Dear Wolfgang Schwanghart,

Thank you very much for the thoughtful critique of the manuscript. We have responded to the comments and updated the manuscript accordingly. For example, an additional section was created that includes limitations to our approach. We look forward to any additional comments or concerns.

97: I understand that MCSST only supports regression model of first-order polynomials. How does MCSST deal with more complicated surfaces, e.g. if the fault is located on a convex or concave slope? What about if the fault has experienced erosion? A diffusion-type process may lead to a more sigmoidal shape

of the scarp. How sensitive is your model to this? Moreover, you could have also chosen a segmented (or broken-stick) regression model instead of three separate linear models. Please discuss.

Thank you for your comment. We have added some of this text to the User Manual and to a new section, (as suggested by the review) 'Limitations of MCSST', prior to the conclusions.

Complicated surfaces – The MCSST approach should be used with caution or not used when the fault is located at the base of a concave or complex slope, as it requires markers that were originally parallel, and ideally demonstrated to be the same age.

Diffusion – In the farther field, there should be parallel markers regardless of how diffuse the scarp is. The workflow allows the user to select the farther field data if erosion has affected the scarp, thus we do not feel as though diffusion is a major issue with selecting the hanging wall and footwall features. However, selecting the scarp slope could be more challenging, as one will need to approximate the originally linear free face in amongst the now diffuse scarp. Our approach allows the trained the geologist to incorporate their best judgement. The scarp slope is important to get 'right', but a sensitivity analysis is outside the scope of introducing this toolbox.

A broken stick regression would incorporate additional, mathematically derived parameters into the model, whereas, a tri-linear model allows the trained geologist to manually identify these breakpoints. We feel as though this is a more accurate approach since the geologist who has done the surveying or work on the ground has better judgement than the mathematical model.

99: How does this improve compared to your previous method? Consider removing this statement.

Removed.

103: Please provide a different heading for this section (e.g. Visual interpretation and manual editing)

3

Done. Thank you for the suggestion.

106: How do you decide what is a good fit? Is this purely visual interpretation or is the user guided by some metric of goodness-of-fit?

The goodness of fit is determined by the user and is purely a visual interpretation. Features, such as erosion or 'roll-over' would require the use the fit specific segments of the profiles that may reduce a quantitative metric of fit, but nevertheless, be a better fit. "Visual interpretation" is added to the text of this section.

116: "commonly the case" is a bit unspecific

Phrase removed

126: "simply": Please avoid subjective statements.

Removed

132: Is "bootstrapping" the right term here? It seems to me that the parameter PDFs are just randomly sampled. Bootstrapping refers to the sampling of observations with replacement. Moreover, are the parameters independent from each other? Or do you actually need to deal with a multivariate PDF? Moreover, the Monte-Carlo approach might eventually lead to a Bayesian approach to modelling the uncertainties and including prior knowledge about fault geometries. Did you consider such an approach?

We have removed the word bootstrapping from the manuscript to avoid confusion. As you mentioned, the PDFs are randomly sampled through the Monte Carlo approach.

The parameters (e.g., geologic age, fault position, fault geometry, hanging wall geometry, footwall geometry, scarp geometry) are all independent. Thus, a multivariate PDF is not necessary. This would not be the case if a segmented regression was used.

4

We appreciate the concern that Monte Carlo may eventually lead to a Bayesian approach and agree that this may be something to consider in the future as additional field work is completed in the region (e.g., updating prior distributions with measurements from specific scarps studied in the case study). Since we do not have specific measurements for the input parameters (e.g., fault scarp intersection, fault angle, etc.), and instead rely on solely prior distributions supported by regional expert opinion, we are unable to currently complete a Bayesian approach where prior distributions are updated by observations to generate posterior distributions. In future studies outside the scope of this work, this could be an improvement to the workflow. Thank you!

140: What I don't understand is: How do you finally almagamate your results from the individual profiles (i.e., getting to the values in Line 186)? Is there such automated step?

In the case study here, we were interested in calculating the cumulative near-surface horizontal extension rate across the Taupo Volcanic Zone. Thus, we simply summed the values for each fault analyzed across our transect. This step is automated. The output table includes a 'cumulative' column that completes this step. We have included language in the manuscript to address this. Thanks for pointing out the confusion!

"The table also includes a column for cumulative statistics for each group of faults analyzed simultaneously. This was useful for automatically calculating the near-surface horizontal extension rate across the Taupo Volcanic Zone in our case study."

Done

165: attempted? or did you actually obtain data from as close ...

We did obtain the data from as close as possible. Changed to "obtained".

166: "This is one limitation of the MCSST". Remove this statement here and discuss it and the subsequent sentences in a short section (e.g. before the conclusions). If this is one limitation, what are the others?

Done.

"Limitations of MCSST

Scarp heights appear to vary along strike of the fault traces due to the complex nature of faulting in many geologic settings. This is one limitation of the MCSST. The user must define unique profiles along the fault scarp for each measurement and thus may not choose the position of maximum displacement, a location that can resolve the full 3D slip vector, or reveal the complex nature of displacement on the fault (Mackenzie and Elliot, 2017). Additionally, the MCSST approach should be used with caution or not used when the fault is located at the base of a concave or complex slope, as it requires markers that were originally parallel, and ideally demonstrated to be the same age. However, the approach allows the geologist to incorporate best judgement in selecting fault components, and may select far-field, linear features if erosion or diffusion is present at the scarp."

Abstract. Manual approaches for analyzing fault scarps in the field or with existing software can be tedious and time consuming. Here, we introduce an open source, semi-automated, Python-based graphical user interface (GUI) called the Monte Carlo Slip Statistics Toolkit (MCSST) for estimating dip slip on individual or bulk fault datasets that (1) makes the analysis of a large number of profiles much faster, (2) allows users with little or no coding skills to implement the necessary statis-

5 tical techniques, (3) and provides geologists a platform to incorporate their observations or expertise into the process. Using this toolkit, profiles are defined across fault scarps in high-resolution digital elevation models (DEMs) and then relevant fault scarp components are interactively identified (e.g., footwall, hanging wall, and scarp). Displacement statistics are calculated automatically using Monte Carlo simulation and can be conveniently visualized in Geographic Information Systems (GIS) for spatial analysis. Fault slip rates can also be calculated when ages of footwall and hanging wall surfaces are known, allowing for

10 temporal analysis. This method allows for analysis of tens to hundreds of faults in rapid succession within GIS and a Python coding environment. Application of this method may contribute to a wide range of regional and local earthquake geology studies with adequate high-resolution DEM coverage, both regional fault source characterization for seismic hazard and/or estimating geologic slip and strain rates, including creating long-term deformation maps. ArcGIS versions of these functions are available, as well as ones that utilize free, open source Quantum GIS (QGIS) and Jupyter Notebook Python software.

15 1   Introduction

The field of tectonic geomorphology is increasingly employing computer-based algorithms for displaying and analyzing digital topographic data (Whittaker et al., 2008; Kirby and Whipple, 2012; Zhou et al., 2015; Whipple et al., 2016). As a result, broad scale tectonic geomorphology toolboxes for automated high-level stream channel analysis and landscape evolution have been rapidly evolving (e.g., TopoToolbox, Topographic Analysis Kit (TAK), Stream Channel and Floodplain Metric Toolbox, etc.)

20 (Whipple et al., 2007; Schwanghart and Scherler, 2014; Hopkins et al., 2018; Forte and Whipple, 2019). Several relatively complete and distinct sets of computational tools and libraries also exist for completing an array of complex topographic and

fault zone analysis at the fault zone and outcrop scale [e.g., SPARTA, Structure-from-Motion, etc.] (Westoby et al., 2012; Bemis et al., 2014; Hodge et al., 2019], including those that attempt to resolve the full 3D slip vector (Mackenzie and Elliot, 2017).

25 These toolboxes are important because fault zones can be extraordinarily complex and require a method for systematically estimating net slip and slip rates across them (Fossen and Rotevatn, 2016). Where original landform geometries are known or can be inferred, fault scarp profiles from GPS surveys or transects across high-resolution digital elevation models (DEMs) can be used to characterize components of fault slip (DeLong et al., 2010; Spencer, 2010; Klimczak et al., 2018). The deformation within these fault zones can be spatially and temporally variable, thus motivating the analysis of large numbers of faults over

30 broad areas (Wallace, 1977; Avouac, 1993; Villamor and Berryman, 2001; Personius et al., 2017; Pérouse and Wernicke, 2017). In most cases, where along-strike variability in slip and/or slip rate are observed, multiple measurements from the same fault are required to delineate the slip history of one feature.

Light Detection and Ranging (LiDAR) can be used to identify submeter scale geomorphic features (Dong, 2015). Currently, this is done by analyzing individual profiles across fault scarps, manually picking fault components on distance vs. elevation plots,

35 calculating statistics and regressions for each, and then running unique analyses for each profile, which is both tedious and time consuming.

In this paper we introduce a new Python-based graphical user interface (GUI), the Monte Carlo Slip Statistics Toolkit (MCSST), that streamlines and improves on the approach for calculating slip statistics from fault scarps present in high-resolution digital elevation models (DEMs). We describe the basic functionality of MCSST and provide a representative example of the

40 potential utility of this approach for selecting and analyzing fault scarps across a 25 km-wide transect of distributed normal faulting. Using this approach, hundreds of profiles can be analyzed in a few hours, allowing for efficient analysis of spatial and temporal patterns of deformation. The methodology also allows for easy visualization of slip statistics on the original fault profiles in GIS so that spatial patterns of fault slip can be identified and anomalous values quickly identified and interrogated. A detailed user manual that lays out step-by-step usage of these tools and discusses how the underlying functions and algorithms 45 work is included as a supplement and within the code repository.

2 Background

The concept and mathematics behind using a Monte Carlo approach to calculating dip slips were developed by Thompson et al. (2002). The motivation behind using this approach is that it accounts for uncertainty in key parameters required for calculating slip from structural data and topographic profile (Fig. 1). Regression statistics are calculated for lines fit to each

9

50 of the hanging wall, scarp, and footwall. Each line has a mean value of slope and y-intercept, with 95 percent confidence intervals for each component, and can thus be modelled as a normal distribution. The fault dip can be modelled as any type of distribution depending on how well constrained the values are. For example, if fault dips can be measured in adjacent outcrops, it may be most appropriate to model the value as a normal distribution with a mean and 95 percent confidence interval; if dip is constrained only by regional fault geometry data, the user may choose a uniform or trapezoidal distribution to reflect the

55 additional epistemic uncertainty. In the simplest case, the only other parameter required to calculate dip slip is the location of the fault projected up to the scarp.

This approach has been widely used on dip slip faults around the world (Thompson et al., 2002; Amos et al., 2010; Rood et al., 2011; Stahl et al., 2016; Stahl and Niemi, 2017). Thompson et al. (2002) first used their method to quantify slip rate variability in a transect across the Tian Shan mountains of Kyrgyzstan. Amos et al. (2010) showed that it could be used

60 to identify previously unrecognized offsets along the Kern Canyon fault in east-central California, highlighting its role in accommodating internal deformation of the southern Sierra Nevada. Rood et al. (2011) analyzed a suite of geomorphic markers along the transition from the Sierra Nevada to the Eastern California Shear Zone-Walker Lane belt to reveal interactions among multiple faults. Stahl et al. (2016) used manually surveyed GPS profiles along the Fox Peak fault in New Zealand to demarcate segment boundaries based on slip rate. Stahl and Niemi (2017) compared manually surveyed fault scarps to geodetic estimates

65 of strain in the Sevier Desert, Utah to discern a local magmatic versus far-field tectonic extension regime along the Wasatch Front. The broad interest in calculating slip statistics from fault scarps around the world, and the increasing access to highresolution DEMs and powerful coding environments, motivates our development of a semi-automated toolkit for analyzing bulk fault datasets.

70 The primary goals of creating the MCSST are to: (1) lower the barrier to entry for scientists by limiting the required knowledge of coding languages or general programming techniques; (2) allow the user to check for consistency and accuracy in their interpretations of fault components (e.g., fault scarp, hanging wall, and footwall) before proceeding with the slip statistics calculations; (3) optimize the functionality of GIS environments by combining previously created plugins when possible; (4) introduce a methodology for efficiently analyzing numerous fault scarps and delineating distributions of spatial and temporal

75 patterns for slip statistics; and (5) provide open source software for those who do not have access to commercial products. We reference hanging wall and footwall throughout because this code was developed for use in a rift setting; however, upthrown and downthrown are equally viable terms considering the underlying math should be consistent for reverse faults as well.

MCSST was designed to leverage the power and broad code base of the open source QGIS plugin environment. It also utilizes the key data manipulation and visualization tools developed for comma-separated, value-file formats analyzed in the

Deleted: →3→Principles of design for MCSST¶

10

80 Jupyter Notebook Python coding environment. Free, open source applications, such as QGIS and Jupyter Notebook, provide increased access and functionality for scientific computing and displaying and analyzing spatial datasets. We also provide version compatible with ArcGIS.

3 Workflow

3.1 Define fault scarp profiles in QGIS or ArcGIS and extract data

85 The user first defines profiles across fault scarps imaged in high-resolution digital elevation models with UTM coordinates. Profiles are defined on a vertical plane normal to the structural trend of the fault. For each profile, distance and elevation (and optionally, geologic age) data are extracted at a user-defined spacing interval chosen to adequately resolves the vertical offset across the fault.

3.2 Monte Carlo Slip Statistics Toolkit (MCSST)

Automated methods of extracting fault scarp components have shown that mathematically identifying inflection points in a
90 profile is often not adequate (Gallant and Hutchinson, 1997; Hilley et al., 2010; Stewart et al., 2018; Hodge et al., 2019). Therefore, the input of a geologist is needed to analyze each fault scarp and our methodology makes this as easy as possible.

Within the Jupyter Notebook Python coding environment, the MCSST is used to analyze each profile. Profiles are loaded individually and then interactively displayed continuously to identify relevant fault scarp components (e.g., footwall, hanging wall, and scarp) (Fig. 2). To facilitate visual interaction with the data, a slider has been included to select the distance along the profile each
95 fault scarp component exists at (e.g., in Figure 2b the red line in Figure 2a was fit using the data selection shown in Figure 2b).

The choices are visualized in real-time as a regression line is automatically fit to the values within the modified data frame and displayed in the interactive plot (e.g., red line in Figure 2a fit to the footwall surface). The least squares linear regressions of these points in an x-y coordinate system determine the mean and standard error of both the slope and the intercept of the lines, which represent the hanging wall and footwall, where the tangent of the surface dip is the slope.

3.3 Visual interpretation and manual editing

Though potentially subject to bias, picking fault scarp components requires human input (Gillespie et al., 1992; Zielke et al., 2015; Middleton et al., 2016; Hodge et al., 2019). Therefore, it is vital that users check each fault scarp component for accuracy.
105 As shown in Figure 2a, selections are checked for accuracy by the user and updated, as necessary, by repeating the fault component selection step until a solution that fits the observations is obtained. If the user does not like a specific selection, the user can reselect data from the initial profile, and thus a new best fit least squares linear regression can be redefined for a surface and that data selection saved instead. Once the user has the desired representation for the fault scarp components,

Deleted: Step 3

it is saved by running the next code box. The user then loads in the next fault profile and repeats the fault component selection and visual quality check for each new profile. Data selections are saved as

110 a comma-separated file format, where different columns represent the separated data for the hanging wall, footwall, and scarp segments of the profiles. These data are saved together in a separate folder for organization and to be read by the MC Slip Statistics calculator.

3.4   Calculate slip statistics

Dip slip (assumed to be net slip in this instance), as well as horizontal and vertical displacement are calculated automatically

115 in this step (Thompson et al., 2002). The advantage of this step is that multiple transects, faults, and uncertainties in input parameters are analyzed simultaneously. If the hanging wall and footwall strain marker surfaces are not parallel, the dip slip calculation requires a knowledge of the position or projection of the fault tip onto the scarp. A line fit to the scarp face contains all possible points for the intersection of the fault tip and scarp. The amount of dip slip is then split into two parts: the distance from the footwall projection up to this point and the distance from the hanging wall down to this point.

120 Additional input parameters are first defined, including fault dip and intersection with the scarp distributions and geologic age distributions, if available (Fig. 1). Fault dip and uncertainty therein are determined through direct measurement from outcrops, nearby paleoseismic trenches, or by estimating from geomorphic expression. A range of probability density functions (PDFs) can be assigned for fault dip as well as uncertainty of where the fault projects onto the scarp. For example, in our case study below, we chose a trapezoidal distribution for fault dip centered around the most probable dip values and a uniform distribution

125 for the geologic age since only a minimum and maximum age are given for surfaces. Normal distributions for both parameters could have also been chosen. The user would signify this option (see the User Manual, which is included as a supplement to the manuscript). If the user was interested in defining separate input values for different combinations of fault scarps, the user would manually define these values for each iteration and run the code more than once.

The code calculates the net dip-slip component, as well as the vertical separation and horizontal extension, as stated above.

130 Geologic age data can be used to define an age distribution for the geologic surface in question and thus slip rates can be conveniently calculated.

The Monte Carlo approach to calculating slip statistics relies on repeated random samples from the PDFs of the input parameters to obtain numerical results and generate histograms with 95 percent confidence intervals for the slip statistics from multiple uncertain estimations.

135 Plots of slip distributions for each fault profile are displayed as output, so the user can easily visually analyze for anomalies in the dataset (Fig. 3). Lastly, the script outputs a CSV file for each group of faults analyzed simultaneously. This can be useful if the user wants to categorize data based on spatial or temporal differences; this was useful in determining displacements on different geologic surfaces, corresponding to different geologic ages, separately. The table also includes a column for

Deleted: Steps 3 and 4

Deleted: 4

cumulative statistics for each group of faults analyzed simultaneously. This was useful for automatically calculating the near-surface horizontal extension rate across the Taupo Volcanic Zone in our case study.

4   Display data in GIS

140 The data calculated in the previous step can be added to the original shapefile layer to allow for spatial analysis. As outlined in the user manual, the QGIS software allows for seamless 'joining' of the CSV file with the original fault scarp profile shapefile layer. When using the ArcGIS software, the ArcGIS tool developed in this study, 'attachStats2Profiles', and its Python standalone version can also complete this task.

5   Case study – Taupo Volcanic Zone (TVZ), NZ

145 The Taupo Volcanic Zone (TVZ), in the central North Island of New Zealand, is a northeast-southwest trending, 250-km long, 14 to 40-km wide active rift (Wilson et al., 1995; Wallace et al., 2004; Seebeck et al., 2014). Extension across the TVZ over the last 1.6 Myr is expressed primarily as regional volcanism, extensional fractures, and northeast-southwest trending normal faults (Pilar Villamor et al., 2017).

The TVZ represents the ideal case study area to test our methodology because the Quaternary geology of the region has 150 been extensively studied through detailed mapping of geological units and active fault locations. The regional kinematics and near-surface geometry of faults are known and contribute to one of the best paleoseismic data sets in the world and results from which we can compare our findings (Villamor and Berryman, 2001). Many fault scarps are clearly imaged to offset a relatively planar geologic horizon which is easily correlated and has been mapped across the relatively narrow tectonic province.

Additionally, many high-resolution datasets exist (e.g., the QMAP Geological Map of New Zealand Project, LiDAR-based 155 DEM of 1-meter horizontal resolution, and regional active fault map) [GNS Science, Leonard et al., 2010, Villamor et al., 2010] (Fig. 4).

We analyzed fault surface displacements on the Earthquake Flat Formation ignimbrite of the Okataina Group (Nairn, 2002), a volcanic formation of pyroclastic material, lapilli, and ash, which has been dated to 60-62 ka (Wilson et al., 2007). The constructional surface of the ignimbrite is well-preserved and represents a previously continuous, sub-horizontal, planar feature, 160 which has displaced by normal faults in the TVZ.

Here, we applied the methodology for the QGIS-based tool to a transect across the Central TVZ. By choosing to analyze fault displacements of a single age surface we can determine the deformation rates across the region occupied by the surface for the time period represented by the surface chosen. In this case the Earthquake Flat ignimbrite covers practically the entire width of the active rift (only a couple of moderately high scarps on the western margin of the rift do not displace 165 the ignimbrite). We obtained data from as close to the transect line as possible because scarp heights appear to vary along strike of the fault traces due to the complex nature of faulting in the TVZ.

13

170 We analyzed 33 faults in a 25-km transect from northwest to southeast in the direction of regional extension. We chose faults with significant offset (>5 m) because smaller faults contribute insignificantly to the overall extension of the region and often represent splays of the larger faults. Thus, because of the filtering small scarps and two missing moderately high-relief scarps on the west of the transect in this study, we report a minimum extension rate for the Central TVZ below.

For each fault, we identified the key fault components (e.g., fault scarp, hanging wall, and footwall) and determined slip

175 estimates using MCSST. For our fault geometry distribution, we chose a trapezoidal distribution, centered around 70-80 degrees in dip. This is consistent with data obtained from geological observations in trenches and superficial exposures within 40 meters from the ground surface (Grindley 1959; Villamor and Berryman, 2001; Lamarche et al., 2006; Villamor et al., 2010, 2017).

The dip slip values obtained for each fault were in line with reasonable estimates based on extensive experience conducting field campaigns in the region (e.g., altimeter measurements along transects and detailed logging of faults in exploratory

180 trenches) and visual inspection of the digital elevation model (Villamor and Berryman, 2001; Villamor et al., 2010; P. Villamor et al., 2017). Further, the values plotted in Figure 3 are consistent with visual inspection of the distance vs. elevation profile (this study). We used recently derived age constraints on the Earthquake Flat Formation to convert these values into dip slip rates.

MCSST automatically converts dip slip rate estimates into horizontal extension rate values by using a trigonometric relation185 ship defined by the fault angle distribution we input. This resulted in a minimum cumulative near-surface horizontal extension rate of 2.77 mm yr^{-1} (± 0.69 mm yr^{-1}) summed across the mean net slip rate value for all faults along the transect. The minimum cumulative near-surface horizontal extension rate when summed across the median net slip rate values for all faults along the transect is 2.73 mm yr^{-1} with a 95 percent confidence interval of 0.56-5.26 mm yr^{-1}.

This is similar to the values provided by the current best-estimate of Quaternary extension rates derived from fault data of:

190 2.4 mm yr^{-1} (± 0.4 mm yr^{-1}) for the Central TVZ (Villamor and Berryman, 2001) and only 8 km southwest of this study's transect; 2.9 mm yr^{-1} (± 0.74 mm yr^{-1}) for the Northern TVZ immediately offshore (Lamarche et al., 2006); and 2.7 mm yr^{-1} (± 0.3 mm yr^{-1}) for the Southern TVZ at the Tongariro Volcano latitude (Gomez-Vasconcelos, 2017).

Note that near-surface fault derived extension rates along the TVZ have been converted to higher (more realistic) total extension rates (from 4 to 15 mm yr^{-1} from south to north) in the various studies by applying correction factors that include

195 shallower fault dips and larger fault slips at depth, and contribution from small to moderate earthquakes (small faults that do not rupture the surface) (see Villamor and Berryman, 2001 for method). The differences in fault-derived total extension rate from south to north are mainly dependent on the average "deep" fault dip value chosen (60 degrees for Southern and Central TVZ and 45 degrees for Northern TVZ), which remains one of the largest uncertainties for the TVZ faults. Geodetic derived extension rates show a clear extension rate increase from north to south (Wallace et al., 2004).

14

200 6   Efficiency of MCSST

The utility of MCSST is best demonstrated by the efficiency with which this study was conducted and the agreement with the current geological understanding of the Central TVZ. Once our methodology was defined and the workflow implemented, the analysis of the transect (33 faults across 25 km) was completed in one day at a work station. We note that installing and running the Python code packages, navigating the GIS software, and inputting parameters and gaining comfort with the interface for

205 the Jupyter Notebook pose the greatest challenges to employing the MCSST toolkit, so we provide a detailed user manual to accompany the manuscript to lower the barrier of entry.

7 Limitations of MCSST

Scarp heights appear to vary along strike of the fault traces due to the complex nature of faulting in many geologic settings. This is one limitation of the MCSST. The user must define unique profiles along the fault scarp for each measurement and thus may not choose the position of maximum displacement, a location that can resolve the full 3D slip vector, or reveal the complex nature of displacement on the fault (Mackenzie and Elliot, 2017). Additionally, the MCSST approach should be used with caution or not used when the fault is located at the base of a concave or complex slope, as it requires markers that were originally parallel, and ideally demonstrated to be the same age. However, the approach allows the geologist to incorporate best judgement in selecting fault components, and may select far-field, linear features if erosion or diffusion is present at the scarp.

8   Conclusions

The Monte Carlo Slip Statistics Toolkit (MCSST) allows users to quickly and accurately estimate fault slip across several faults imaged in DEMs. This approach improves upon similar studies because it allows for rapid analysis of tens to hundreds
210 of faults simultaneously within GIS, and anomalous values can quickly be identified. The underlying functions are built upon open-source Python code base and are specifically designed to lower the bar of entry for researchers wishing to include robust, quantitative fault scarp analysis in their work or teaching.

Application of this method may contribute to a wide range of regional and local paleoseismic studies with adequate highresolution DEM coverage, both regional fault source characterization for seismic hazard and/or estimating geologic slip and

215 strain rates. In our case study, initial estimates for minimum near-surface extension rates along a northwest to southeast transect (33 faults; 25 km) across the Taupo Volcanic Zone are in line with the current paleoseismological and

15

tephrochonological understanding of the region and provide useful constraints on the uncertainty associated with these values (Villamor and Berryman, 2001).

Figure 1. Slip statistics inputs. A schematic of inputs into the Monte Carlo Slip Statistics code, which include uncertainty in intercept, slope, fault dip, fault position on scarp, and the age of the geologic surface in question. For surface age, a uniform distribution is shown; however, the user could define a normal or trapezoidal distribution as well.

Figure 2. The general workflow. a) A user-defined profile drawn perpendicular to the strike of a mapped fault. For location of this feature, see Figure 4. The red, blue, and black lines represent linear least square fits to the footwall, hanging wall, and scarp of a normal fault, respectively. The purple line is a representation of the geometry of a fault responsible for this scarp. b) Sliders can be used within the data frame manipulation tool to select data points to represent each relevant component of the fault scarp (e.g., hanging wall, footwall, and scarp). Initially, the red line is fit to all the data in the profile. By using the sliders, you can select a subset of the data as shown in (a) for the generation of the red line. Once data points are selected, the user can visualize the choices for fault component selection before moving forward and calculating slip statistics for the fault in the same Jupyter Notebook environment. The red, blue, and black lines in (a) are generated through this method.

Figure 3. The slip statistics results from the fault scarp visualized in Figure 2 and with location shown in Figure 4.

Figure 4. Taupo Volcanic Zone Case Study. Base images of (a), (b), and (c) are LiDAR hillshade maps of the North Island and Taupo Volcanic Zone, New Zealand. a) Tectonic features of New Zealand where the green box represents the enlarged image in (b). The red fault traces are from the New Zealand Active Faults Database (NZAFD). Active faults have deformed the ground surface of New Zealand within the last 125,000 years. The blue arrow and rate represents geologic extension rates from geodetic and Quaternary fault data (P. Villamor et al., 2017). The yellow line represents the Case Study Transect. b) Fault scarp profiles used in this case study are shown in blue and across the northwest-southeast transect shown in yellow. Mapped faults in the region are shown in red (NZAFD). For simplicity, only the Earthquake Flat Formation of the Okataina Group outcrops is shown from the Geologic Map of New Zealand Project (GMAP). This is the formation that was analyzed in this study. The light blue box represents the map extent of part (c). c) LiDAR hillshade map of the location of the profile shown in Figure 2 and analyzed in Figure 3.
