Abstract. Several studies have demonstrated the importance of alluvial cover; furthermore, several mathematical models have also been introduced to mimic the alluvial cover in bedrock channels. Here, we provide an extensive review of research exploring the relationship between alluvial cover, sediment supply and bed topography of bedrock channels, describing various mathematical models used to analyse deposition of alluvium. To test one-dimensional theoretical models, we performed a series of laboratory-scale experiments with varying bed roughness under simple conditions without bar formation. Our experiments show that alluvial cover is not merely governed by increasing sediment supply, and that bed roughness is an important controlling factor of alluvial cover. A comparison between the experimental results and the five theoretical models shows that: (1) two simple models that calculate alluvial cover as a linear or exponential function of the ratio of sediment supply to capacity, produce good results for rough bedrock beds but not for smoother bedrock beds; (2) two roughness models which include changes in roughness with alluviation and a model including the probability of sediment accumulation can accurately predict alluvial cover in both rough and smooth beds; (3) however, except for a model using the observed hydraulic roughness, it is necessary to adjust model parameters even in a straight channel without bars.

1 Introduction

Economic growth worldwide has fuelled the demand for the construction of straightened river channels, sabo dams, the collection of gravel samples for various research, etc., leading to a decline in sediment availability and alluvial bed cover. Sumner et al. (2019) reported that the straightening of the Yubari River, which was carried out to improve the drainage of farmland, caused the bedrock to be exposed and the knickpoint to migrate upstream. Also, construction of a dam in the upstream section of Toyohira river in Hokkaido – Japan, decreased the sediment availability to the downstream section contributing to the formation of a knickpoint (Yamaguchi et al. 2017). Sediment availability plays a very important role in controlling landscape evolution and determining the morphology of rivers over geologic time (Moore 1926; Shepherd 1972), and has two contradicting effects on bedrock-bed, known as Tools and Cover effect (Gilbert, 1877; Sklar and Dietrich, 1998). It acts as a tool by increasing the number of impacting-particles and erodes the bedrock bed, known as tools effect. As sediment availability increases, the sediment starts settling down on the river bed providing a cover for the bed underneath from further erosion, known as the cover effect. In the last 20 years, various field-scale (Turowski et al., 2008b; Turowski and Rickenmann, 2009; Johnson et al., 2010; Jansen et al., 2011; Hobley et al., 2011; Cook et al., 2013; Inoue et al., 2014; Beer and Turowski, 2015; Beer et al., 2017), laboratory-scale (Sklar and Dietrich, 2001; Chatanantavet and Parker, 2008; Finnegan et al., 2007; Johnson and Whipple, 2007, 2010; Hodge and Hoey, 2016a, 2016b; Hodge et al., 2016; Turowski and Bloem, 2016; Inoue et al., 2017b; Mishra et al., 2018; Fernandez et al., 2019; Inoue and Nelson, 2020), and theoretical and numerical studies (Hancock and Anderson, 2002; Sklar and Dietrich, 2004, 2006; Lague, 2010; Nelson and Seminara, 2011, 2012; Johnson, 2014; Nelson et al., 2014; Zhang et al., 2015; Inoue et al. 2016, 2017a; Turowski and Hodge 2017; Turowski, 2018) have been performed for revealing the effects of tools and cover on bedrock erosion and erosional morphology.

Sediment availability strongly affects vertical bedrock incision including knickpoint propagation. Reach scale studies at the Erlenbach performed by Turowski et al. (2013) showed how extreme flood events can contribute to incision by ripping off the

channel's alluvial cover. Yanites et al. (2011) studied the changes in the Peikang River in central Taiwan triggered by the thick sediment cover introduced by landslides and typhoons during the 1999 Chi-Chi earthquake. Their results show slowed or no incision in high transport capacity and low transport capacity channels. Cook et al. (2013) suggested that rapid knickpoint propagation are dominantly controlled by the availability of bedload. Their field surveys of bedrock gorge cut by Daán River in Taiwan showed that the channel bed did not erode in the absence of coarse bedload, despite floods and available suspended sediment. Izumi et al. (2016) showed that sediment transport and bedrock abrasion lead to the formation of cyclic steps, and Scheingross et al. (2019) suggested that undulating bedforms like cyclic steps grow to become waterfalls and knickpoints. Sediment availability also controls the width of bedrock channel. Finnegan et al. (2007) conducted laboratory-scale experiments and studied the interdependence between incision, bed roughness and alluvial cover. Their results indicated that alluvial deposition on the bed shifted bedrock erosion to higher regions of the channel or bank of the channel, and suggested that the sediment supply rate controls the thalweg width of bedrock channel. Similar findings were noted in flume studies conducted by Johnson and Whipple (2010). They have shown the importance of alluvial cover in regulating the roughness of the bedrock bed by providing a cover for the local lows and thereby inhibiting the erosion and focusing erosion on local highs. Field observations also show that channels with higher sediment supply to capacity ratio are expected to be wider as alluvial cover shifts erosion from bed to banks of the channel (Beer et al. 2016; Turowski et al., 2008a and Whitbread et al., 2015). Inoue et al. (2016) and Inoue and Nelson (2020) showed the formation of several longitudinal grooves at low sediment supply to capacity ratio. As the sediment supply increases, one of the grooves attracts more sediment supply and progresses into a comparatively straight, wide and shallow inner channel which further progresses into a more sinuous, deeper inner channel (Wohl and Ikeda, 1997; Shepherd and Schumm, 1974).

Some studies have credited the seasonally and climatically driven higher sediment supplies during floods to be the driving force for bedrock meander and strath terrace formation (De Vecchio et al., 2012; Hancock & Anderson, 2002). Periods of higher sediment supply promote lateral erosion and strath terrace formation, whereas periods of lower sediment supply lead to vertical erosion and steep slip-off slopes (e.g., Fuller et al. 2009; Inoue et al., 2017a). Mishra et al. (2018) showed that in the bend, lateral abrasion followed a monotonically increasing linear relationship with sediment feed rate. Fuller et al. (2016) performed laboratory-scale experiments and established the importance of bed-roughness in determining lateral erosion rates because high roughness scatters the direction of bedload transport, increasing the frequency with which it collides with the wall.

There have been advances in theoretical and numerical methods mimicking, reproducing and predicting the morphodynamics of laboratory scale and field-scale observations. A majority of traditional bed-erosion models are classified as the stream power and shear stress family of models (cf. Shobe et al., 2017; Turowski, 2018) (e.g., Howard, 1994; Whipple and Tucker, 1999), in which bed erosion is a function of discharge and bed-slope. These models, however, cannot describe the role of sediment in controlling the bed dynamics. Several models remedy this shortcoming by considering the tools and cover effect of sediment supply (Sklar and Dietrich, 1998, 2004; Turowski et al., 2007; Chatanantavet and Parker, 2009; Hobley et al., 2011; Inoue et al., 2017a, 2017b; Shobe et al., 2017;).

Predicting tools and cover effect is essential for better understanding the bedrock landscape evolution. In this study, we review the advances of alluvial cover models in the past two decades and test several major models. In section 1.1, we introduce previous theoretical and numerical models that take into account sediment cover in bedrock channel. In sections 1.2 to 1.6, we describe in detail the governing equations of the five models dealt with in this study.

1.1 Previous Models for Sediment Cover

The sediment cover models predict cover from taking into account factors like sediment flux, roughness, discharge, grain size, etc. One of the simplest and first models to incorporate effects of sediment availability and transport capacity of the channel was introduced by Sklar and Dietrich (1998; 2004). According to the saltation-abrasion model proposed by Sklar and Dietrich

(1998; 2004), the alluvial cover P_c increases linearly with the ratio of sediment supply to sediment transport capacity q_{bs}/q_{bc} . In contrast, Turowski et al. (2007) proposed a model that considered the cover effect as an exponential function of the ratio of sediment flux to sediment transport capacity. The model uses a probabilistic argument i.e. when sediment supply is less than the capacity of the channel, grains have an equal probability of settling down over any part of the bed. Also, the deposited grains can be static or mobile.

The erosion formula including the above model was able to reproduce the relationship between the sediment mass and the erosion rate observed in the rotary-abrasion mill experiment performed by Sklar and Dietrich (2001). However, subsequent experiments using straight channel pointed out a phenomenon that cannot be reproduced by the above models. Chatanantavet and Parker (2008) conducted laboratory-scale experiments in straight concrete bedrock channels with varying bedrock roughness and evaluated bedrock exposure with respect to sediment availability. In their experiments, alluvial cover increased linearly with increasing sediment supply in case of higher bed roughness, whereas in case of lower bed roughness and higher slopes, the bed shifted abruptly from being completely exposed to being completely covered. This process of the bedrock bed suddenly becoming completely alluvial from being completely exposed is known as rapid alluviation. Rapid alluviation was also observed in the laboratory scale experiment conducted by Hodge and Hoey (2016a; 2016b) in a 3D printed flume of natural stream Trout Beck, North Pennines-U.K. Their first set of experiments focused on quantifying hydraulic change with varying discharge, suggesting that hydraulic properties fluctuate more during higher discharge. Their second set of experiments (Hodge and Hoey, 2016b) concentrated on quantifying the sediment dynamics for varying discharge and sediment supply. They supplied 4 kg and 8 kg sediment pulse to the channel and observed a similar alluvial pattern in both cases suggesting that the deposition of sediment on the bed may not only depend on the amount of sediment supplied but may be strongly influenced by the bed topography and roughness. Inoue et al. (2014) conducted experiments by excavating a channel into natural bedrocks in Ishikari River, Asahikawa, Hokkaido – Japan. They conducted experiments with different combinations of flow discharge, sediment supply rate, grain size and roughness. Their experiments advocated that the dimensionless critical shear stress for sediment movement on bedrock is related to the roughness of the channel. Their experiments also showed that in the case when the alluvial cover is smoother than the bedrock, with an increase in alluvial cover, the hydraulic roughness in a mixed bedrock – alluvial bed decreases.

Besides, the simple models described above cannot capture the sediment mass in a channel that changes due to sediment supply and runoff because they do not conserve sediment mass. Lague (2010) employed the Exner equation to calculate alluvial thickness with respect to average grain size d . Their model, however, lacks the tools effect for bed erosion. Recently, Johnson (2014) and Inoue et al. (2014) proposed reach-scale physically-based models that encompass the effects of bed roughness in addition to mass conservation. Inoue et al. (2014) also conceptualised ‘Clast Rough’ and ‘Clast Smooth’ bedrock surfaces. A bedrock surface is clast-rough when bedrock hydraulic roughness is greater than the alluvial bed hydraulic roughness (supplied sediment), otherwise, a surface is clast-smooth i.e. when the bedrock roughness is lower than the alluvial roughness. Inoue et al. (2014) and Johnson (2014) clarified that the areal fraction of alluvial cover exhibits a hysteresis with respect to the sediment supply and transport ratio in a clast smooth bedrock channel. They described that along with rapid alluviation, perturbations in sediment supply can also lead to rapid entrainment. Whether the bed undergoes rapid alluviation or rapid entrainment is determined by the bed condition when perturbations in sediment supply occur. If the perturbations occur on an exposed bed, it undergoes rapid alluviation, conversely, when perturbations happen on an alluviated bed, it undergoes rapid entrainment. Zhang et al. (2015) proposed a macro-roughness saltation-abrasion model (MRSA) in which cover is a function of alluvial thickness and macro-roughness height. Nelson and Seminara (2012) proposed a linear stability analysis model for the formation of alternate bars on bedrock bed. Inoue et al. (2016) expanded Inoue et al. (2014) to allow variations in the depth and width of alluvial thickness in the channel cross-section. They further modified the numerical model (Inoue et al., 2017a) and implemented the model to observe changes in a meander bend.

Turowski and Hodge (2017) generalized the arguments presented by Turowski et al. (2007) and Turowski (2009) and proposed a reach-scale probability-based model that can deal with the evolution of cover residing on the bed and the exposed bedrock.

125 Turowski (2018) proposed a model and linked the availability of cover in regulating the sinuosity of the channel. Shobe et al. (2017) proposed The SPACE 1.0 model for the simultaneous evolution of an alluvium layer and a bedrock bed. These models utilise the entrainment/deposition flux for sediment mass conservation.

Hodge and Hoey (2012) introduced a reach-scale Cellular Automaton Model that assigned an entrainment probability to each grain. The assigned probability of each grain was decided by the number of neighbouring cells containing a grain. If five or

130 more of total eight neighbouring cells contained grain, the grain was considered to be a part of the cover, otherwise, it was considered an isolated grain. They suggested that rapid alluviation occurred only in cases when isolated grains were more than the cover on the bed. Also, they advised a sigmoidal relationship between q_{bs}/q_{bc} and $1 - P_c$. Aubert et al. (2016) proposed a Discrete-Element Model where they determined P_c from the velocity distribution of the grains. If the velocity of a grain is $1/10^{\text{th}}$ or lower than the maximum velocity, the grain settles as cover on the bedrock surface. The model, however, cannot deal

135 with non-uniform velocity fields and hence cannot predict results for varying alluvial cover.

Except for the Lagrangian description models that track individual particles (i.e., Hodge and Hoey, 2012; Aubert et al., 2016), the Eulerian description models are roughly classified into four categories; the linear model proposed by Sklar and Dietrich (1998, 2004), the exponential model proposed by Turowski et al. (2007), the roughness models proposed by Nelson and Seminara (2012), Inoue et al. (2014), Johnson (2014), Zhang et al. (2015) and the probabilistic model proposed by Turowski

140 and Hodge (2017). In this study, we focus on a detailed study of the similarities and differences among the Eulerian description models proposed by Sklar and Dietrich (2004), Turowski et al. (2007), Inoue et al. (2014), Johnson (2014) and Turowski and Hodge (2017). These one-dimensional models have already been compared to experiment with bars (Chatanantavet and Parker, 2008) and experiments with irregular roughness arrangement (Hodge and Hoey, 2016a, 2016b; Inoue et al., 2014), but a test in one-dimensional flow fields has not been performed. In this study, we compare the efficacy of these models from

145 comparisons with our experimental results without bars with relatively regular roughness distribution. In addition, we apply the roughness models (Inoue et al., 2014; Johnson, 2014) to the experiments conducted by Chatanantavet and Parker (2008) in order to discuss the effect of bar formation on alluvial cover in a mixed bedrock - alluvial river.

1.2 Linear Model

150 When the sediment supply is larger than the transport capacity, the bedrock eventually becomes completely covered by alluvial material and the alluvial cover ratio P_c is equal to 1. If there is no sediment supply, the sediment deposit disappears and eventually, the bedrock bed becomes completely exposed and P_c is equal to 0. Sklar and Dietrich (2004) linearly connected these two situations, and proposed a linear model to include the cover effect in their saltation – abrasion model;

$$P_c = \begin{cases} q_{bs}/q_{bc} & \text{for } 0 \leq q_{bs}/q_{bc} \leq 1 \\ 1 & \text{for } q_{bs}/q_{bc} > 1 \end{cases} \quad (1)$$

155 where, P_c is the mean areal fraction of alluvial cover, q_{bs} and q_{bc} are the volume sediment supply rate per unit width and transport capacity, respectively.

1.3 Exponential Model

When the dimensionless mass of sediment on the bed M_s^* is increased by a small amount dM_s^* , a fraction of this amount will

160 fall on exposed bedrock and cover it. Hence, $d(1 - P_c) = -\phi dM_s^*$, where, ϕ is a dimensionless cover factor parameter and determines sediment deposition on covered areas for $\phi < 1$ and deposition on uncovered areas for $\phi > 1$. Integration gives

$P_c = 1 - \exp(-\varphi M_s^*)$. Turowski (2007) assumed that the M_s^* is equal to the ratio of sediment supply to capacity, and derived the following exponential model using a probabilistic argument;

$$P_c = 1 - \exp\left(-\varphi \frac{q_{bs}}{q_{bc}}\right) \quad (2)$$

165

1.4 Macro Roughness Model

The experimental results of Inoue et al. (2014) motivated their mathematical model formulating the interaction between alluvial cover, dimensionless critical shear stress, transport capacity and the ratio of bedrock hydraulic roughness to alluvial hydraulic roughness. They calculated the total hydraulic roughness height (k_s) as a function of alluvial cover:

$$k_s = \begin{cases} (1 - P_c)k_{sb} + (P_c)k_{sa} & \text{for } 0 \leq P_c \leq 1 \\ k_{sa} & \text{for } P_c > 1 \end{cases} \quad (3)$$

where k_s is the total hydraulic roughness height of bedrock channel, P_c is the cover fraction calculated as proposed by Parker et al. (2013) that depends on the ratio η_a/L where η_a is the alluvial cover thickness and L is the bedrock macro-roughness height (i.e. topographic unevenness of the bed). k_{sb} and k_{sa} ($= 1 \sim 4$ d, here set to 2) represent the hydraulic roughness height of bedrock and alluvial bed respectively. The total transport capacity per unit width q_{bc} in Inoue et al.'s model is calculated as

175 follows:

$$q_{bc} = \alpha(\tau_* - \tau_{*c})^{1.5} \sqrt{Rgd^3} \quad (4)$$

$$\tau_{*c} = 0.027(k_s/d)^{0.75} \quad (5)$$

where α is a bedload transport coefficient taken as 2.66 in this study, τ_* and τ_{*c} are the dimensionless shear stress and dimensionless critical shear stress, R is the specific gravity of the sediment in water (1.65), g is the gravitational acceleration and d is the particle size. In this model, P_c is back-calculated from Equations (3), (4) and (5) under the assumption that the sediment supply rate q_{bs} and the sediment transport capacity q_{bc} are balanced in a dynamic equilibrium state (i.e., $\partial\eta_a/\partial t = 0$ in Exner's mass conservation equation).

180

The sensitivity analysis of bedrock roughness and sediment supply rate conducted by Inoue et al. (2014) showed that for a given sediment supply, the deposition (P_c) is higher when bedrock roughness is larger. They also showed that if sediment supply rate is larger than the transport capacity of bedrock bed, the clast-smooth surface shows a sudden transition from completely exposed bedrock to completely alluvial, i.e., clast-smooth surfaces show rapid alluviation.

185

1.5 Surface Roughness Model

Johnson (2014) proposed a roughness model using the median diameter grain size. They also calculated the hydraulic roughness using the aerial alluvial cover fraction.

190

$$k_{sa} = r_d d [1 + (k_{\#D} - 1)P_c] \quad (6)$$

where $r_d = 2$ is a coefficient and $k_{\#D}$ is called a non-dimensional alluvial roughness representing variations in topography. For a fully alluviated bed, $k_{sa} = 2d$. The bedrock hydraulic roughness $k_{sb} = r_d r_{br} \sigma_{br}$ where r_{br} is a scaling parameter for bedrock roughness to grain roughness and σ_{br} is the bedrock surface roughness (this method for estimating k_{sb} applies only to Johnson's model. The method of calculating the observed value of k_{sb} is explained in section 2.3). Their model calculates bedrock shear stress using Wilcock and Crowe (2003) hiding/exposure function (b_r), modified to depend on a standard deviation of bedrock elevations and a bedrock roughness scaling parameter. Johnson (2014) calculated the total transport capacity using bedload equations proposed by Meyer-Peter and Müller (1948) and Wilcock and Crowe (2003). Here we introduce Johnson's model that employs Meyer-Peter and Müller (MPM) equation:

195

$$q_{bc} = (1 - P_c)q_{bcb} + (P_c)q_{bca} \quad (7)$$

200

$$q_{bca} = \alpha(\tau_* - \tau_{*c})^{1.5} \sqrt{Rgd^3} \quad (8)$$

$$q_{bcb} = \alpha(\tau_* - \tau_{*cb})^{1.5} \sqrt{Rgd^3} \quad (9)$$

$$\tau_{*cb} = \frac{\tau_{*c} k_{sb}}{r_d d} \left(\frac{r_d d}{k_{sb}} \right)^{b_r} = \frac{\tau_{*c} r_{br} \sigma_{br}}{d} \left(\frac{d}{r_{br} \sigma_{br}} \right)^{b_r} \quad (10)$$

$$b_r = \frac{0.67}{1 + \exp(1.5 - d/r_{br} \sigma_{br})} \quad (11)$$

205 where q_{bca} is the transport capacity per unit width for sediment moving on purely alluvial bed and q_{bcb} is the transport capacity per unit width for sediment moving on purely bedrock bed. τ_{*cb} is the dimensionless critical shear stress for grains on bedrock portions of the bed.

The models proposed by Inoue et al. (2014) and Johnson (2014) may seem rather similar in that they estimate the transport capacity of a mixed alluvial – bedrock surface. However, both models opt for different approaches when it comes to estimating hydraulic roughness. The model by Inoue et al. (2014) uses the observed hydraulic roughness, but the model by Johnson (2014) calculates the hydraulic roughness from the roughness (topographic unevenness) of the bed surface. The model by Inoue et al. (2014) needs measurements of observed bedrock hydraulic roughness, and the model by Johnson (2014) needs topographic bedrock roughness. In the model by Inoue et al. (2014), the macro roughness of the bed acts only when converting the alluvial layer thickness to the alluvial cover ratio. The macro roughness affects the temporal change of the alluvial cover ratio but does not affect the alluvial cover ratio in the dynamic equilibrium state. In addition, in the model by Johnson (2014), first, the sediment transport capacities for the bedrock and alluvial bed are separately calculated, then total transport capacity is estimated using P_c . Whereas, in the model by Inoue et al. (2014), first, the total hydraulic roughness height is calculated using P_c , then total transport capacity is estimated using the total hydraulic roughness.

1.6 Probabilistic Model

220 Turowski and Hodge (2017) proposed a probability-based model for prediction of cover on bedrock channels and investigated the distribution of sediment on the bedrock. Because they mainly focused on the transformation between a point of view considering sediment masses and one considering sediment fluxes, they did not treat the interaction between the alluvial cover and the bed roughness. However, there is a possibility to capture the effects of bedrock roughness on the alluvial cover by adjusting the probability of grain entrainment and deposition included in the model. They defined P as the probability that a grain will settle on the exposed bed and used a power-law dependence of P on the exposed area $(1 - P_c)$, taking the form $P = (1 - P_c)^\omega$, here ω is a model parameter. Similar to the exponential model (Turowski, 2007), integrating $d(1 - P_c) = -PdM_s^*$,

$$P_c = 1 - [1 + (1 - \omega)M_s^*]^{\frac{1}{1-\omega}} \quad (12)$$

They further introduced the mass conservation equation and derived the following equation.

$$P_c = 1 - \left[1 + (1 - \omega) \ln \left\{ 1 - \left(1 - e^{-\frac{M_0^* q_{bs}}{q_{bca}}} \right) (q_{bs}/q_{bca}) \right\} \right]^{\frac{1}{1-\omega}} \quad (13)$$

230 where M_0^* is the dimensionless characteristic sediment mass obtained as follows:

$$M_0^* = \frac{3\sqrt{3}\tau_{*c}}{2\pi} \frac{(\tau_*/\tau_{*c}-1)^{1.5}}{(\tau_*/\tau_{*c})^{0.5}-0.7} \quad (14)$$

Their model also provides two other analytical solutions and potentially other variables (Equation 30, 31 in Turowski and Hodge, 2017), however, we are employing Equation 13 in this study as the equation has the highest flexibility of P and is likely to be able to include roughness feedbacks.

235 We hereafter refer Sklar and Dietrich (2004) model as linear model, Turowski et al.'s model (2007) as exponential model, Inoue et al.'s model (2014) as macro roughness model, Meyer-Peter and Müller (MPM) based Johnson's model (2014) as surface roughness model and Turowski and Hodge's model (2017) as probabilistic model.

2 Experimental Method

2.1 Experimental Flume

We conducted experiments to measure how sediment cover developed over surfaces of different roughnesses and different sediment fluxes. The experiments were conducted in a straight channel at the Civil Engineering Research Institute for Cold Region, Sapporo, Hokkaido, Japan. The experimental channel was 22 m long, 0.5 m wide and had a slope of 0.01. The width-depth ratio was chosen to achieve no-sandbar condition (i.e., small width-depth ratio, 6.1 to 8.3 in our experiments). Chatanantavet and Parker (2008) conducted several flume experiments with sandbar conditions (i.e., large width-depth ratio, 11 to 30 in their experiments) and suggested that the alluvial cover increases linearly to the ratio of sediment supply and transport capacity of the channel when the slope is less than 0.015. The formation of bars strongly depends on the width – depth ratio (e.g., Kuroki and Kishi, 1984; Colombini et al., 1987). Generally, neither alternate bars nor double-row bars are formed under conditions with width-depth ratios < 15 . In this study, we investigated the influence of bedrock roughness on the alluvial cover under conditions where the slope and width - depth ratios were small compared to the experiments of Chatanantavet and Parker (2008).

2.2 Bed characteristics and conditions

The channel bed consisted of hard mortar that was not eroded by the bed load supplied in this experiment. In order to achieve different roughness conditions, the bed in Gravel30 was embedded with gravel of particle size 30 mm, Gravel50 was embedded with 50 mm gravel, and Gravel5 was embedded with 5 mm gravel. We performed an additional 2 cases with net-installation on the riverbed. The net was made of plastic. An installed net on the riverbed can trap sediment during high flow, eventually protecting the bed from further erosion from abrading sediment (Mutsuura et al., 2015). A net of mesh size 30 mm X 30 mm was installed on the bed in Net4 and Net2. The height of the net was 4 mm and 2 mm respectively. Figure 1 shows the experimental channel bed of all 5 runs. For each bed roughness (example: Gravel50 series), a group of experiments with varying sediment supply were performed for different time durations.

Figure 1: Initial channel bed for each run. (a) Gravel30 is embedded with 30 mm gravel (b) Gravel50 is embedded with 50 mm gravel (c) Gravel5 is embedded with 5mm gravel (d) Net4 is installed with a net of height 4 mm (e) Net2 is installed with a net of height 2 mm.

2.3 Measurement of observed bedrock roughness

In order to measure the initial bed roughness (before supplying sand), a water discharge of $0.03 \text{ m}^3/\text{s}$ was supplied, and the water level was measured longitudinally at every 1 m at the centre of the channel. The hydraulic roughness height for bedrock (k_{sb}) was calculated using Manning – Strickler relation and Manning’s velocity formula.

$$k_{sb} = \left(7.66n_m\sqrt{g}\right)^6 \quad (14a)$$

$$n_m = \frac{1}{U} D^{2/3} S_e^{1/2} \quad (14b)$$

where n_m is the Manning's roughness coefficient and U is the average velocity ($U = Q/wD$ where U is the water discharge, w is the channel width, D is the water depth), S_e is the energy gradient. Several previous studies have suggested that in bedrock rivers the Manning's n_m value can depend on the discharge (Heritage et al., 2004; Hodge and Hoey, 2016a), but in our experiments, the discharge is held constant between the different runs.

In order to compare the hydraulic roughness height and the riverbed-surface unevenness height, the riverbed height before water flow was measured along a 1-metre length (12 m to 13 m) with a laser sand gauge. The measurements were taken longitudinally at every 5 mm. The measurements were taken at three points: 0.15 m away from the right wall, the centre of the channel, and 0.15 m away from the left wall. The standard deviation representing the topographic roughness σ_{br} was obtained by subtracting the mean slope from the riverbed elevation and then calculating the standard deviation of the remaining elevations (Johnson and Whipple; 2010).

2.4 Measurement of dimensionless critical shear stress on bedrock

To measure the dimensionless critical shear stress of grains on completely bedrock portion, i.e. τ_{*cb} , 30 gravels of 5mm diameter each, were placed on the flume floor at intervals of 10 cm or more to make sure that there was no shielding effect between the gravels (there was shielding effect due to unevenness of the bedrock). Next, water flow was supplied at a flow discharge that no gravel moved, and was slowly increased to a flow discharge at which all the gravels moved. The water level and the number of gravels displaced were measured and recorded for each flow discharge. These measurements were performed for all the 5 bedrock surfaces.

We calculated the dimensionless shear stress $\tau_*(= DS_e/Rd)$, here R is the specific gravity of the submerged sediment (1.65). We defined the critical shear stress was τ_{*cb} is the weighted average of τ_* using the number of displaced gravels.

2.5 Measurement of Alluvial cover

In order to perform the main set of experiment, different amounts of gravel (5mm, hereafter called as sediment) was supplied manually at a constant rate while the flow rate was kept constant at 0.03 m³/s. The alluvial cover ratio was measured once equilibrium state was achieved. Once the areal fraction became stable in qualitative observations and the variation of hydraulic roughness of mixed alluvial – bedrock bed k_s calculated from the observed water depth decreased despite sediment being supplied, we considered that the experiment has reached its equilibrium state. Equilibrium conditions were achieved after 2~4 hours of sediment supply. The sediment supply amounts and other experimental conditions for various cases are provided in Table 1. Each run has multiple cases, each with different sediment supply and time duration. Each case was performed until the P_c became constant. The gravels were supplied from Run-0 of no sediment to Run-4~5 of completely alluvial cover. The Run-0 with no sediment supply in each run represents the bedrock-roughness measurement experiment explained in section 2.3.

For each roughness condition, initially, we supplied sediment at the rate of 3.73×10^{-5} m²/s and observed the evolution of P_c . A sediment supply rate of 3.73×10^{-5} m²/s is used as it was measured in the flume with complete alluvial bed and it is in good agreement with the calculated value obtained from Equation 4. If $P_c \approx 1$, the sediment supply was approximately reduced by 1.5 times in the subsequent run, and then the sediment supply was further reduced to 2 times and 4 times in subsequent runs (example: Gravel30, Gravel50 and Net4). In roughness conditions where sediment supply of 3.73×10^{-5} m²/s resulted in $P_c \approx 0$, the sediment supply was increased by 1.25 or 1.5 times and 2 times in the subsequent runs (example: Gravel15 and Net2). However, for ease of understanding, we will present each experimental run in ascending order of sediment supply rate.

The alluvial cover was calculated at the end of the experiment, using black and white photographs of the flume by taking the ratio of the number of pixels. The dark/black colour represented sediment cover while white represented exposed bedrock. The water level was measured and recorded every hour at the centre of the channel, to calculate the hydraulic roughness during and at the end of the experiment. The cross-sectional profile of the channel bed was measured with a laser sand gauge at

315 longitudinal intervals of 1 m from 10 m to 15 m from the downstream end before and after each run. We calculated the alluvial thickness from the difference between the two data.

Table 1: Experimental Conditions.

Run	k_{sb} (mm)	k_{sb}/d	q_{bs} ($\times 10^{-5} \text{m}^2/\text{s}$)	Time (hour)	P_c	D	U	Fr	k_s/d

320 Here, k_{sb} represents the hydraulic roughness height of purely bedrock bed, k_{sb}/d is the relative roughness of the bedrock bed, q_{bs} represents sediment supply rate, P_c is the alluvial cover, D is the water depth, U is the depth-averaged velocity, Fr is the Froude number ($= u/(gD)^{0.5}$), k_s/d is the ratio of hydraulic roughness height to grain size.

3 Experimental results

3.1 Initial topographic roughness and hydraulic roughness

Figure 2 shows the relationship between the hydraulic roughness height of bedrock bed k_{sb} and the topographic roughness height of bedrock bed σ_{br} . This figure suggests that Gravel30 with 30 mm sized embedded gravel, has the largest hydraulic roughness and Gravel5 with 5 mm sized embedded gravel has the lowest hydraulic roughness. Gravel50 embedded with 50 mm gravel has large topographical roughness error bars for the reason that, the large gravels were embedded randomly in the bed, resulting in unintended longitudinal spatial variation in the unevenness of the channel bed. The error bars here represent the minima, average and maxima of the calculated standard deviation of measurements taken along the left wall, centre and right wall of the channel, as mentioned in section 2.3. Although the hydraulic roughness tends to increase with an increase in topographical roughness, it has a large variation. This variation is due to the fact that the hydrological roughness height does not only depend on the topographical roughness but also on the arrangement of the unevenness.

Figure 2: Relationship between initial bed hydraulic roughness height and topographic roughness height. The black circles in the image represent the average values measured on the three data collection lines, and the error bars represent the minimum and maximum value.

3.2 Relative roughness of the bedrock bed, sediment supply and alluvial cover

Figure 3 shows the channel bed after the experiments of the Gravel30 series (Gravel30-1, Gravel30-2, Gravel30-3 and Gravel30-4) with the highest relative roughness of the bedrock bed (k_{sb}/d). Figure 4 shows the channel bed after the experiments of the Gravel5 series (Gravel5-1, Gravel5-2, Gravel5-3) which has the lowest relative roughness of the bedrock bed. In these two figures, we can compare Gravel30-4 and Gravel5-1 with equal sediment supply rates. The bed in Gravel30-4 is completely covered with sediment whereas the bed in Gravel5-1 has almost no accumulated sediment on the bed.

Figure 5 shows the relationship between alluvial-cover fraction P_c and sediment supply per unit width q_{bs} . P_c is obtained by dividing the sediment-covered area by the total area of the channel from photographs. The value of P_c is 1 for a completely covered channel and 0 for a completely exposed bedrock bed. In Figure 5, if we compare Gravel30-4, Gravel50-4, Gravel5-1, Net4-4 and Net2-1, the cases with equal sediment supply rate of $3.73 \times 10^{-5} \text{ m}^2/\text{s}$, it can be observed that alluvial-cover fraction is increasing with an increase in the bedrock roughness. Moreover, in Gravel30 series, Gravel50 series and Net4 series with high relative roughness of the bedrock bed k_{sb}/d (ratio of the hydraulic roughness height of bedrock bed k_{sb} to the grain size d), P_c is roughly proportional to the sediment supply rate q_{bs} . However, in Gravel5 series and Net2 series, which have lower k_{sb}/d (relative roughness of the bedrock bed), P_c shows hardly any increase when q_{bs} is low (Gravel5-0, Gravel5-1, Gravel5-2, Net2-0, Net2-1) and when sediment supply (q_{bs}) increases (Gravel5-3, Net2-2), the bedrock suddenly transitions to completely alluvial bed. In clast-smooth bedrock (i.e., Gravel5 and Net2), it is possible to supply more sediment flux than q_{bca} because q_{bcb} (transport capacity on completely bedrock bed) is larger than q_{bca} (transport capacity on a completely alluvial bed).

370

3.3 Time series change of relative roughness

Figure 6 shows the change in relative roughness in a mixed alluvial – bedrock channel i.e. k_s/d with time in Gravel30 and Gravel5 series. In Gravel30 series with a higher initial relative roughness, relative roughness decreased due to the increase in alluvial deposition and cover. In Gravel5 series which has a lower initial relative roughness, relative roughness increased due to the increase in alluvial deposition and cover. The relative roughness nears ~ 2 for both Gravel30-4 and Gravel5-3 in which the alluvial cover fraction approaches 1.

Figure 6: Change in Relative roughness with time.

Figure 7 shows the variation in P_c with respect to relative roughness. In cases with lower initial relative roughness, for example: Gravel50 and Net2, the relative roughness is increasing with an increase in P_c . Whereas, in cases with higher initial relative roughness, Gravel30, Gravel5 and Net4, an increase in P_c reduces the relative roughness. Besides, irrespective of the initial relative roughness, the bed becomes completely alluvial as $P_c \approx 1$ and its relative roughness becomes a similar value (i.e., 1 to 4). Several studies in the past have suggested that when the bed consists of uniform grain size, the hydraulic roughness height k_s for such a gravel bed is 1 to 4 times the grain diameter d (Inoue et al., 2014; Kamphuis, 1974; Parker, 1991) which is also the case in our experiments as shown in Figure 7.

4 Discussion and Comparison of the Existing Models with Experimental Results

4.1 Relationship between gravel layer thickness and alluvial cover fraction

The ratio of the alluvial thickness η_a to macro-roughness L is not used in the model comparison in this study. However, we experimentally investigate η_a/L because various numerical and theoretical models have predicted alluvial cover as a function of relative alluvial thickness (Zhang et al., 2015; Inoue et al., 2014; Parker et al., 2013; Tanaka and Izumi, 2013; Nelson and Seminara, 2012)

$$P_c = \begin{cases} \eta_a/L & \text{for } 0 \leq \eta_a/L \leq 1 \\ 1 & \text{for } \eta_a/L > 1 \end{cases} \quad (15)$$

here, η_a is the average thickness of the alluvial layer calculated from the total flume area instead of the area of sediment patches, L is the macro-roughness height of the bedrock bed. Parker et al. (2013) define L as the macroscopic asperity height of rough bedrock rivers L_b ($\approx 2\sigma_{br}$). Tanaka and Izumi (2013) and Nelson and Seminara (2012) define L as the surface unevenness of alluvial deposits on smooth bedrock river L_a ($\approx d$). In this study, we define $L = 2\sigma_{br} + d$ so that it can cope with both smooth and rough bedrocks. Figure 8 shows the relationship between relative gravel layer thickness η_a/L and alluvial cover ratio. The figure confirms that the alluvial cover ratio of the experimental result can be efficiently evaluated by Equation (15).

Figure 8: Relationship between relative gravel layer thickness and alluvial cover. The black line represents the 1:1 line.

4.2 Relative Roughness of the bedrock bed and dimensionless critical shear stress

Figure 9 shows the relationship between the ratio of the hydraulic roughness height of bedrock bed k_{sb} to the grain size d (k_{sb}/d : referred to as the relative roughness of the bedrock bed in section 3.2) and the dimensionless critical shear stress over bedrock bed τ_{*cb} . In this figure, we compare the results obtained from Inoue et al. (2014) (Eq. 5) and Johnson (2014) (Eq. 10) with the experimental results in this study, experimental results of Inoue et al. (2013) (the same channel and grain size as this study, but with a smoother bedrock bed) and Inoue et al. (2014) (the channel excavated in Ishikari river).

According to Figure 9, the non-dimensional critical shear stress depends on the relative roughness of the bedrock bed to the power of 0.6. Besides, the results obtained from Eq. (5) of the macro-roughness model are not compatible with the experimental results in the region where relative roughness of the bedrock bed is small. In this study, we used the power approximation shown below instead of Eq. (5) in the macro roughness model by Inoue et al. (2014).

$$\tau_{*c} = 0.03(k_s/d)^{0.6} \quad (16)$$

Likewise, the results obtained from Johnson's model (2014) (Eq. 10) (surface-roughness model) are roughly consistent with our experimental results (i.e., $0.8 < k_s/d < 9.6$), but inconsistent with the experimental results of Inoue et al. (2013) (i.e., $k_s/d < 0.8$).

Figure 6: Relationship between relative roughness of the bedrock bed and dimensionless critical shear stress. The black squares show the results of this experiment, the white circles show the results of an investigation using the bedrock of Ishikari River in 2011 (Inoue et al., 2014), the grey rhombus represents a smooth aquifer floor (Inoue and Ito, 2013 (in Japanese)), the grey line shows the power approximation of all the experimental results. The dotted line shows the results from Eq. 5 proposed by Inoue et al. (2014). The black double dotted lines show the results obtained by Eq. 10 (Johnson, 2014). The grain size (d) in the case of Inoue et al., (2013) is 5mm. Inoue et al., 2014 used gravels sized: 12mm and 28mm.

4.3 Predicting experimental results of alluvial cover ratio using the models

For the purpose of model comparisons with experimental results, we first calibrate the model parameters included in the exponential model, the surface roughness model and the probabilistic model to minimize RMSD (root mean square deviation) of cover between experimental data and the model. We do not calibrate the linear and macro-roughness models as they do not include model parameters.

The parameter φ in the exponential model implies that the probability of sediment deposition in uncovered areas (Turowski et al, 2007) can vary with the roughness of the bedrock. The parameter $k_{\#D}$ in the surface roughness model (Johnson, 2014) represents the change in alluvial roughness that varies with the cover. When $k_{\#D} = 1$, it means the alluvial hydraulic roughness is proportional to the grain diameter size and is independent of the cover fraction. For our calculations, we have used $k_{\#D} = 4$ as applied in Johnson (2014). The parameter r_{br} in the surface roughness model is used to calculate the hydraulic bedrock roughness k_{sb} from the topographic roughness σ_{br} . This value can be back-calculated from the experimental results (Fig. 2), but using the back-calculated value (i.e., using the observed k_{sb} instead of the calculated k_{sb}) did not minimize the RMSD of cover. Hence we adjusted r_{br} to minimize the RMSD of cover. The parameter ω is introduced to express the relation between the deposition probability and the cover ratio exponentially and can vary with bedrock roughness. The parameter M_0^* represents the dimensionless value of sediment mass at sediment transport capacity. Although this parameter is calculated from Equation 14, the experimental results could not be reproduced only by adjusting ω . Hence we adjusted both ω and M_0^* by trial and error. Table 2 provides the calibration values.

Table 2: r_{br} and φ values for comparison with experimental results.

	Observed k_{sb} (mm)	Observed σ_{br} (mm)	Adjusted r_{br} ($k_{\#D}=4$) (Johnson, 2014)	Calculated k_{sb} (mm, $k_{sb}=r_d$ $r_{br}\sigma_{br}$) (Johnson, 2014)	Adjusted φ (Turowski, 2007)	Adjusted ω (Turowski and Hodge 2017)	Adjusted M_0^* (Turowski and Hodge 2017)
Gravel30	48.0	3.7	3.0	22.2	3.1	0.1	143.3
Gravel50	24.8	3.9	2.1	16.4	1.1	3.0	36.4
Gravel5	3.8	1.1	3.0	6.6	0.4	288.3	0.7
Net4	36.3	2.3	4.6	21.2	2.2	0.6	143.3
Net2	9.6	1.8	2.6	9.4	0.9	94.1	3.4

Figure 10 shows the comparison among experimental results presented in this paper, Sklar and Dietrich's linear model (2014) and Turowski et al.'s exponential model (2007). In order to calculate the model results for Figure10, we altered the ratio of q_{bs}/q_{bca} by 0.01, 0.02, 0.03 and so on. This Figure suggests that the linear model is generally applicable to rough bed with relative roughness of the bedrock bed (k_{sb}/d) of 2 or more, but not to smooth bed with relative roughness of the bedrock bed (k_{sb}/d) less than 2 (Gravel30, Gravel50 and Net4). As suggested by Inoue et al. (2014), in this study, "clast-smooth bed" refers to the bed with roughness less than the roughness of supplied gravel and "clast-rough bed" stands for the bed with roughness more that the roughness of the supplied gravel. The exponential model is also more suitable for a clast-rough bed. Figure 11 shows the comparison of our observed experimental values with Inoue et al.'s macro-roughness model (2014) and Johnson's surface-roughness model (2014). In roughness models, q_{bc}/q_{bca} ($= q_{bs}/q_{bca}$ in dynamic equilibrium state in the roughness models) is calculated with a given P_c at intervals of 0.01. It shows that the macro-roughness model proposed by Inoue et al. (2014) can predict the increasing alluvial cover for cases with high relative roughness of the bedrock bed (k_{sb}/d), as well as the rapid alluviation and hysteresis (green shaded region) for cases with lower relative roughness of the bedrock bed (Gravel5 and Net2), without adjusting the roughness. The surface-roughness model proposed by Johnson (2014) also shows good agreement in predictions of alluvial cover and rapid alluviation and hysteresis if r_{br} are adjusted.

As mentioned earlier, the major difference between the macro-roughness model (Inoue et al., 2014) and the surface-roughness model (Johnson., 2014) is the way the transport capacity is calculated. In the case of the surface-roughness model (Johnson, 2014), first, the transport capacities for bedrock (q_{bcb}) and alluvial bed (q_{bca}) are separately calculated, then the total transport capacity (q_{bc}) is calculated for a range of cover fractions (P_c). Hence, in cases when $\tau_{*ca} < \tau_* < \tau_{*cb}$, the transport capacity over bedrock portion $q_{bcb} = 0$ and thereby the bedrock roughness hardly affects the alluvial cover fraction which can also be the reason for inconsistency between the surface-roughness model (Johnson, 2014) results and experimental study for Gravel30 and Net4 in Figure 11. Whereas, in the case of the macro-roughness model (Inoue et al., 2014), the critical shear stress takes into account the value of total hydraulic roughness, which depends on cover fraction, alluvial hydraulic roughness and bedrock hydraulic roughness. Hence, even when τ_* is smaller than τ_{*cb} , the bedrock roughness tends to affect the cover fraction. The macro-roughness model (Inoue et al., 2014) is more capable of dealing with clast-rough surfaces.

Figure 12 shows the comparison of experimental results with Turowski and Hodge's probabilistic model (2017), here we altered the ratio of q_{bs}/q_{bca} by 0.01, 0.02, 0.03 and so on. The model produces favourable results following some parameter adjustments. Because the probabilistic model (Turowski and Hodge, 2017) does not consider the effect of bedrock roughness on entrainment and deposition, the model parameter ω and characteristic sediment mass M_0^* needs to be adjusted by trial and error. The value of ω can be as high as 94 or 288 for runs with rapid alluviation hysteresis, whereas it is as low as ~ 3 for other runs.

In Figure 11, in Gravel5 and Net2 series with relatively smooth beds, rapid alluviation occurred because the transport capacity over bedrock q_{bcb} is larger than that over alluvial bed q_{bca} . The reverse-line slopes produced by macro-roughness and surface-roughness models depict similar hysteresis relationship between alluvial cover and sediment supply. The shaded portion shows that as q_{bs}/q_{bca} increases, the cover does not increase unless it reaches a threshold ($q_{bs}/q_{bcb} > 1$, i.e. sediment supply rate is higher than transport capacity over fully exposed bed), after which the cover increases abruptly, showing rapid alluviation. The shaded portion, however, is unstable between $P_c = 0$ and $P_c = 1$, i.e. it shows the hysteresis of rapid alluviation and rapid entrainment. If q_{bs} becomes smaller than q_{bca} , P_c will decrease until $P_c = 0$ (rapid entrainment). For the bed to become alluviated again, q_{bs} must reach a condition where $q_{bs}/q_{bcb} > 1$, in which case rapid alluviation will happen again. This phenomenon has also been observed in sufficiently steep channels, for slopes greater than 0.015 by Chatanantavet and Parker (2008). Hodge and Hoey (2016b) also suggested a similar relationship between sediment cover and sediment supply. However, our study shows that rapid alluviation occurs irrespective of the slope steepness, if roughness of the bed is less than the roughness of supplied gravel, i.e. when relative roughness of the bedrock bed is less than 2.

In a channel without bars and with a relatively regular roughness distribution (i.e., a channel close to a one-dimensional flow field), the macro-roughness model (Inoue et al., 2014) is the most suitable because it can predict alluvial cover ratio without adjusting the parameters. When the observation of hydraulic roughness is difficult, it is useful to obtain the hydraulic roughness from the topographical roughness like the surface roughness model (Johnson, 2014). However, accurate prediction of hydraulic roughness should not only take into account the bedrock topographic roughness but also the arrangement of bed unevenness. For example, in Figure 2, the topographic roughness of Gravel50 is higher than that of Gravel30, but hydraulic roughness of Gravel50 is lower than that of Gravel30. Ferguson et al. (2019) argued that the standard deviation of exposed bed is an effective way of roughness estimation, however, their finding is for a relatively smooth bedrock. Also, in order to deploy models on field-scale, they must take into account bank-roughness and its effects on shear stress and other hydraulic parameters (Ferguson et al., 2019). Prediction of hydraulic roughness from topographic roughness requires further work.

Another solution is to use the probabilistic model (Turowski and Hodge, 2017). The probabilistic model proposed by Turowski and Hodge (2017) could reproduce experimental results but the model needed optimisation of ω and M_0^* to minimize the RMSD. Small ω means that the deposition probability gradually decreases with increasing alluvial cover, in contrast, large ω means that the deposition probability rapidly approaches zero with increasing alluvial cover. The model, however, does not emulate the hysteresis for clast-smooth beds. In this case, we may need to use different probability functions for entrainment

510 and deposition. In addition, M_0^* calculated physically from Equation (14) is 0.04 (alluvial bed) to 0.06 (smoothest bedrock, i.e., Gravel5) in this experiment, which is significantly different from the adjusted M_0^* . Because the model does not include the effects of bed roughness yet, further alterations to take into account the effect of the probability of grain entrainment and deposition can greatly extend the applicability of the model. How to link ω and M_0^* with topographic roughness is a future issue.

515

4.4 The Effects of Bar formation on Alluvial Cover

For investigating the influence of bed roughness and bar formation on the alluvial cover, we also compared the experimental results of Chatanantavet and Parker (2008) with the model results of the physically based models including interaction between roughness and alluvial cover (i.e., Inoue et al., 2014; Johnson, 2014). Chatanantavet and Parker (2008) conducted experiments 520 in a metallic straight channel with three different types of bedrock bed surfaces namely Longitudinal Grooves (LG), Random Abrasion Type 1 (RA1) and Random Abrasion Type 2 (RA2), where RA1 is smoother than RA2. They performed various cases for each type with varying slope range of 0.0115 – 0.03. They also varied the sediment supply rate and grain size (2mm and 7mm). The major difference between their experiment and our experiments is the width – depth ratio. The width-depth ratios of their experiments were 11 – 30 and thus allowed for the formation of alternate bars. In contrast, the width – depth 525 ratios of our experiments were 6.1 – 8.3, as a result, alternate bars usually cannot develop. Although we can see alternate alluvial patches in Figure 5, their thickness was less than 1 cm, and the patches did not progress to alternate bars with large wave height.

Figure 13 shows the comparison among the two models and Chatanantavet and Parker's experiment (2008). The experimental conditions are taken from Table 1 of Chatanantavet and Parker (2008). Figure 13a represents runs 2-C1 to 2-C4, Figure 13b 530 represents runs 2-E1 to 2-E3, Figure 13c represents runs 3-A1 to 3-A5, Figure 13d represents runs 3-B1 to 3-B5, Figure 13e represents runs 1-B1 to 1-B4 (Chatanantavet and Parker 2008, Table 1). Because the two models do not include the 2-D effects caused by bar formation, we adjusted k_{sb} in the macro-roughness model in addition to r_{br} in the surface model. In the case of the surface-roughness model, $k_{\#D} = 4$ is used, the bedrock surface roughness required for calculations is taken as mentioned in Table 1 Johnson (2014), r_{br} is adjusted to minimize RMSD of cover between experiments and the model. In the case of the 535 macro-roughness model by Inoue et al. (2014), k_{sb} is adjusted to minimize RMSD of cover. The two models can accurately predict the cover fraction and rapid alluviation for the experimental study conducted by Chatanantavet and Parker (2008). However, the adjusted roughnesses were significantly different from the observed value. In the case of Chatanantavet and Parker's experiment, $k_{sb} \sim 0.4$ mm to 3.5mm (Chatanantavet and Parker 2008, Table 1), whereas, in Johnson's surface-roughness model (2014), $k_{sb} (= r_d r_{br} \sigma_{br})$ can be as much as 13 – 27 mm. Also, in the case of Inoue et al.'s macro-roughness 540 model k_{sb} is adjusted to 32 – 53 mm (Table 3).

In Table 3, when we compare the observed k_{sb} with the adjusted k_{sb} in the roughness models proposed by Inoue et al. (2014) and Johnson (2014), the adjusted k_{sb} strongly depends on observed k_{sb} in our experiments without alternate bars (Figure 14a). Whereas, the adjusted k_{sb} is not dependent on the observed k_{sb} in case of experiments with alternate bars conducted by Chatanantavet and Parker (2008) (Figure 14b). This suggests that bedrock roughness has a smaller effect on the alluvial cover 545 in case of mixed alluvial – bedrock rivers with alternate bars. In such rivers, the bed slope may affect the alluvial cover fraction (Figure 14c) because bar formation process depends on the slope as well as the width-depth ratio (e.g., Kuroki and Kishi, 1984).

The roughness models are adjusted to produce the experimental results with alternate bars by fine-tuning r_{br} and k_{sb} values which must be determined by trial and error method. While this method can be applicable to laboratory-scale experiments, the 550 model calibration is unfeasible for a large-scale channel or natural rivers. In general, the formation of alternate bars is barely reproduced with a one-dimensional model as introduced in this study. In the future, research to incorporate the effects of bars

into a one-dimensional model, or analysis using a two-dimensional planar model (e.g., Nelson and Seminara, 2012; Inoue et al., 2016, 2017) is expected.

555

Table 3: Parameter calibration values for comparison with experimental results of Chatanantavet and Parker (2008)

Type	Slope	Observed k_{sb} (mm)	σ_{br} (mm)	Adjusted k_{sb} for the macro-roughness model (mm) (Inoue et al., 2014)	Adjusted r_{br} for the surface- roughness model $k_{\#D=4}$ (Johnson, 2014)	Calculated k_{sb} in the surface- roughness model (mm, $k_{sb}= r_d r_{br}\sigma_{br}$) (Johnson, 2014)

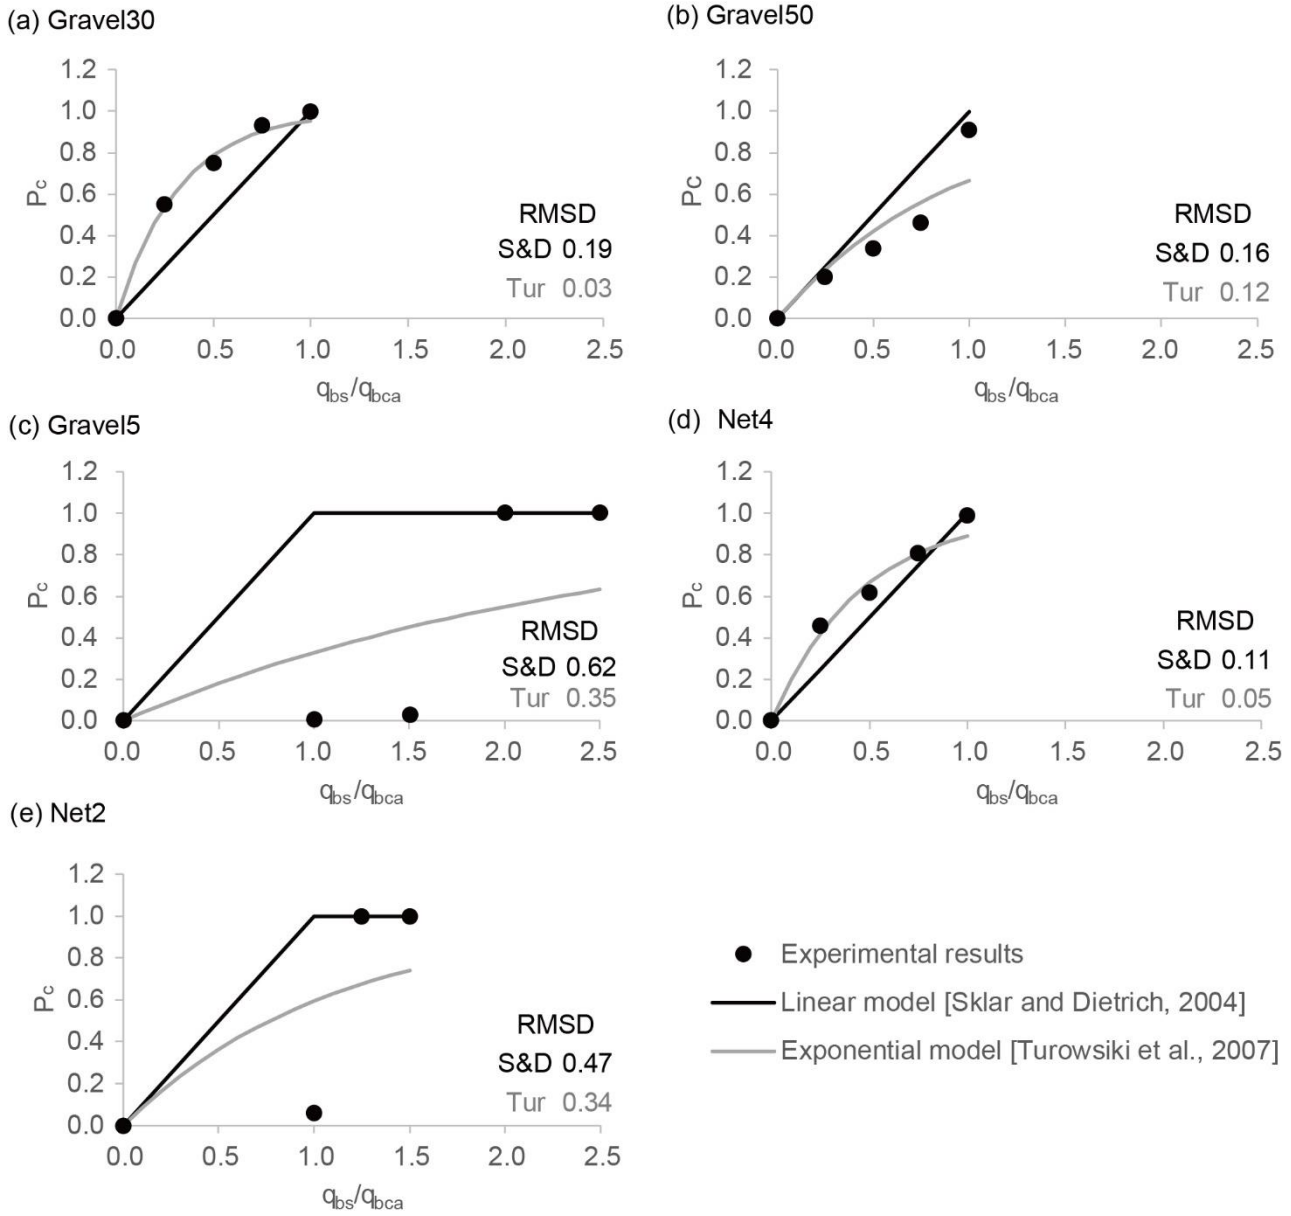

Figure 7: Comparison of our experimental results, linear model by Sklar and Dietrich (2004) and exponential model by Turowski et al. (2007),

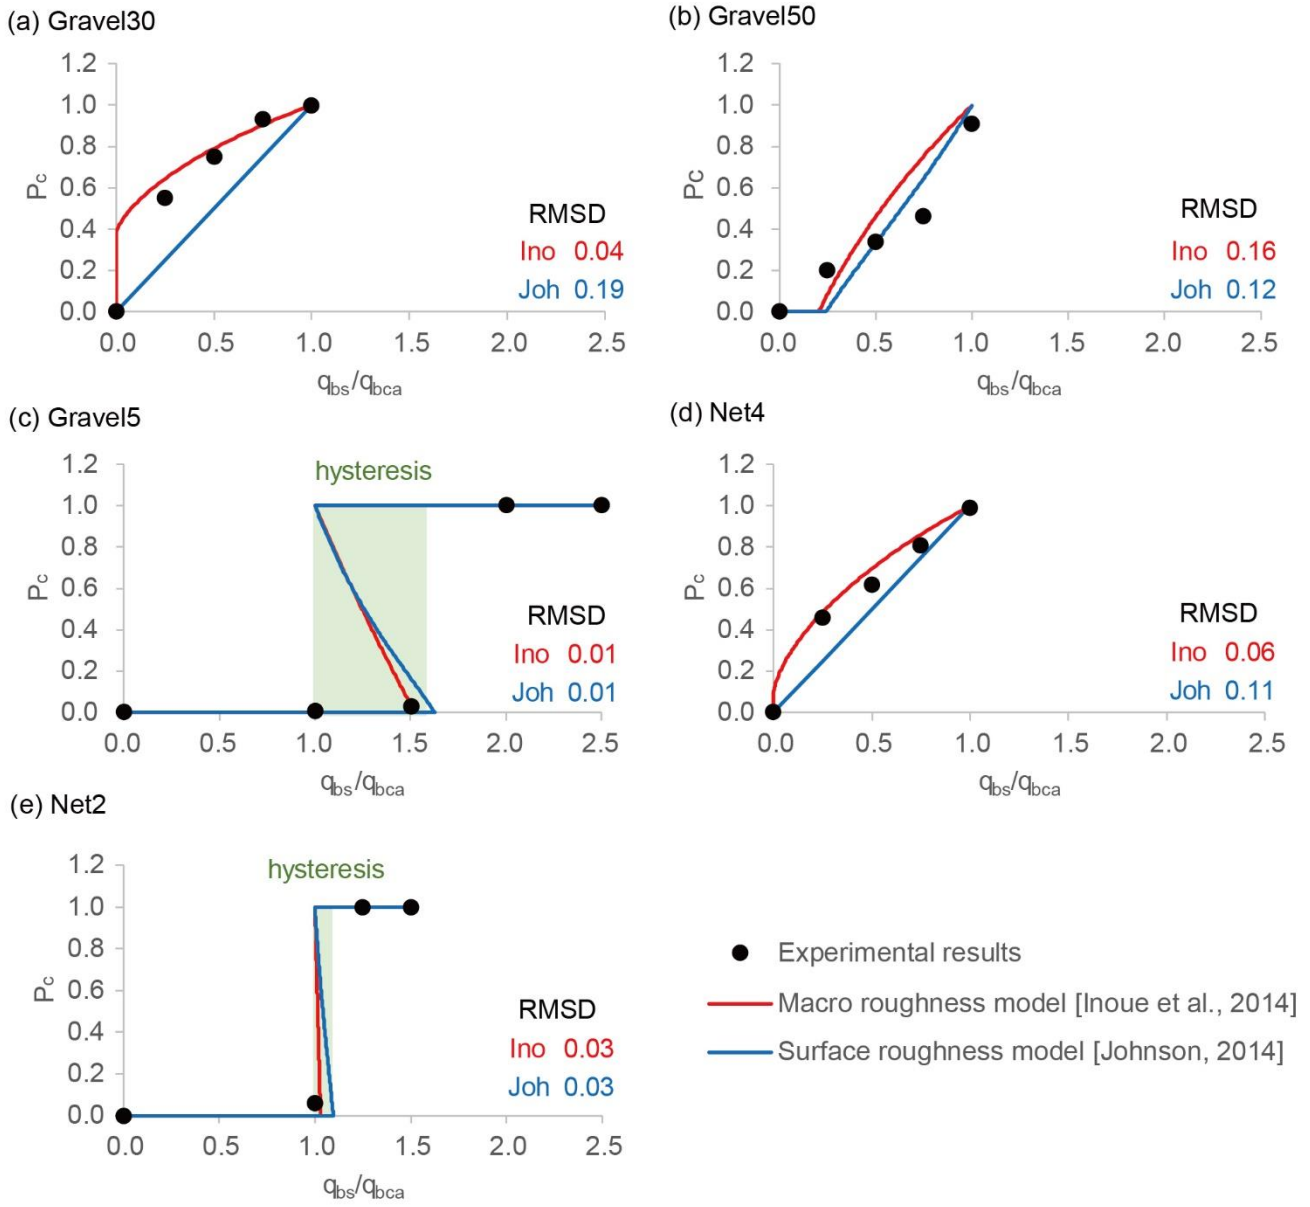

Figure 8: Comparison of our experimental results with roughness models by Inoue et al. (2014) and Johnson (2014). The r_{br} for the surface roughness model and the φ for the exponential model are adjusted to minimize RMSD of the alluvial cover (see Table 2). Note that there is no adjustment of k_{sb} in macro-roughness model.

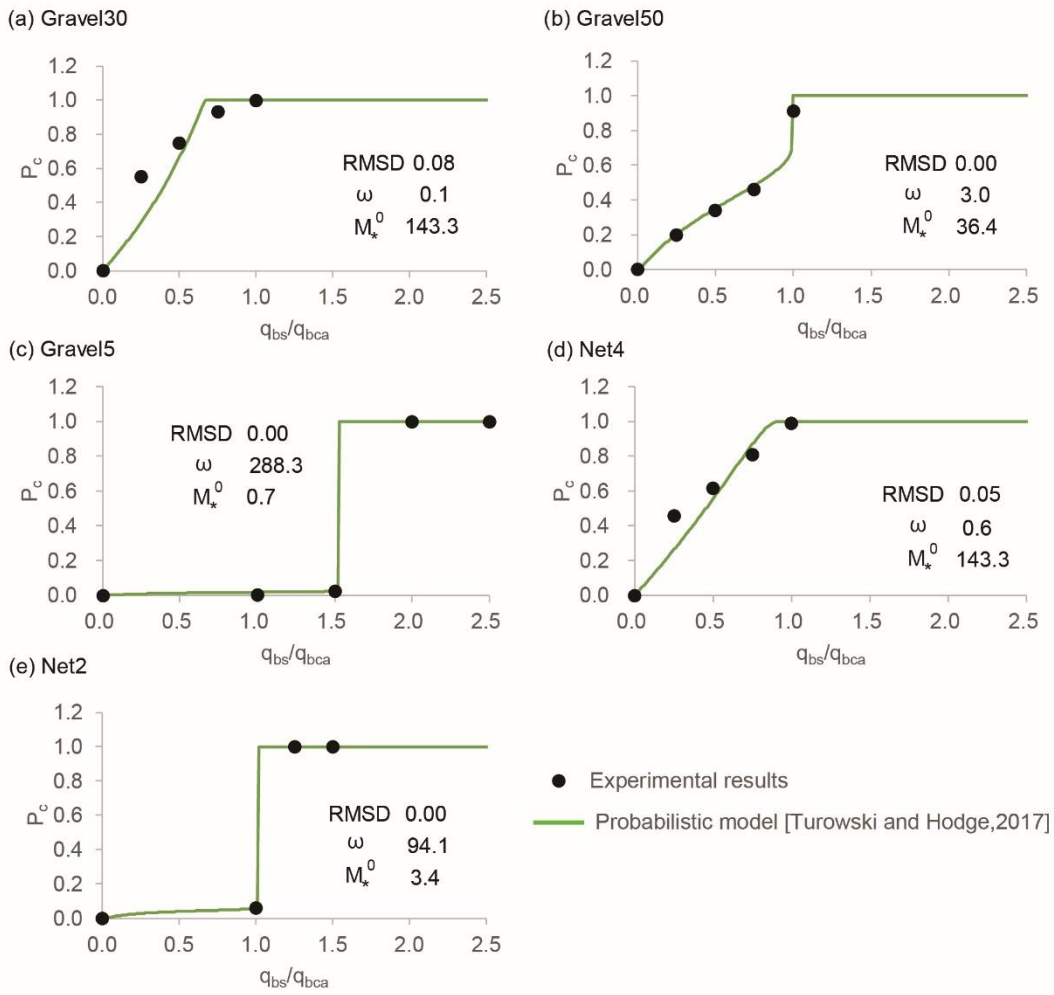

Figure 9: Comparison of our experimental results with the probabilistic model proposed by Turowski and Hodge (2017).

Figure 10: Comparison of the experimental results (Chatanantavet and Parker, 2008) with the macro roughness model (Inoue et al., 2014) and the surface roughness model (Johnson, 2014). RA1, RA2 and LG represent the type of bedrock surface in the experiments conducted by Chatanantavet and Parker (2008); RA1 is Random Abrasion type 1, RA2 is Random Abrasion type 2 and LG is Longitudinal grooves, respectively. The r_{br} for the surface roughness model and the k_{sb} for macro roughness model are adjusted to minimize RMSD of the alluvial cover (see Table 3).

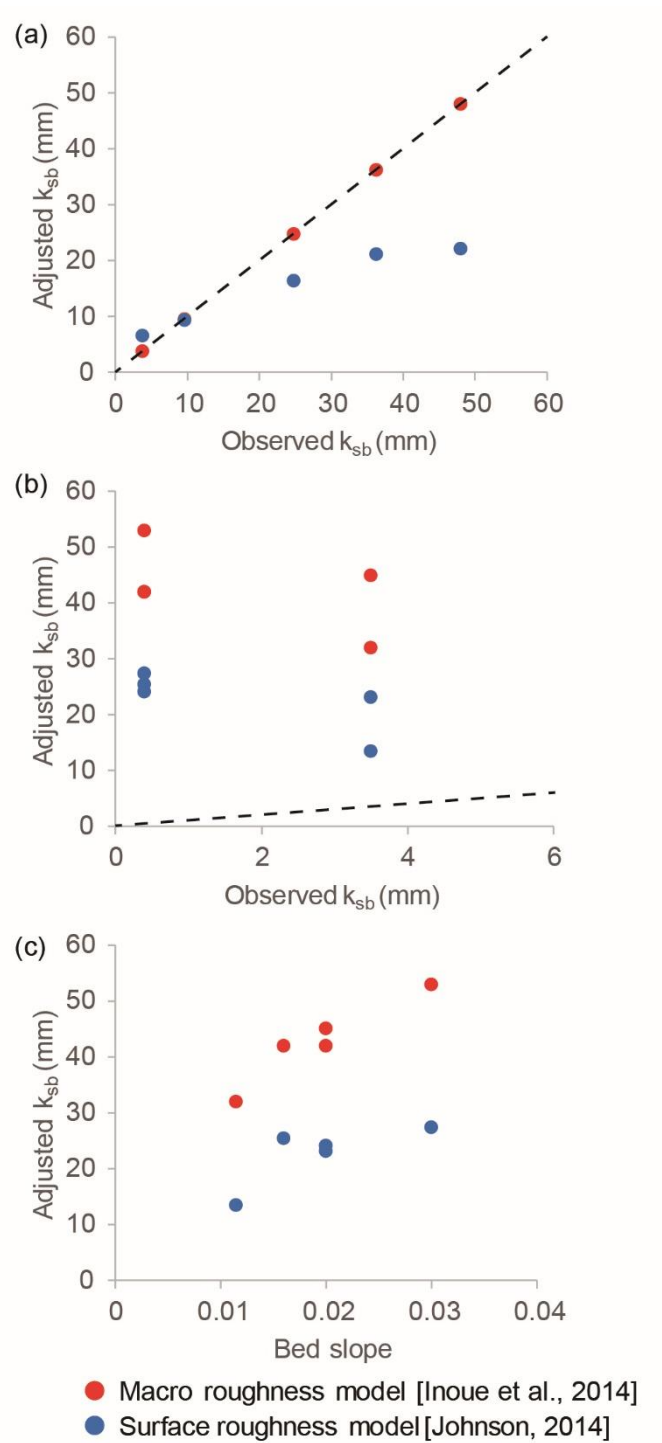

Figure 11: (a) Comparison between adjusted and observed hydraulic roughness height of bedrock bed for our experiments. k_{sb} for the macro roughness model is equal to the observed values because there was no need for adjustment. (b) Comparison between adjusted and observed hydraulic roughness height of bedrock bed for the experiments conducted by Chatanantavet and Parker (2008). (c) Sensitivity of adjusted k_{sb} to bed-slope S for experiments conducted by Chatanantavet and Parker (2008). Note: The black dotted line is the 1:1 line.

5 Summary

Here we provide a review of models and studies focused at discovering the interaction between alluvial cover and bed roughness. For evaluating the previous models, we conducted laboratory-scale experiments with multiple runs of varying bed roughness and sediment supply. The experimental results show that the change in alluvial cover with the sediment supply rate is controlled by bedrock roughness to a great extent. When the bedrock hydraulic roughness is higher than the hydraulic roughness of the alluvial bed (i.e., clast-rough bedrock), the alluvial cover increases proportionately with the increase in sediment supply and then reaches an equilibrium state. However, in cases where bedrock roughness is lower than the roughness of the alluvial bed (i.e., clast-smooth bedrock), the deposition is insignificant unless sediment supply exceeds the transport capacity of the bedrock bed. When sediment supply exceeds transport capacity, the bed is abruptly covered by sediment and quickly reaches a completely alleviated bed.

We have also implemented the previous models for alluvial cover, i.e., the linear model proposed by Sklar and Dietrich (2004), the exponential model by Turowski et al. (2007), the macro-roughness model by Inoue et al. (2014), the surface-roughness model by Johnson (2014) and the probabilistic model by Turowski and Hodge (2017) to predict the experimental results. The linear model and exponential model are inefficient for cases with a clast-smooth bedrock specifically, they cannot predict the rapid-alluviation. The macro-roughness model (Inoue et al. 2014) and surface-roughness model (Johnson, 2014) can predict the rapid-alluviation and hysteresis for clast-smooth bedrock as well as the proportionate increase in alluvial cover for clast-rough bedrock. Although the macro-roughness model (Inoue et al. 2014) was able to reproduce the observed alluvial cover ratio without adjusting the parameters, the surface roughness model needs parameter adjustments. The probabilistic model by Turowski and Hodge (2017) also needs parameter adjustments to make it sensitive to rapid alluviation in clast-smooth bed, however, it does not reproduce the hysteresis. Connecting model parameters with roughness parameters is an exciting challenge in the future.

We also tested the macro-roughness model (Inoue et al. 2014) and surface-roughness model (Johnson, 2014) for their capability to predict the experimental results observed by Chatanantavet and Parker (2008), in which the bedrock surface has alluvial alternate bar formations. Both models required significant parameter adjustments to reproduce the alluvial cover fraction. The two models do not include the 2-D effects caused by variable alluvial deposition and formation of bars on bedrock. Although models that extended the roughness model into two-dimensional planes (e.g., Nelson and Seminara, 2012; Inoue et al., 2016) will be able to capture the bar formation in a bedrock river, these models require long calculation time. Building a simpler model that can predict alluvial cover fraction with bar formation represents another exciting challenge in the future contributing to a better understanding of long-time evolution of natural bedrock channel.

Author Contribution: Both authors contributed equally to the manuscript.

Acknowledgements: Data used in this publication is available in this paper itself or available in the papers referred (Chatanantavet and Parker, 2008 and Johnson 2014). In proceeding with this research, we received valuable comments from Professor Yasuyuki Shimizu, Professor Norihiro Izumi, and Professor Gary Parker. We would like to express our gratitude here. The authors would also like to thank Jens M Turowski, Rebecca Hodge and an anonymous referee for their constructive feedback that helped improve the earlier version of this paper.

Notations:

α	bedload transport coefficient
b_r	exposure function by Johnson (2014)
d	particle size (m)

D	water depth (m)
g	gravitational acceleration (9.81 m/s ²)
k_s	hydraulic roughness height (m)
k_{sa}	hydraulic roughness height of purely alluvial bed (m)
k_{sb}	hydraulic roughness height of purely bedrock bed (m)
$k_{\#D}$	dimensionless alluvial roughness
κ	Karman constant
l	flume length (m)
L	macro-roughness height of bedrock bed (m)
M_0^*	dimensionless sediment mass
n_m	Manning's roughness coefficient (m ^{-1/3} s)
η_a	average thickness of alluvial layer (m)
P_c	mean areal fraction of alluvial cover
φ	cover factor proposed by Turowski et al. (2007)
q_{bs}	sediment supply rate per unit width (m ² /s)
q_{bc}	transport capacity per unit width (m ² /s)
q_{bca}	transport capacity per unit width for sediment moving on purely alluvial bed (m ² /s)
q_{bcb}	transport capacity per unit width for sediment moving on purely bedrock bed (m ² /s)
Q	water discharge (m ³ /s)
r_d	scaling coefficient for d and hydraulic roughness length
r_{br}	fitting parameter that scales bedrock roughness to d
R	specific gravity of sediment in water (1.68)
S	Bed slope
S_e	energy gradient
τ_*	dimensionless shear stress
τ_{*c}	dimensionless critical shear stress
τ_{*ca}	dimensionless critical shear stress for grains on purely alluvial bed
τ_{*cb}	dimensionless critical shear stress for grains on purely bedrock bed
U	depth averaged velocity (m/s)
w	flume width (m)
ω	Exponent by Turowski and Hodge (2017)
σ_{br}	topographic roughness height of purely bedrock bed (m)
