^{\theta_{ref}} dx' \quad \text{Eq. 2.}$$

For each divide edge, we computed these topographic metrics as well as the erosion rate (Eq. 1) for the two neighbouring pixels that belong to adjacent drainage basins and denoted the across-divide minimum, maximum, sum, difference, and average in any one topographic-metric  $X$ , as  $X_{min}$ ,  $X_{max}$ ,  $\sum X$ ,  $\Delta X$ , and  $\bar{X}$ , respectively. Erosion rates were based on the erosion rate of the first downslope stream pixel to reduce the impact of local noise along hillslopes. Topographic metrics of entire divide segments are based on those of the divide edges that it is composed of. For quantifying across-divide differences in topographic metrics as well as erosion rates, irrespective of the actual values, we used normalized indices of the form  $\Delta X / \sum X$ . One such index that we frequently used in our study is related to the cross-divide difference in hillslope relief, and we define its absolute value as the divide asymmetry index ( $DAIDAI = |\Delta HR / \Sigma HR|$ ), which is the absolute value of the normalized hillslope relief difference, and which ranges between 0 (symmetric) and 1 (most asymmetric).

The above described across-divide differences in topographic metrics essentially aim to quantify divide mobility. In contrast, Spotila (2012) studied focusing on the stability of divides; Spotila (2012) and argued that divide junctions and pyramidal peaks are more stable than solitary linear solitary divides and might therefore act as anchor points for drainage divide networks. He proposed his idea is based on the view that divide junctions are more difficult to erode than linear divides, due to their greater volume of topography per unit area, their greater mechanical stability, and their reduction of confluent flows (Spotila, 2012).

Spotila (2012) He also suggested that the stability of divide junctions is related to the number of joining drainage divides. Because divide junctions, obtained from our algorithm as defined here, cannot connect more than four divides segments (cf. Scherler and Schwanghart, submitted) – and most often connect three segments – we introduce a new metric to quantify divide junction connectivity,  $C_J$ :

$$C_J = \frac{dx}{d_{d,max}} \sum_{i=1}^n \frac{d_i}{d_{d,i}} C_J = \left( \int_0^{d_{d,max}} \frac{d}{dx} dx \right) / d_{d,max} \quad \text{Eq. 3.}$$

We define  $C_J$  to correspond to the sum of the ratios of the Euclidean distance,  $d$ , and the divide distance,  $d_d$ , integrated over of all divide edges,  $n$ , within a specified maximum divide distance,  $d_{d,max}$ , times the ratio of the cell size,  $dx$ , normalized by and  $d_{d,max}$ . The dimensionless quantity  $C_J$  is sensitive to the number of divides within a given divide distance from a junction, weighted by their orientation towards the junction (Figure 33). The value  $d_{d,max}$  reflects the divide distance, over which differences in junction connectivity are measured. For junctions that connect a constant number of straight and infinitely long divide segments,  $C_J$  is not sensitive to the value of  $d_{d,max}$ . However, for actual junctions,  $C_J$  is typically sensitive to the value of  $d_{d,max}$ , because as  $d_{d,max}$  grows, increasingly more junctions are at a distance  $d_d < d_{d,max}$  of a specific junction and thus the number of divide segments grows with  $d_d$  (Figure 33a). In general,  $C_J$  will be sensitive to the position of a junction within the drainage divide network, if the junction's maximum divide distance from an endpoint is smaller than  $d_{d,max}$ . In other cases,  $C_J$  will provide a measure of how connected a junction is within a network, or, in other words, how prominent the junction is compared to other junctions in the network. In this study, we used a  $d_{d,max}$  value of 5 km.

### 3 Results of numerical experiments

#### 3.1 General behaviour

The simulated landscapes along with their drainage divide networks at the end of the numerical experiments are shown in Figure 4 and Figure 5, and in the Supplementary Material we provide movies of all simulations. To provide a measure of the mobility of drainage divides, we computed the percentages of drainage area that were exchanged during the simulations between individual catchments that drain to the margin of the model domain during the simulations (Figure 6). Except for the Reference model, all models are characterized by significant notable changes in drainage area and thus mobile drainage divides. Area changes in the Initialize model were large in the beginning but levelled off rapidly during the first 1 Myr. Although area changes are small after 1 Myr, they continue for another 20 Myr, during which they are mostly decreasing. In the Rotating model, large area changes appeared ed as discrete pulses, induced by drainage captures of major streams (Figure 5b), whereas the background area changes during the rotation/faulting were relatively small ( $<0.1\%/40\text{kyr}$ ). Area changes in the Inclined model were moderate ( $\sim 0.25\%/40\text{kyr}$ ) throughout the simulation and oscillated ed in conjunction with the passage of more resistant layers through the landscapes (Figure 5c). Area changes in the Spheres model were generally more pronounced if the resistant spheres appeared ed in the course of rivers, which forced ed them to steepen and to induced ed surface uplift upstream, as

~~compared-opposed~~ to their appearance at drainage divides, ~~which increases the height of the divide, but which does not induce drainage divide migration at larger scale.~~ (Figure 5d).

### 3.2 Network topology

180 ~~We first analysed the response of the entire drainage network topology to the perturbations by quantifying the aggregated length of divide segments as a function of their order (Figure 77).~~ ~~shows how the frequency of exceedance of divide lengths for different orders changed during the landscape evolution experiments.~~ The first ~~1-2~~ few Myr of the Initialize model ~~are~~ characterized by large changes in divide lengths and orders. ~~Initially, the divide network extends to orders as high as 100, but it rapidly contracts as the drainage network becomes dendritic.~~ ~~and a~~ After about 5 Myr, the highest orders are down to 60.

185 ~~Subsequent changes result in some scatter of the divide lengths, but not in the range of divide orders.~~ ~~but relatively few changes thereafter.~~ Compared to the Reference model, in which the divide network structure ~~does~~ not change ~~much after~~ ~~5 Myr~~ anymore, the Rotating, Inclined, and Spheres models exhibit changes in the divide network, mostly at ~~higher~~ divide orders greater than  $\sim 20$ . This observation is related to the fact that low-order divides are distributed across the entire model domain and their number is accordingly high. Any of the perturbations we imposed only affects some of these divides, and thus the

190 ~~impact on their average length is rather small. In contrast, high-order divides are constrained to the highest parts of the modelled land surface and their numbers are much lower. The imposed perturbations typically affect a greater portion of them and hence the scatter in divide lengths is biggerwider. In the Rotating and Spheres models, we also observed that maximum divide orders occasionally extend to higher values, but these changes are rather small. We note that the above observations also prevailare also true~~ when considering divide distance instead of divide order, because the two are linearly related (Scherler and

195 ~~Schwanghart, submitted), with divide distance  $\sim 430 \text{ m} \times$  divide order. The factor on divide order corresponds to the mean length of the divide segments.~~

### 3.3 Topographic metrics

~~We next studied~~ ~~Figure 8 shows~~ how the above-described disturbances affected drainage-divide metrics ~~of the simulated landscapes~~ during the simulations (Figure 8). For all models, we computed the averages of ~~several~~ topographic parameters, measured at drainage divides of ~~a~~ specific divide distance intervals (Figure 8~~Figure 8a-d~~). ~~As in the analysis of divide segment lengths by order, it should be kept in mind that the numbers of divide segments, or their aggregated lengths (Figure 77), are much higher for low orders and distances as compared to higher ones. For reference, a divide order of 20 corresponds to a divide distance of approximately 9 km. In the Initialize model, all of the studied metrics attain a constant value that remains~~

200 ~~unchanged do not change any further~~ in the Reference model (Figure 8), and which may or may not depend on the divide distance. ~~Together with the mean elevation it is the only parameter, where the actual magnitude of  $C_L$  depends strongly on the divide distance, simply because of the chosen  $d_{L,max}$  value (see section 2.2).~~ For example, the mean elevation and junction

205

connectivity ( $C_j$ ) clearly increase with divide distance, whereas the flow distance exhibits only minor dependence on divide distance, and hillslope relief appears unrelated to divide distance. The dependency of some metrics on divide distance is partly explained by the model setup. Although divides with low distances occur also at higher elevation, the bulk of them is near the model edge, close to zero elevation. In contrast, divides at high distances are exclusively found near the centre of the model, where elevations are also high. Similarly, the junction connectivity ( $C_j$ ) is high in the model centre, where the divides are far from most of the endpoints, which are more abundant near the edges of the model.

It is also worth noting that none of the normalized across-divide differences in the topographic metrics attains values in the Reference model. This means that even at topographic steady state, there exist residual across-divide differences in hillslope relief, flow distance and  $\gamma$ . In the case of  $\gamma$ , these also depend on the divide distance, and are greater closer to the model edge, where divide distances are low. In the perturbed models, we observed fluctuations in all topographic metrics, although of different magnitudes. For example,

Amongst the studied parameters, we find that mean elevation ( $z$ ), hillslope relief ( $HR$ ), and flow distance ( $FD$ ) approach constant values in the Reference model, but are prevented to do so in the disturbed models. Temporal variations in junction connectivity ( $C_j$ ), which captures the relative connectivity of drainage divide junctions for a  $d_{d,max}$  value of 5 km, is similarly high in the Reference model as in the disturbed models. Together with the mean elevation it is the only parameter, where the actual magnitude of  $C_j$  depends strongly on the divide distance, simply because of the chosen  $d_{d,max}$  value (see section 2.2). Whereas the actual value of  $FD$  appears to show some dependency on divide distance, no dependency can be seen for  $HR$ .

Comparison of a cross-divide differences in erosion rate with differences in hillslope relief, flow distance and  $\chi$  (Figure 8e-h) shows that the absolute and normalized differences in hillslope relief (i.e., the divide asymmetry index), appear to be the most sensitive to drainage divide mobility in all perturbed models, whereas a cross-divide differences in  $\chi$  and flow distance are sensitive to divide mobility in the Rotating model, but less so in the Inclined and Spheres models.

In many cases, the deviations from the Reference model are greater the higher up in the divide network, i.e., for higher divide distances. This pattern is particularly well visible in the Inclined model, where the amplitudes of the oscillations in all of the parameters increase with divide distance. The junction connectivity ( $C_j$ ) metric attains values in the perturbed models that in the Spheres model, this pattern is sporadically disrupted (e.g., at ~13-15 Ma), when spheres emerged at the surface in places where they affected only a small portion of the drainage divide network, are temporally averaged quite similar to the constant values in the Reference model. In many cases, the deviations from the Reference model are greater the higher up in the divide network, i.e., for higher divide distances. This pattern is particularly well visible in the Inclined model, where the amplitudes of the oscillations in all of the parameters increase with divide distance.

### 3.4 Minimum hillslope relief and flow distance

240 ~~Motivated by the observation of constant values in hillslope relief and flow distance in the Reference model, as well as in nature actual landscapes (Scherler and Schwanghart, submitted), and by our expectation that small values in either one would be found where one catchment loses area to another (Figure 14), we next compared how~~  
~~Figure 9 shows how~~ minimum hillslope relief ( $HR_{min}$ ), minimum flow distance ( $FD_{min}$ ), and the divide asymmetry index ( $DAI$ ) vary with divide distance in the Reference model and the three models with ~~induced~~ landscape ~~per~~disturbances (Figure 9). In contrast to the average values in Figure 8, we provide these metrics for all divide edges during the last ~~10.8~~ Myr of the model runs. Note also that ~~we plotted data points in an order we sorted the data points which draws~~ ~~ob~~ brings that high  $DAI$  values ~~are in~~ to the front, to better assess where asymmetric divides are located, but that in all four models, relatively high  $DAI$  points may plot on top of low  $DAI$  points. In the Reference model, both minimum hillslope relief and minimum flow distance reach relatively steady values ( $HR_{min}$  ~250-350m;  $FD_{min}$  ~400-600m) at a divide distance of ~~~150~~ km. At lower divide distances, 245 both  $HR_{min}$  and  $FD_{min}$  approach zero – simply because divides are defined to start at the stream network – and these divides can become increasingly more asymmetric. It is notable however, that some of the highest  $HR_{min}$  and  $FD_{min}$  values are also observed at low divide distances of approximately 1-2 km. ~~The cluster of highly asymmetric divides with low  $HR_{min}$  and  $FD_{min}$  values at ~5 km divide distance is related to isolated adjustments in the lower right corner of the model (cf. videos in the Supplementary Material).~~ In the three other models, the transition between quite variable divides at short distances and more steady 'background' values at higher distances appears to be preserved, but we observe generally more variability. For example, in the Rotating model, we observe divides with significantly lower  $HR_{min}$  and  $FD_{min}$  values at higher distances. These divides are particularly prominent at a distance of ~10 km and ~~~15-220~~ km and correspond to the position of the strike-slip fault. Where  $HR_{min}$  and  $FD_{min}$  are low,  $DAI$  values are relatively high (divides are highly asymmetric), although there also exist divides that have high  $DAI$  but regular  $HR_{min}$  and  $FD_{min}$  values. In the Inclined and Spheres models, the  $HR_{min}$  and  $FD_{min}$  values 250 are never as low as in the Rotating model at divide distances ~~>515~~ km, which reflects the lack of drainage captures. Instead, we observe frequent excursions to both higher and lower  $HR_{min}$  and  $FD_{min}$  values, either across all divide distances (Inclined) or at specific locations (Spheres). Deviations from the average values in the Reference model are greatest~~st~~ in the Spheres model compared to all other perturbed models and always correspond to peaks that grow where strong spheres are exhumed. In the three disturbance models,  $DAI$  values are generally higher than in the Reference model (~~except for the cluster at 5 km divide distance~~) – although divides with high  $HR_{min}$  and  $FD_{min}$  values and at great divide distances always mostly appear to 255 have somewhat lower  $DAI$  values.

#### 3.23.5 Junction connectivity

~~Figure 10 shows~~ The spatial pattern of divide junction connectivity ( $C_j$ ) values at the end of the landscape evolution experiments (Figure 10) ~~Figure 10~~ partly follows the pattern of divide distances (Figure 4). In general, ~~j~~ junctions with higher 270  $C_j$  values tend to occur at higher elevation and at greater divide distance ( $d_d$ ). In the Reference model, the highest  $C_j$  values

occupy the centre as well as the centres of the four quadrants of the model domain, ~~mimicking-resembling~~ the five of a six-sided dice. In the Rotating model, these clusters of high  $C_J$  values are maintained, but their connection is disrupted by the strike-slip fault, which induces low  $C_J$  values. The centrally located divide junctions occupy a similar range in  $C_J$  values, but are all shifted to higher elevations (cf., Figure 4). Similar, although lower, offsets to higher elevations occur in the Inclined and Spheres models, where junctions coincide with rocks of reduced erodibility. In the Spheres model, the basic structure of  $C_J$  values is ~~equal-similar~~ to that of the Reference model, but ~~the highest~~  $C_J$  values are steered towards the less erodible spheres, ~~where they also attain  $C_J$  values that are distinctly higher than in any of the other models~~ (Figure 10~~Figure 10b~~). ~~In general, divide junctions with combinations of elevation and  $C_J$  values that are outside the ~~range~~ of values observed in the Reference model are found in the most disturbed parts of the landscape~~ (Figure 10~~Figure 10c~~). In summary, the perturbed models appear to induce mostly changes in junction elevation, whereas changes in junction connectivity ( $C_J$ ) are seemingly constrained to the Spheres model.

## 4 Discussion

### 4.1 Quantifying drainage divide mobility

The analysis of stream networks has become a standard tool for inferring tectonic forcing and landscape history (e.g., Wobus et al., 2006; Kirby and Whipple, 2012; Demoulin, 2012; Schwanghart and Scherler, 2014). The divide network holds the potential for recording similar, but also other aspects of landscape history (e.g., Willett et al., 2014). The question is, which divide metrics are useful to analyse and what ~~do~~ they tell us about landscape history? Our Rotating model induced relatively sudden drainage captures (Figure 6). Because such events are ~~always~~ associated with the dissection of drainage divides, reliable indicators are values of hillslope relief ( $HR$ ) and flow distance ( $FD$ ) that are much lower compared to the values that divides (> ~5 km divide distance) strive for (cf., Figure 9). More gradual divide migration, however, likely lacks such simple diagnostic criteria, and in those cases, ~~a~~cross-divide differences in topographic metrics may be more suitable indicators of divide mobility. The most commonly used metric to infer drainage divide mobility is the ~~a~~cross-divide difference in  $\chi$  (Willett et al., 2014). Although the utility of this metric has recently received some critique (Whipple et al., 2017b; Forte and Whipple, 2018), it became a popular tool for studying drainage divides. Whipple et al. (2017b) and Forte and Whipple (2018) instead advocated the use of other topographic metrics, including mean gradient, mean local relief, and channel bed elevation, measured at or upstream of a reference drainage area. We note that these latter metrics are typically highly correlated and eventually very similar to the hillslope relief ~~and DAI metrics~~ that we included in this study.

~~Figure 11~~Figure 11 shows how normalized ~~a~~cross-divide differences in  $\chi$ , hillslope relief ( $HR$ ), as well as flow distance ( $FD$ ) compare to normalized ~~a~~cross-divide differences in erosion rate ( $ER$ ), evaluated for each divide edge from the last ~~12~~ Myr of the landscape evolution experiments Reference, Rotating, Inclined, and Spheres. We find that ~~a~~cross-divide differences in hillslope relief ( $HR$ ; ~~Figure 11~~Figure 11a) are most sensitive to the disturbances included in the models, whereas ~~a~~cross-divide differences in  $\chi$  are similarly sensitive to disturbances in the Rotating model, but less so in the Inclined and Spheres models

(~~Figure 11~~~~Figure 11~~b; Figure 8). ~~Ac~~Cross-divide differences in flow distance ( $FD$ ) are the least sensitive to disturbances in the models and show the largest scatter when compared with erosion rates (~~Figure 11~~~~Figure 11~~c). However, there also exists substantial scatter in the relationship between ~~a~~cross-divide differences in hillslope relief and erosion rate, which partly depends on the divide distance. In general, we observe that the scatter is higher for divide distances  $< \sim 5$  km (dark blue in ~~Figure 11~~~~Figure 11~~), which corresponds to the value below which we observe ~~more-large~~ variability in divide morphology, even in the Reference model (cf., Figure 9). To quantify the correlation of the normalized cross-divide differences in topographic metrics with normalized cross-divide differences in erosion rate, we fitted a linear model to all drainage divide edges from the entire model runs, categorized into 1-km divide distance bins and show the resulting coefficients of determination ( $R^2$ ) in Figure 12~~2~~. As already suspected from Figure 8 and ~~Figure 11~~~~Figure 11~~, the  $R^2$  values differ in between models and metrics, and also depend on divide distance. In general, we observe that all metrics perform poorly at divide distances  $< \sim 5$  km, and that cross-divide differences in flow distance perform poorly even at higher distances. The highest  $R^2$  values are linked to cross-divide differences in hillslope relief, whereas cross-divide differences in  $\chi$  attain similar  $R^2$  values in the Rotating model, but some of the lowest  $R^2$  values of all metrics in the Inclined and Spheres model. This difference may be explained by the fact that in the latter two models, we introduced spatial variability in the erosional efficiency of rivers ( $K_r$ ) that we did not account for in our ~~a~~cross-divide comparison of  $\chi$ , as would be required (Willett et al., 2014). In natural landscapes, however, these values are rarely well known.

We speculate that ~~this-the~~ influence of divide distance on topographic metric-erosion rate relationships may also account for the differences in scatter observed by Sassolas-Serrayet et al. (2019) in landscape evolution experiments similar to our Initialize ~~and Reference~~ models between larger and smaller basin areas. But even when excluding divides of low order or low divide distance, we still observe considerable scatter in the topographic metric-erosion rate relationships, which, at the very least, demand caution when interpreting divide morphology in terms of mobility. In this regard, Figure 5 and studying the videos of the landscape evolution experiments (see Supplementary Material) is insightful: where drainage divides are migrating, one typically observes a range of ~~a~~cross-divide topographic metric values that vary considerably during the migration. In other words, despite a continuous divide migration at large scale, there often exists small-scale variability in divide morphology that may in part be related to ~~a~~cross-divide differences in topographic metrics lagging behind ~~a~~cross-divide differences in erosion rate.

As a final note, we emphasize that the above ~~observations are from conclusions\_ focus on the results from~~ our numerical experiments, which depict an idealized world. It is clear that complexities present in nature, such as anisotropic and variable rock properties, hydro-climatic gradients, or biological influences on erosion processes and rates can lead to landscape patterns ~~which that~~ bias any of the above topographic metrics, and need to be taken into account when inferring divide dynamics from divide metrics in natural landscapes~~interpreting both stream and divide networks~~.

## 4.2 Divide network dynamics

335 Stream networks tend to attain configurations that are in equilibrium with the geological and climatic environment, given an  
initial condition (e.g., Rinaldo et al., 2014). Because drainage divides ~~result from the~~ are defined by ~~adjacent~~ ey-of drainage  
basins, the geometry of divide networks should attain a similar equilibrium, which expresses itself both in the geometry of  
divides and in the topology of divide networks. Our numerical experiments have shown that during the initial establishment  
of a stream network, on a relatively flat surface, both stream and divide networks are far from their steady-state configuration  
340 and characterized by networks that extend to high orders ([Figure 77](#)), and divide distances. During the subsequent extension  
and shrinkage of individual streams towards their steady-state configuration, the divide network contracts and primarily high-  
order divide segments shorten and become fewer, whereas divides of low orders maintain their frequencies ([Figure 77](#)).  
In general, divide segments of high order, i.e., at great distance from endpoints, appear to be the most responsive to landscape  
disturbances (Figure 8). In the case of the Rotating model, this is in part expected; because the inner rotating part of the  
345 landscape contains the highest order divide segments (Figure 4b). In the cases of the Inclined and Spheres models, it may be  
related to the increased probability of recording a disturbance, because the adjoining basins cover a larger area compared to  
lower-order divides. In other words, if divide-drainage captures happen somewhere within a drainage basin, this will most  
likely influence divides further upstream. Over a distance of less than ~5 km from divide network endpoints, the divide  
segments transition from low interfluves at river junctions to high topographic ridges, as seen in the Reference model (Figure  
350 9). In the other models, most of the investigated morphometric parameters are quite variable over the same distance and can  
be seen to rapidly adjust to disturbances such as drainage captures or migrating divides. Such ~~behavior~~ behaviour is consistent  
with the observation that the timescale of a rivers' response to changes in drainage area increases with the distance from the  
divide to the outlet of a river (Whipple et al., 2017b). To reliably distinguish the morphologic effects of real disturbances from  
'noise' close to the river, a minimum divide distance of perhaps ~5 km, as in our analysis of the Big Tujunga divide network  
355 ([Scherler and Schwanghart, submitted](#)), appears appropriate. This minimum divide distance could be lower or higher,  
depending on factors like drainage density and average hillslope relief, for example.

Our new junction connectivity index ( $C_j$ ), complements existing topographic metrics in assessing ~~drainage-divide~~ network  
stabilitydynamics. For example, the junction connectivity in our Rotating model is low along the fault ([Figure 10](#)~~Figure 10~~),  
consistence with the absence of stable divides. In the Spheres model, however, the appearance of more resistant rocks at the  
360 surface often resulted in migration of divides towards the spheres (Figure 5c, Supplementary Material). In this case, parts of  
the drainage divide network were mobile, not stable, but they moved towards particularly stable portions in the landscape.  
Therefore, the junction connectivity index ( $C_j$ ) may also be interpreted as ~~an attractor or~~ an attractor ~~centrality~~ index ([Phillips et](#)  
[al., 2015](#)) that quantifies how strong a drainage divide network has been pulled towards and anchored at a certain junction  
(Spotila, 2012).

## 365 5 Conclusions

Based on landscape evolution model experiments in which we forced divides to migrate, we found that stable drainage divides strive to attain a constant hillslope relief as well as flow distance from the nearest stream, provided a sufficiently large divide distance to avoid confounding influences near the edges of the divide network. In our experiments ~~and in the case study of the Big Tujunga catchment, San Gabriel Mountains,~~ this distance is ~5 km from endpoints. Simple indicators of mobile divides are thus anomalously low hillslope relief or flow distance values, which could signal beheaded valleys or future capture events. Overall, drainage divides located high up in the network, i.e., at great distance from endpoints, are more vulnerable than divides closer to endpoints of the network and are more likely to record disturbance for a longer time period. In our comparison of different topographic metrics to assess drainage divide mobility, we found that across-divide differences in hillslope relief proved more useful for assessing divide migration than other tested metrics.

## 375 6 Code availability

The divide algorithm developed in ~~this study~~ Scherler and Schwanghart (submitted) has been implemented in the TopoToolbox v2 (Schwanghart and Scherler, 2014). The codes will be made available with the next TopoToolbox release, and shall be accessible through <https://github.com/wschwanghart/topotoolbox>.

## 7 Supplement

505 **Figure 1:** Example of mobile drainage divide in the Hindukush, Afghanistan. (a) Digital elevation model draped over hillshade image. Colours denote elevations that range from ~2000 m (blue) to ~4000 m (yellow). Black line traces drainage divide with clear signs of mobility. Centre of map lies at approximately 37.10°N and 71.06°E. (b) Profiles of elevation (upper panel) and mean slope (lower panel) along the drainage divide shown in (a). Mean slope angles were computed along swath profiles that extend 500 m to the north (blue) and south (red) of the drainage divide.

**Figure 2:** Graphical representation of the model setups in the landscape evolution experiments. The starting condition of each model is shown at the top of each rock column. During the experiments, the entire rock column is eroded and deeper lying regions are exhumed. (a) 'Initialize' started from a nearly flat surface and reached almost steady state topography; the end of 'Initialize' provided the starting point for all other models. (b) 'Reference' included no changes. (c) 'Rotating' included a circular left-lateral strike slip fault, active throughout the experiment. (d) 'Inclined' included 1-km thick and 5-km spaced layers of 50-% reduced erodibility, dipping 30° towards northwest. (e) 'Spheres' included 30 randomly assembled spheres of 3 km diameter with 75-% reduced erodibility.

515

520

**Figure 3:** Illustration of junction connectivity ( $C_j$ ) of different drainage divide junctions. (a) Map-view of four hypothetical divide junctions. Grey circles indicate Euclidean distance from the junction. Numbers to the southeast in each map gives the  $C_j$  value, based on a  $d_{d,max}$  of 3000 m. (b) Sum of distance ratios ( $\sum d/d_q$ ; cf. Eq. 3) as a function of the maximum divide distance for each case in (a).

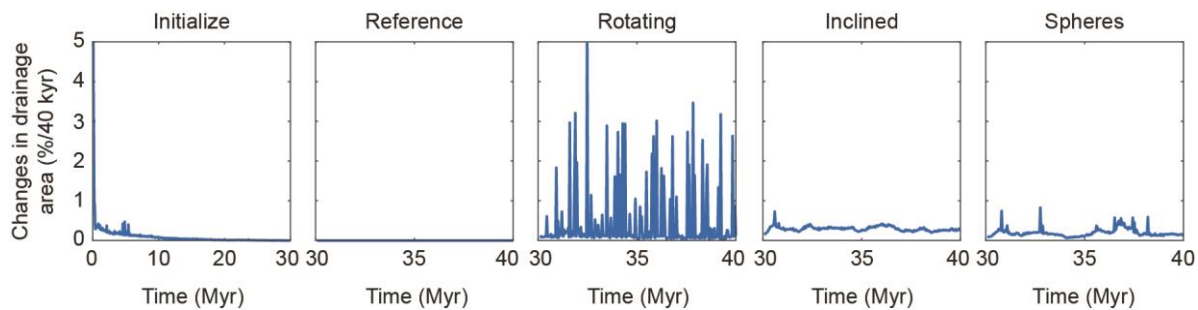

525

**Figure 4:** Modelled topography and drainage divide network (red solid lines) at the end of the landscape evolution experiments: (a) Reference, (b) Rotating, (c) Inclined, and (d) Spheres. White stippled lines show strike-slip fault in (b) and regions with reduced erodibility in (c) and (d).

530

**Figure 5:** Erosion rates and divide asymmetry index (DAI) at the end of the landscape evolution experiments: (a) Reference, (b) Rotating, (c) Inclined, and (d) Spheres. Black stippled lines show strike-slip fault in (b) and regions with reduced erodibility in (c) and (d).

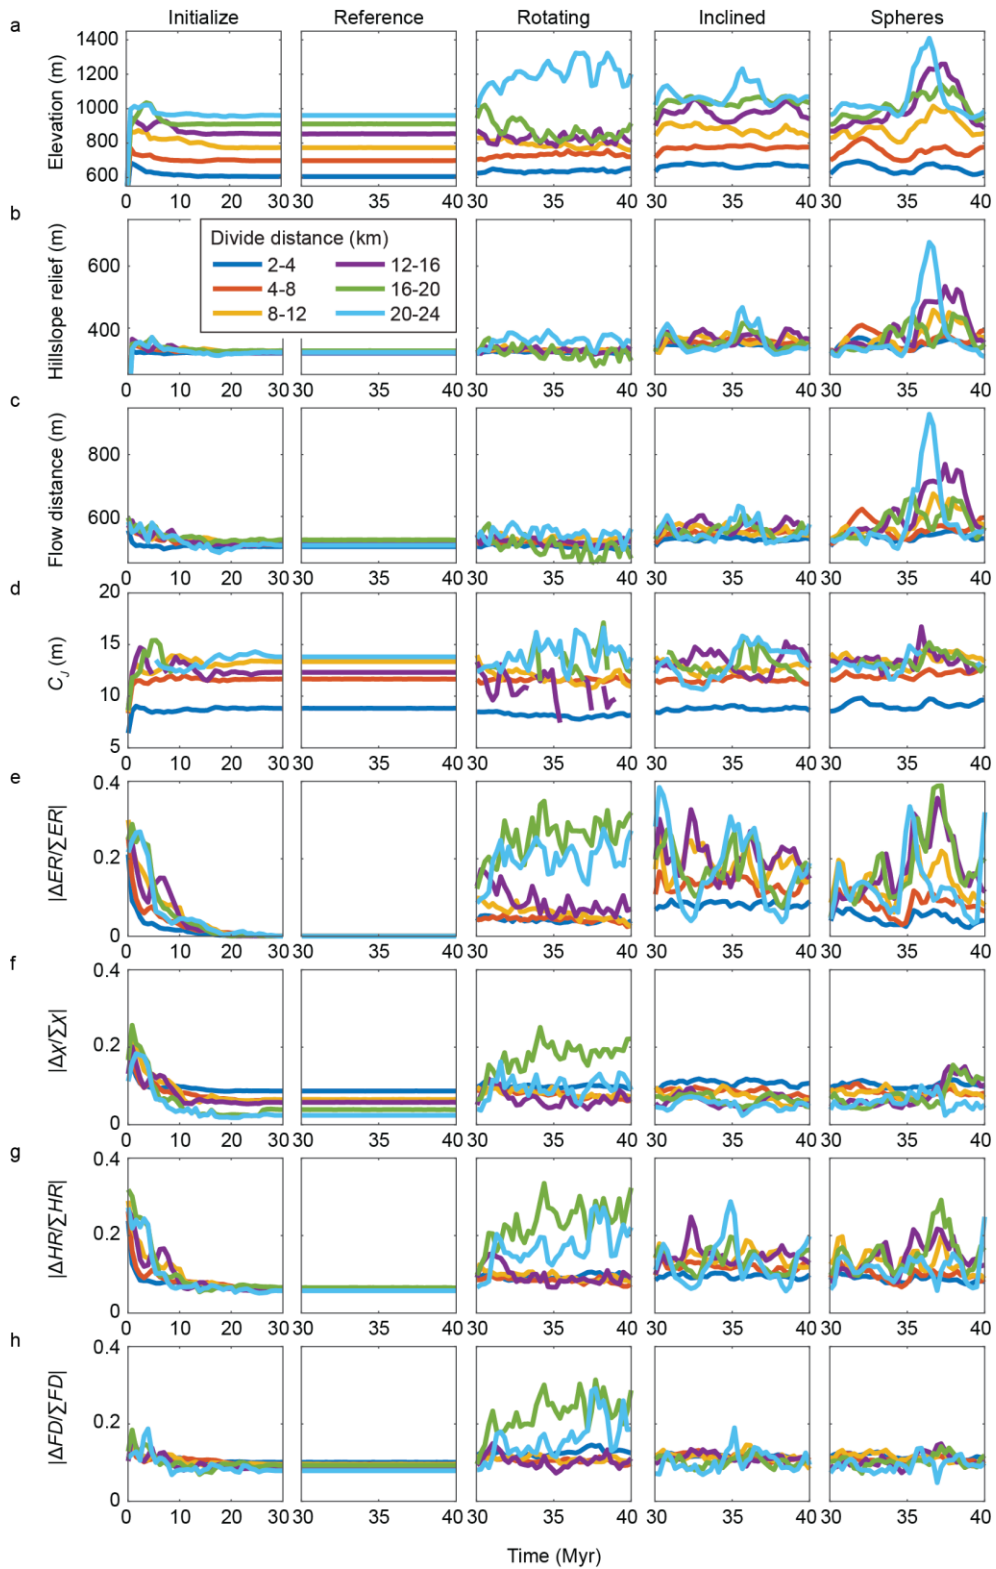

535 **Figure 6:** Changes in drainage area during the landscape evolution experiments. Y-axis unit is in percent per time step, which was 40 kyr.

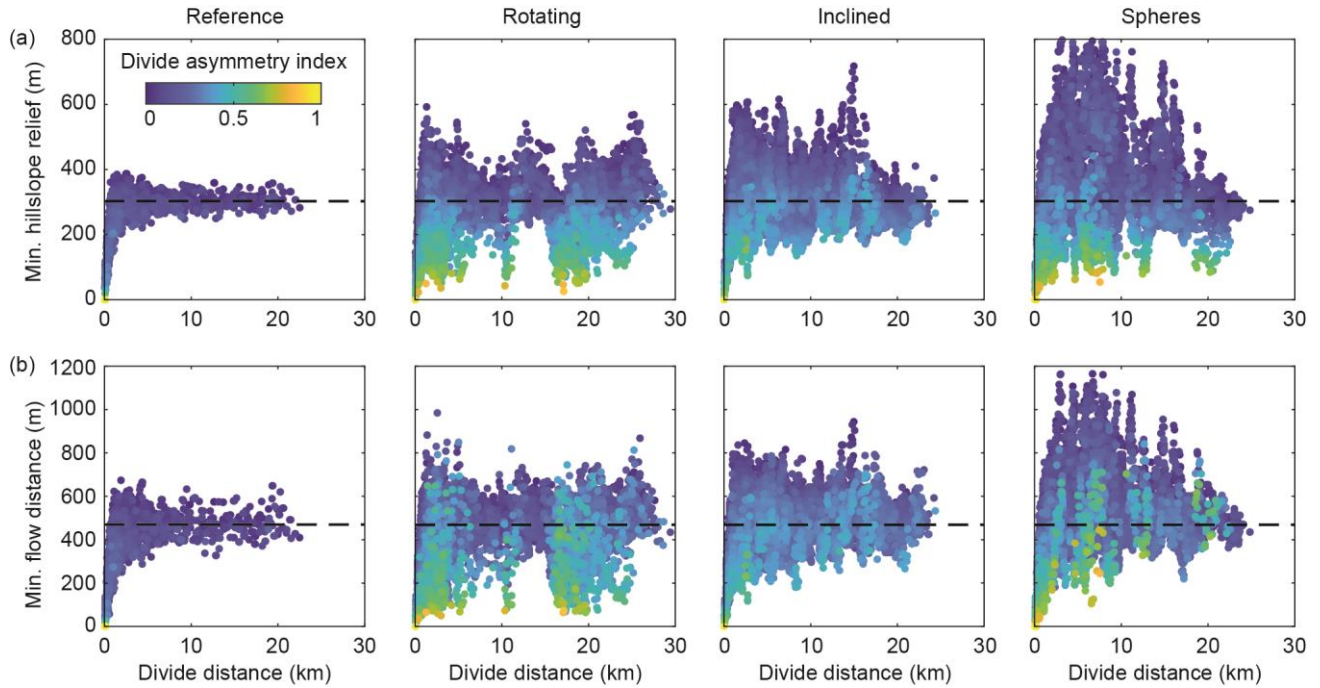

**Figure 7:** Changes in divide length for divides of different orders during the landscape evolution experiments. Divides have been ordered with the *Topo* ordering scheme.

540

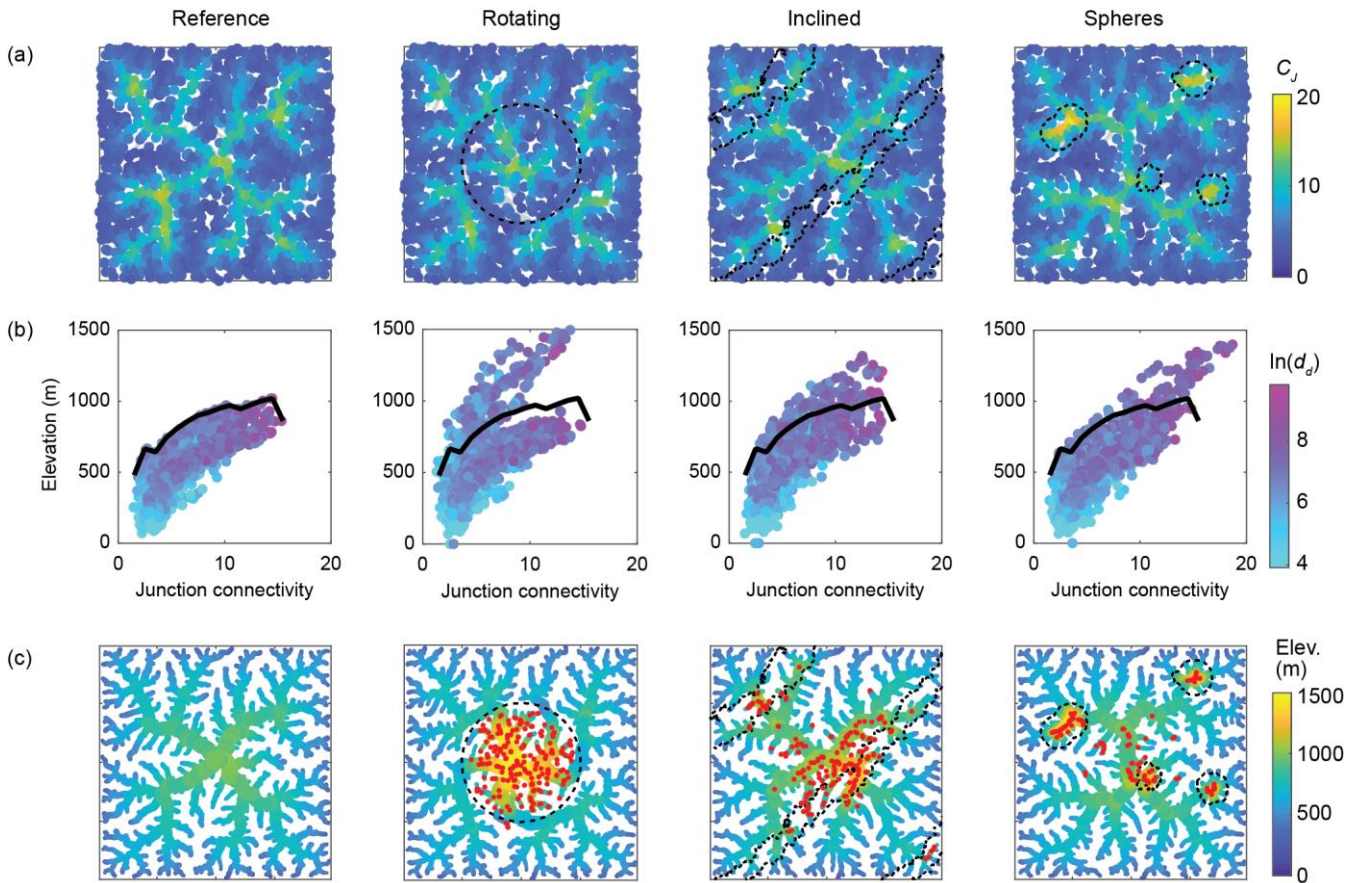

545 **Figure 8:** Temporal evolution of the drainage divide network during the landscape evolution experiments. Colored curves show mean values for divide segments at different divide distances. (a) Elevation. (b) Hillslope relief ( $HR$ ). (c) Flow distance ( $FD$ ). (d) Junction connectivity ( $C_j$ ). (e) Across-divide difference in erosion rate ( $|\Delta ER/\Sigma ER|$ ). (f) Across-divide difference in chi ( $|\Delta \chi/\Sigma \chi|$ ). (g) Across-divide difference in hillslope relief ( $|\Delta HR/\Sigma HR|$ ); which is equal to the divide asymmetry index ( $DAI$ ). (h)  $\rightarrow$  Across-divide difference in flow distance ( $|\Delta FD/\Sigma FD|$ ).

550 **Figure 9:** Minimum hillslope relief (a) and minimum flow distance (b) of all divide segments along the drainage divide network from the last 0.81 Myr of the landscape evolution experiments Reference, Rotating, Inclined, and Spheres. Colours denote the divide asymmetry index ( $DAI$ ). Black stippled line indicates the average values of minimum hillslope relief and minimum flow distance from the model Reference, measured between a divide distance of 10 and 20 km.

555 **Figure 10:** Divide junction connectivity ( $C_j$ ) from the final stage of the landscape evolution experiments Reference, Rotating, Inclined, and Spheres.  $C_j$  was calculated with a  $d_{d,max}$  value of 5000 m. (a) Map-view of divide junction  $C_j$  values. Black dashed lines indicate perturbation elements in the models. (b) Scatter plot of  $C_j$  by elevation, coloured by the natural logarithm of the divide distance ( $d_i$ ). Thick black dashed line follows upper boundary of indicates area occupied by divide junctions in the Reference model. (c) Drainage divide network coloured by elevation. Red dots correspond to junctions in the perturbed models that lie higher than the junctions in the Reference models.

560

**Figure 11:** Relationship between across-divide differences in the topographic metrics hillslope relief ( $HR$ ), chi ( $\chi$ ), and flow distance ( $FD$ ), with across-divide differences in erosion rates ( $ER$ ) for all divide edges in the last 2-1 Myr of the landscape evolution experiments Reference, Rotating, Inclined, and Spheres. Marker colour denotes the divide distance ( $d_d$ ). Note that the markers are sorted by their divide distance to show the highest divide distance above data points with lower divide distance, and that data points with lower divide distance occur beneath those with higher divide distance.

565

570 **Figure 12:** Coefficient of determination for linear regressions between normalized across-divide differences in different topographic metrics ( $HR$  = hillslope relief;  $FD$  = flow distance;  $\chi$  = chi) and normalized across-divide differences in erosion rates, as a function of drainage divide distance in the three perturbation models.
