Abstract

Boulder bars are a common form of riverbed morphology that could be affected by landslide dams. However, few studies have focused on the formation and geometry characteristics of boulder bars due to outburst floods triggered by landslide dam failure. In such way, eight group landslide dam failure experiments with movable bed length for 4 to 7 times of dam length with 25 boulder bars were carried out. In addition, 38 boulder bars formed in the field triggered by four landslide dam failures were investigated. The aim of this paper is to study the formation and geometry characteristics of boulder bars along the riverbeds. The results show that boulder bars are formed after peak discharge of outburst flow. The number of boulder bars is 0.4 to 1.0 times the ratio of river bed length to dam bottom length. Besides, boulder bars have the characteristic of lengthening towards upstream during the failure process. Boulder

bar's upstream edge has a more extensive development than boulder bar downstream edge. The length of a boulder bar along the channel changes faster than the boulder bar's width and height. After the dam failure, the boulder bar's length is about 8 to 14 times of width. The relationship between ratio of boulder bar length to width and boulder bar's dimensionless length could be described with a hyperbolic equation. The dimensionless area of boulder bar increases linearly with the dimensionless area of the river section, and the linear ratio is about 0.5. With the field data, it demonstrates the formation and geometry characteristics of boulder bars in tests are consistent with the field boulder bars. Therefore, the results in this paper are credible, and can be applied to the river bed's geomorphological characteristics analysis triggered by overtopped landslide dam failure. The plenty of experimental and field data could contribute to the community for the boulder bars' research.

Landslide dam · Overtopping failure · Boulder bar · Formation and geometry characteristics

1. Introduction

Activities such as rainfalls and earthquakes often cause landslides, which block the river to form a water-retaining body similar to a reservoir dam, called a landslide dam (Takahashi, 2007; Costa and Schuster, 1988; Casagli, 2003). According to statistics, 85 % of the dams failed within one year after formations, and more than 50 % of the dams breached with overtopping mode (Costa and Schuster, 1988). When the

dam breach, the storage water erupt and flown carrying the dam materials to the downstream riverbed, which may change original riverbed geomorphology.

Many studies on the influence of flood geomorphology and sedimentary characteristics have proved that the outburst flood energy is huge, and it can entrain and transport materials of various sizes, from clay to boulders. A large number of boulders gather in the river to form bars, namely boulder bars. The downstream riverbed's geomorphology will be significantly affected and undergo significant changes (Lamb and Fonstad, 2010; Maizels, 1997; Russell and Knudsen, 1999; Marren and Schuh, 2009; Benito and O'Connor, 2003; Carling, 2013; Wu et al., 2020). Boulder bars are one common landform formed during the outburst flood evolution (Turzewski et al., 2019; Jiang and Wei, 2020; Wu et al., 2020). For example, in the 2000 year, Yigong outburst flood, due to its huge lake storage, formed many huge boulder bars on the river bed. The boulder bars had a significant impact on the development of the river bedform. And Wu et al. (2020) investigated the impact of this event on river morphology and analyzed the shapes and geometric characteristics of the boulder bars caused by the overtopping flood. And they found that the boulder bar components are poorly sorted. Turzewski et al. (2019) studied the particle gradation of the boulder bars during the Yigong River landslide dam failure process. They found that the boulder bars' particle sizes decrease along the lower reaches of the river bed. But they did not analyze the evolution characteristics of boulder bar's size in detail. Lamb and Fonstad (2010) suggested that the rising and falling stages of the outburst flood had a greater impact on riverbed geomorphology and analyzed the characteristics of the median diameter of

material in boulder bar.

The boulder bars triggered by landslide dam failure are formed under a nonequilibrium sediment transport condition. Sediment pulses delivered to downstream are dispersive under this condition. It is very different from river dunes under steady flow conditions, which is an equilibrium sediments transport condition, and the sandbars maintain their geometry when they migrate downstream. It means that the boulder bars' shape and geometry size are variation during its formation process. Furthermore, the formation of boulder bars is different from sandbars which formed by translative depositional processes (Mohrig and Smith, 1996; Ashworth et al., 2000; Shaw and McElroy, 2016).

Because lack of investigations about the growth characteristics of boulder bars during the landslide dam failure process in the field, some researchers had conducted landslide dam failure experiments in the lab (Ashworth, 1996; Jiang and Wei, 2020). Ashworth (1996) used flume experiments to study the boulder bar's growth. However, in their experiments, the inflow conditions are quite different from the outburst flood. Therefore, the research results' applicability to the boulder bar formed by the outburst flood remains uncertain. Jiang and Wei (2020) qualitatively analyzed the formation process of boulder bar in the evolution of overtopping outburst floods using dam failure experiments and initially discussed the characteristics of geometric size of boulder bars after dam failure. However, the characteristics of the boulder bar's distribution and geometric size characteristics during the dam failure process have not been analyzed.

Above all, there is a common academic consensus that outburst flow triggered by

landslide dam failure could change the geomorphology of downstream riverbed. Although, the failure process of the dam and the hydraulic characteristics of the outburst flood, such the characteristics of breaching hydraulic graph, erosion rate and peak discharge (Morris et al., 2009; Jiang and Wei 2018; Jiang, 2019), are clear, the impact of the outburst flood triggered by landslide dam failure on the geomorphology of the downstream riverbed during the failure process and after failure is still lack of research. Boulder bar is the substance occurred during the dam failure process which is an indicator for the variation of riverbed geomorphology. What are the formation characteristics of boulder bars during the dam failure process? And what geometry characteristics of boulder bar are during the dam failure process and after the dam failure? These questions are still not clear and should be answered. Understanding these questions is helpful for predication of riverbed landform influenced by landslide dam failure, and benefit to assessment of stream restoration and river navigation.

This paper focuses on the formation processes and the geometrical size characteristics of boulder bars in the downstream channel during and after the overtopping failure process. Firstly, through flume experiments, boulder bars' formation processes on the downstream channel under the dammed lake failure condition were reproduced. Then, based on the experimental data, the development characteristics of boulder bars' upstream and downstream edges were analyzed. Furthermore, statistical analysis of boulder bars geometrical sizes at each moment during and after the failure process, such as length, width, height, volume and area of boulder bar, had been carried out to obtain boulder bars' size characteristics. Finally, compare the distribution and

geometry characteristics of the boulder bar formed in the experiment and field to verify experiment results' reliability. The results can be applied to the river bed's geomorphological characteristics research affected by the outburst flood triggered by landslide dam failure. And also, this paper provides a large number of experimental and field boulder bars' data reference to the analysis of the erosion and accumulation characteristics of the downstream river channel.

2. Experimental design

2.1 Model design and experimental materials

The longitudinal profiles of experimental landslide dams were trapezoidal and triangular. The trapezoidal dam height and crest width were both 0.3 m, and the triangular dam height was also 0.3 m. In the experiment, river bed slope angle θ was fixed at 10°, and the landslide dam upstream slope angle α was set to 40°, and the landslide dam downstream slope angles β were set to five different values. The moveable bed was set downstream of the model dam, which had a length of 8 m. The downstream channel bed's length was about 4 to 7 times of dam length along the channel. The test parameters are shown in Table 1.

Table 1 test parameters

No.	Dam shape	β (°)
T1	Trapezoid	10
T2	Trapezoid	15
T3	Trapezoid	20
T4	Trapezoid	25
T5	Trapezoid	30
T6	Tringle	10
T7	Tringle	15
T8	Tringle	20

Peng and Zhang (2012) proposed that landslide dam height (H_d), dam bottom width parallel to the channel (W_d), dam volume (V_d), and reservoir volume (V_l) are the key geometric parameters of landslide dam, and proposed a set of dimensionless numbers, $\frac{H_d}{W_d}$, $\frac{V_d^{1/3}}{H_d}$ and $\frac{V_l^{1/3}}{H_d}$, to verify whether the established dam model is consistent with the landslide dam in the field (Zhou et al., 2019). As the field data show that the $\frac{H_d}{W_d}$, $\frac{V_d^{1/3}}{H_d}$ and $\frac{V_l^{1/3}}{H_d}$ are ranged about 0.001 to 2, 0 to 40, and 0 to 20 for filed landslide dam (Zhou et al., 2019). Table 2 shows the dimensionless numbers of the experimental dams, which are all within the acceptable range of the field landslide dams, indicating that the dams in the experiments are relatively close to field landslide dams.

Table 2 landslide dam parameters. The value of $\frac{H_d}{W_d}$ ranges from 0.1 to 0.3, and $\frac{V_d^{1/3}}{H_d}$ and $\frac{V_l^{1/3}}{H_d}$ both range from 1 to 2, which all fall within the acceptable range of values of the field landslide dams (Zhou et al., 2019).

No.	H_d (m)	W_d (m)	$\frac{H_d}{W_d}$	$\frac{V_d^{1/3}}{H_d}$	$\frac{V_l^{1/3}}{H_d}$
T1	0.3	2.359	0.127	1.643	1.477

T8	0.3	1.182	0.254	1.254	1.477

In the field, the landslide dam and the boulder bars are almost consisted of mixtures. The dam materials used in this study were mixtures of sand and gravels. Considering the grain size effect and the flume space limitation, the maximum sediment particle size was set to 20 mm. The materials used in the tests had a median particle size of D_{50} =3.8 mm. A dimensionless parameter measure of the spread in the grain-size

distribution, $\sigma_g = d_{90}/d_{10}$ =14.3 represents a wide grain size range of granular materials for landslide dams. While the materials of riverbed are different from that of landslide dam, it is hard to find a general description of the difference. Thus, we designed the materials of riverbed and landslide dam the same for present experiments. Moreover, the compositions of field dam and riverbed can be heterogeneous, i.e. the distribution of coarse particle within landslide dam is inhomogeneity, there is still no quantitative representation of the heterogeneity. Therefore, the coarse particles and fines were mixed uniform, which means the distribution of coarse particles were homogeneous. The channel morphology in nature is complex and diverse, which was not considered in the experiments. Instead, a straight, aequilate and flat channel was set, which is helpful to reveal the fundamental mechanism of the formation process and geometric characteristics of boulder bars. The thickness of the riverbed was set to 0.06 m. The gradation curve of material particles' sizes is shown in Fig. 1.

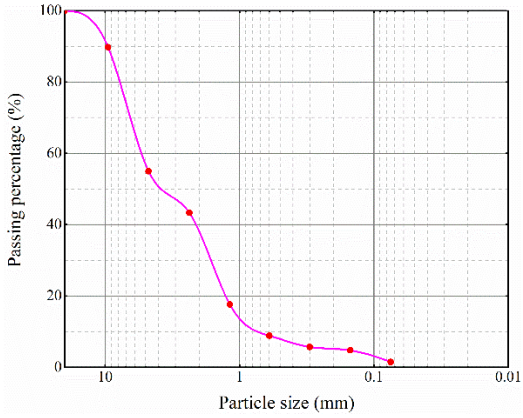

Figure. 1. Gradation curve of the dam materials

2.2 Experimental apparatus

The experimental setups are shown in Fig. 2. The flume was 15 m long, 0.3 m wide, and 0.6 m high. The flume slope was adjustable from 10 to 30°. One side of the

flume was transparent glass, and scale lines were drawn on the glass to facilitate observation and recording of experimental phenomena. The inflow discharge upstream the dam was set as 1.0 L s^{-1}. Under the control of the electromagnetic flowmeter, the error range could be controlled within ±0.01 L s^{-1}. During the tests, the toe of the dam upstream slope was set at 4.5 m away from the water supply tank. A baffle with a height of 6 cm was set at the flume end as a boundary condition. Seven cameras were placed on the transparent glass side of the flume, one camera was placed on the top of the dam, and one camera was placed directly behind the flume. A total of nine cameras recorded the whole experimental phenomena.

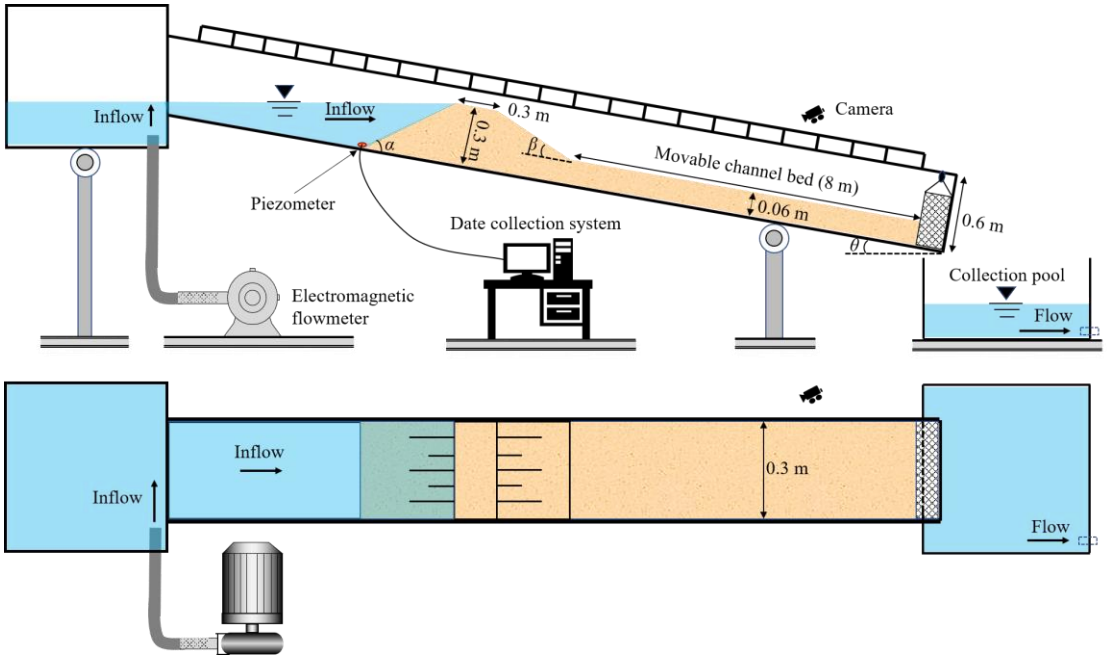

Figure. 2. Experimental setups. (a) Front view of the flume. (b) Top view of the flume.

2.3 Measurements

In the experiment, using the scale lines on the transparent glass on the side of the flume, we can accurately read the boulder bars' positions at each moment. Boulder bars' lengths, widths, and heights could be obtained from the screen. According to the actual

boulder bars' geometric characteristics, the boulder bars were divided into several parts, and then the volume calculation formula of the similar geometric body was used to calculate the volume of each part respectively, and finally, the boulder bars' volumes were obtained by summing. The method of obtaining the boulder bar area was the same as that of the volume. After the dam was completely failed, we collected all the boulder bar materials. Then dried and screened silt to obtain the boulder bar material gradation information.

3. Experimental results

3.1 Formation processes of boulder bars

The formation processes of boulder bars are almost similar for all the tests. Therefore, it takes the T7 test as an example to analyze below in this section, as shown in Fig. 3. When the flow overtopped the dam crest, the outburst flood carried the dam materials to the dam downstream slope (T=5 s) and then to the channel bed (T=19 s) with outburst flow discharge increasing. It should be noted that although a large number of sediments were transported on the channel bed before the peak discharge, no boulder bar formed on the downstream channel bed. After the moment of peak discharge, the flow discharge gradually weakened, and dam materials were transported to the position near the dam toe. The flow could not transport all the sediments away, and some sediments gradually silted down, then the first boulder bar occurred near the dam toe (T=30 s, the boulder bar in the figure is marked with a blue dotted line). After the first boulder bar was formed, the flow direction was changed when water flow bypassed the

198 boulder bar. And the moving sediments still moved along the original direction due to
199 inertia, which causes sediments piled up to form the second boulder bar on the opposite
200 side of the first boulder bar (T=33s).

201 Similarly, the first and second boulder bars affected the formation of the boulder
202 bar downstream. Eventually, boulder bars were scattered on both sides of the channel,
203 forming a meandering channel downstream (T=40 and 47 s). This phenomenon is in
204 good agreement with the field boulder bars along the Yigong river (Wu et al., 2020). In
205 addition, the Froude number of flows on the downstream were all larger than 2.5 during
206 the bars' formation process, indicating these bars were formed in a supercritical flow
207 (diffusive) condition. It suggests that boulder bars were formed on dispersive sediment
208 pulses which delivered from the upstream during the landslide dam failure process.
209 (Shaw and McElroy, 2016).

210

211 **Figure. 3.** The riverbed morphology at six different moments during the boulder bars' formations
212 and growths process for the T7 experiment. The boulder bars in the figure are marked with blue
213 dotted lines.

214 Turzewski et al. (2019) measured the sizes of field boulder bars. They found that
215 grain sizes of boulder bars decrease downstream. In this experiment, sediments in

boulder bars after dam failure from different locations were collected. After sieving the sediments, the gradation curves of the materials were obtained as shown in Fig. 4. The figures show that the contents of fines in the compositions become much less and their mean diameters become larger than the initial sediments. It means that in the boulder bars coarse sediment tends to comprise much of the bar material. Meanwhile, the figure indicates that as the distance between the boulder bar and the dam increases, the particle diameter in the bars shows a decreasing trend. This feature is consistent with the description of Turzewski et al. (2019).

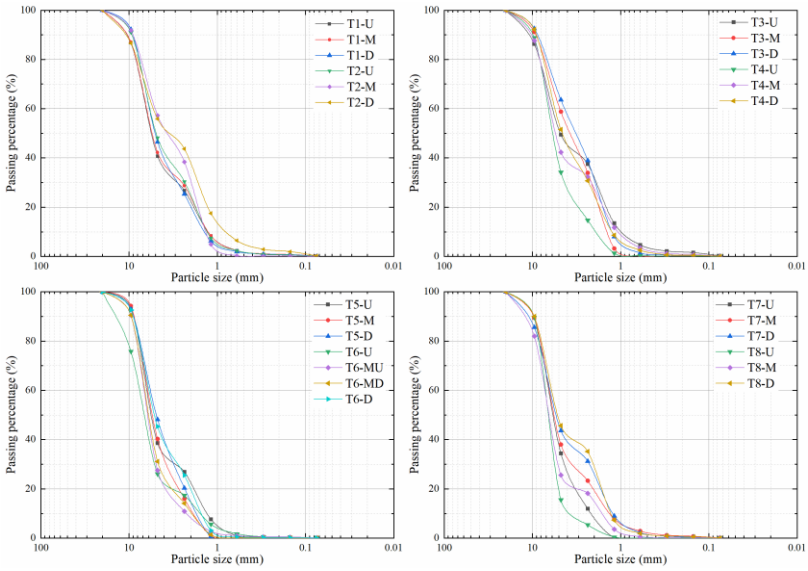

Figure. 4. Gradation curve of the boulder bar materials. Notation: U, M, D, MU, and MD, represent the boulder bar near the upstream reaches, the boulder bar near the middle reaches, the boulder bar near the downstream reaches, the boulder bar near the middle-upstream reaches, and the boulder bar near the middle-downstream reaches, respectively.

3.2 Evolution characteristics of the boulder bars during dam failure process

Figure. 5 shows boulder bars' locations on the channel bed during the dam failure process. The red lines in the figure represent the boulder bars' outlines, and the orange

233 rectangles represent the channels. It clearly shows the formation sequences of boulder
234 bars at different locations. That is, boulder bars were formed first near the dams
235 (upstream reaches of riverbed), and the farther from the dam toe, the later the boulder
236 bar was formed, which is consistent with the content of Sect. 3.1. Boulder bars near the
237 downstream dam toes are all located on the dam breach side across the river. This
238 characteristic has also been found in Chen et al. (2015).

239 According to the boulder bars' formation sequences, the channel bed's boulder bars
240 were divided into three types: I. the boulder bar near the upstream reaches, that is, the
241 boulder bar near the dam toe; II. the boulder bar at the middle reaches; and III. the
242 boulder bar near the downstream reaches. Figure 5 shows that the upstream edges of
243 the boulder bars of type I for all the tests basically moved toward the dams with time
244 development. The movement directions of the downstream edges of boulder bars of
245 type I showed a little different: for T1, T2 and T5, the boulder bars' downstream edges
246 moved toward the dam toes, from a distance from the downstream toe of 3.6 to 2.55 m,
247 3.3 to 2.9 m and 3.7 to 3.4 m, respectively, as shown in Fig.5 (a), (b) and (e); for T6,
248 T7, and T8, the boulder bars' downstream edges first moved away from the dam toes
249 and then moved toward the dam toes, and the downstream edges move forward
250 compared to the original location. However, the distance they moved is 0.1 to 0.2 m, as
251 shown in Fig.5 (f), (g), and (h); for T3 and T4, the boulder bars' downstream edges
252 positions remained almost unchanged, see Fig.5(c) and (d). No matter how the
253 downstream edge positions of the boulder bars type I changed, there is a common
254 feature: compared with the initial positions of the boulder bars, the downstream edges

almost remained original locations, and the movement distances were much smaller than those of boulder bars' upstream edges. The lengths of the boulder bars of type I increased with the failure time. It can be seen that the sediments on the boulder bars' upstream edges played a great role in the length developments of type I boulder bars.

Figure. 5. The boulder bars' locations during the dam failure process. Notation: (a) to (h) represent the boulder bars' locations for T1-T8 tests, respectively. The red lines in the figure represent the boulder bars, and the orange rectangles represent the channels. And, the purple arrow represents the direction of flow. The numbers at both ends of the red lines represent the distances between the upstream and downstream edges of boulder bars and the dam toe.

The positions of the upstream edges of type II and III boulder bar moved toward the dam toe during dam failure, but the downstream edges' positions could move toward or away from the dam. The distances of movement of the downstream edge positions were smaller than that of upstream edge positions. Compared with the boulder bars of type I, the movements of type II and III boulder bars were smaller. The distance between the boulder bars in the middle and downstream reaches is smaller than the distance between boulder bars near the upstream reaches and adjacent boulder bars.

3.3 Geometry size of the boulder bar during dam failure process

It is corresponding to Sect. 3.2, Fig. 6 shows that the lengths of the boulder bars of type I were longer than other types of boulder bars' lengths due to the sufficient incoming materials from the upstream dam. For all the boulder bars, their lengths along

the channel were largest, followed by widths, and lastly the heights. Boulder bars' lengths had a growing trend, and their growth rates were larger than widths and heights.

We recorded in detail the lengths, widths and heights of the boulder bars during the dam failure process at each moment (Fig. 6). The figure shows that boulder bars' heights changed less drastically than widths, which because boulder bars' heights were significantly affected by outburst flow depth. In most cases, flow depth was less than the heights of boulder bars. The sediments mainly accumulated at the boulder bars' edges and middle and could not "climb up" boulder bars' tops. Besides, the reduction of flow depth was not large enough, so the boulder bars' heights did not change seriously. The boulder bars' widths were significantly affected by the discharge of the outburst flow. When the discharge was enough, the sediments around the boulder bars were taken away by the flow, and the widths decreased. The variations of widths and heights both increase slowly with time and then tended to be stable values.

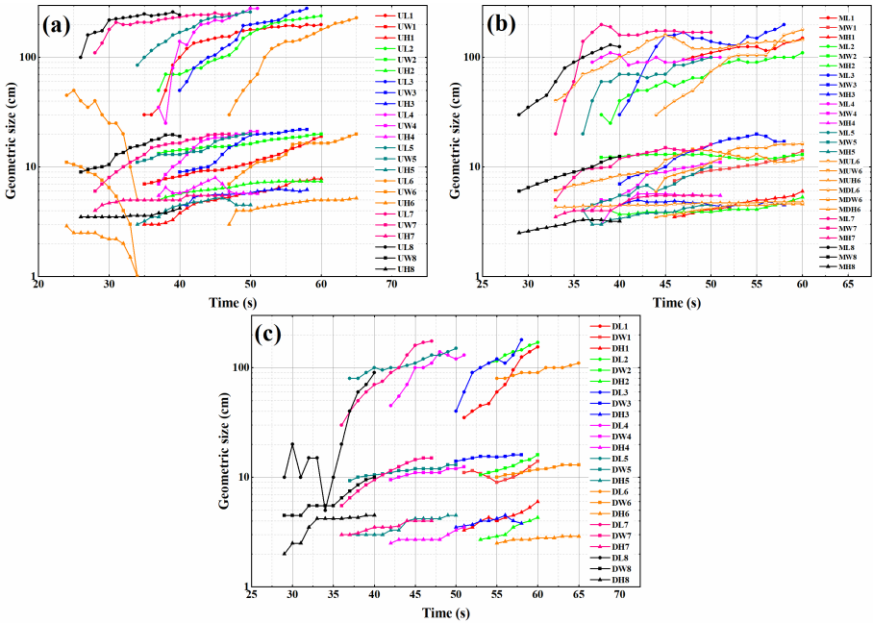

Figure. 6. The lengths, widths, and heights of the boulder bars: (a) sizes of the boulder bars near the upstream reaches; (b) sizes of the boulder bars near the middle reaches; (c) sizes of the boulder

bars near the downstream reaches. Notation: L, W, and H represent the length, width, and height of the boulder bar, respectively. i represents the Ti experiment. For example, MUL6 indicates the length of the boulder bar near the middle-upstream reaches for the T1 test.

When the amounts of sediments deposited on boulder bars were larger than the quantities of eroded sediments, boulder bars' volumes became larger. Otherwise, boulder bars' volumes would decrease or remain at a stable level. Figure. 7 reveals boulder bars' volume characteristic during the dam failure. Most of the 25 boulder bars gradually increased in volume, indicating that the amounts of outburst flow erosions in the boulder bars' vicinities were less than the amounts of siltation during the entire outburst process. Referred to Figs. 6 and 7, the boulder bars' volume characteristics were consistent with the boulder bars' length characteristics. And because the widths and heights developed slightly, boulder bars' volumes were mainly controlled by boulder bars' lengths.

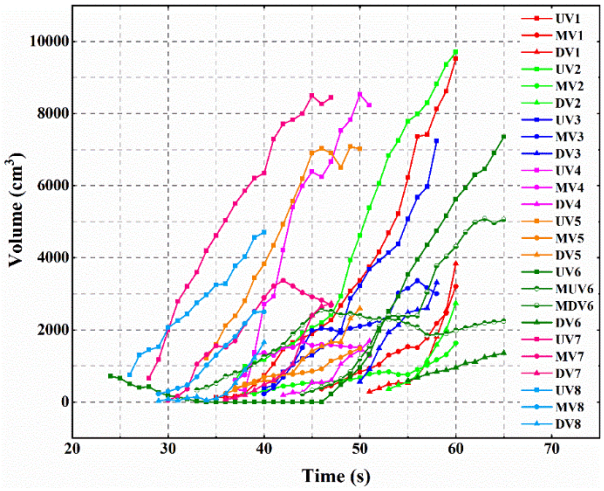

Figure. 7. Volumes of boulder bars. Notation: UVi, MVi, DVi, MUVi, MDVi represent the volume of the boulder bar near the upstream reaches, the boulder bar near the middle reaches, the boulder bar near the downstream reaches, the boulder bar near the middle-upstream reaches, and the boulder

bar near the middle-downstream reaches, respectively. For example, UV1 means the volume of the boulder bar near the upstream reaches of the T1 test.

4. Geometry size of the boulder bars after dam failure

In the Sec.3, we introduced formation characteristics and the geometry characteristics of the boulder bars during the dam failure processes. In this section, we will introduce the geometry characteristics of the boulder bar after the dam failure. After the dam failure, there were 25 boulder bars formed along the channel for all the tests. And it reflected the number of boulder bars was 0.4 to 1.0 times the ratio of river bed length to dam bottom length. The parameter R is defined as the ratio of boulder bar length L to width W in Eq. (1). And the dimensionless length L^* is calculated with Eq. (2), where L_d is dam bottom length.

Figure 8(a) shows the relationship between R and the L^* of the 25 boulder bars after the dams' failure in the experiments. The figure indicates that the values of R of the boulder bars all fell within the range of 8 to 14. And, the R increases with the increasing of L^*. However, the growth rate of R decreases as L^* goes by. The figures show that there is a hyperbola relationship between R and L^*. The hyperbolic function means that R would not sharply increase even become stable with the increasing of L^*.

$$R = \frac{L}{W} \tag{1}$$

$$L^* = \frac{L}{L_d} \tag{2}$$

Two dimensionless parameters A_1^* and A_2^* are defined to reflect boulder bar's area

and channel cross-sectional area where the boulder bar located. They could be obtained by Eqs. (2) and (3) respectively. The relationship between A_1^* and A_2^* is shown in Fig. 8(b). It can be seen that A_1^* increases as A_2^* increases. And there is a linear relationship between A_1^* and A_2^*. The figure suggests that the ratio of boulder bar's area to river channel cross-sectional area is approximately constant, which equals to 0.5.

$$A_1^* = \frac{A_1}{L_d^2} \tag{3}$$

$$A_2^* = \frac{A_2}{L_d^2} \tag{4}$$

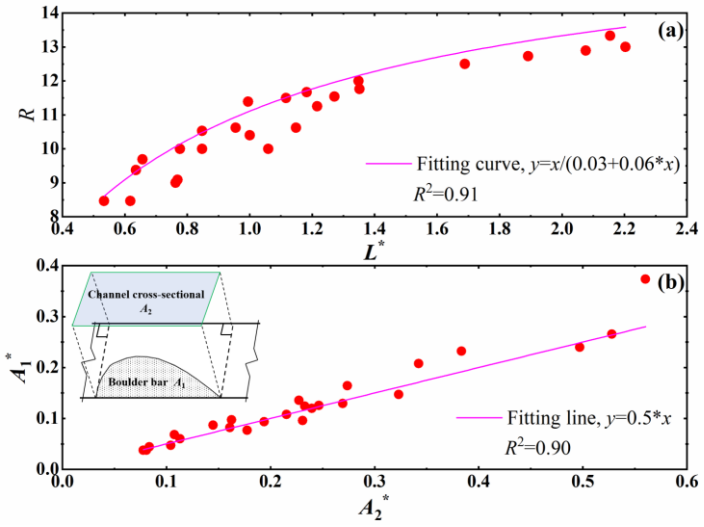

Figure.8. Geometry characteristics of boulder bars after the dam failed in the experiments. (a) the relationship between length to width ratio (R) and dimensionless length (L^*); (b) the relationship between boulder bar's dimensionless area (A_1^*) and the cross-sectional dimensionless area of the river channel along the boulder bar (A_2^*).

5. Discussion

In this paper, eight groups of landslide dam failure tests were conducted to

354 investigate the formation characteristics of boulder bars during the dam failure process,
355 and the geometry characteristics of boulder bars during and after the dam failure, which
356 are the main scientific objective of this paper. The experimental results are analyzed
357 and explained to meet the scientific objective. It should be noted that the materials of
358 riverbed and landslide dam were the same in the experiments. And the present
359 experiments are limited to homogeneous riverbeds and dams.

360 In order to verify the results of the experiments, data of 38 boulder bars in filed
361 formed by four landslide dam failures were used to compare the experimental data. It
362 noticed that the data of boulder bars during the landslide dam failure process are still
363 unavailable since the landslide dam mostly happened in inaccessible places and people
364 could not get there to record the field data in time. Therefore, the filed data in this paper
365 are all concerned about data after dam failure.

366 In this section, four field cases were used to verify the reliability of the boulder
367 bar distribution and geometry characteristics in this paper. In the Fig.9, boulder bars
368 were formed in the downstream river bed after Yigong landslide dam (30°10'38.07" N,
369 94°56'24.62" E), Tangjiashan landslide dam (31°50'26.79" N, 104°25'51.17" E),
370 Sedongpu landslide dam (29°44'53.45" N, 94°56'24.02" E), and Hongshihe landslide
371 dam (32°36'16.05" N, 105°12'49.59" E) failed. The geometric data of boulder bars of
372 the four cases were obtained from Google Earth. The length of the river bed section we
373 selected was about 7 times of the dam bottom length. The detailed statistical data of
374 boulder bars shown as Table 3. It indicates that the number of boulder bars on the 17
375 km downstream river bed of the Yigong landslide dam was 2.67 times the ratio of the

river bed length to the dam bottom length; the number of boulder bars on the 5.6 km downstream river bed of the Tangjiashan landslide dam was 1.29 times the ratio of the river bed length to the dam bottom length; the number of boulder bars on the 6.4 km downstream river bed of the Sedongpu landslide dam is 0.57 times the ratio of the river bed length to the dam bottom length; and, the number of boulder bars on the 1.8 km downstream river bed of the Hongshihe landslide dam was 1.29 times the ratio of the river bed length to the dam bottom length. Generally, the number of boulder bars on the river bed for the four field cases are 0.57 to 2.67 times the ratio of the river bed length to the dam bottom length. These values are almost the same to the experimental values.

In addition, we also analyzed the data about R, L^*, A_1^* and A_2^* of the field boulder bars. The Fig. 10(a) shows that the values of R of filed boulder bar all fall within the range of 2 to 12, which are approximate to the range of values of the experimental boulder bars. Furthermore, the hyperbola relationship in Fig. 8(a) is also suitable for the field data in Fig. 10(a). And, both the experimental and filed data points are all

closed to the fitting curve, whose coefficient of determination (R^2) is 0.92. For the boulder bars in the field, A_1^* and A_2^* show a linear relationship, and the fitting equation of the experimental data (Fig.8 (b)) is very suitable for the field data in Fig.10 (b). It means that the fitting line could predict the relationship between A_1^* and A_2^* for both experimental and field boulder bar well (the coefficient of determination is 0.94).

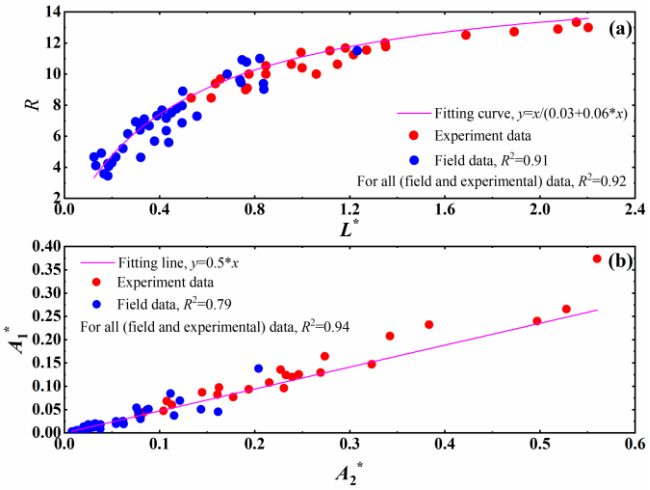

Figure.10. Geometry characteristics of boulder bars after the dam failed in the field. The experimental data are also plot in the figure to compare to the field data. (a) The relationship between boulder bar length to width ratio (R) and dimensionless length (L^*); (b) The relationship between boulder bar's dimensionless area (A_1^*) and the cross-sectional dimensionless area of the river channel along the boulder bar (A_2^*).

Based on the above points, it can be seen that the experimental results in this paper are consistent with the actual boulder bars in the field. Therefore, the experimental results can provide references for the field study of the boulder bar formed by the outburst flood triggered by landslide dam failure. The results in this paper can help researchers deepen their understanding of river channel's geomorphological variation characteristics affected by the outburst flood, and provide a data reference for the

412 analysis of the erosion and accumulation characteristics of the downstream river
413 channel. Especially, with these two relationships, i.e., R-L^* and A_1^*-A_2^*, the boulder bars
414 geometry size could be predicated after a landslide dam formation in the future. Then
415 the new landform after the dam failure could be evaluated. These presentations could
416 contribute to the stream restoration planning, river navigation, and even utilization
417 planning of the boulder bars.

418 Conclusion

419 In this paper, a downstream moveable bed for 4 to 7 times the length of landslide
420 dam length along the channel was set, and through eight flume experiments, 25 boulder
421 bars were formed downstream channel caused by overtopping flow. The boulder bar's
422 formation process and geometry characteristics are studied. The main conclusions are
423 as follows.

424 (1) Boulder bars first appear near dam toes (upstream reaches located on the dam's
425 initial breach sides). Inertia force made sediment accumulate on the opposite banks of
426 the channel bed, resulting in boulder bars' formations downstream. During the landslide
427 dam failure process, the boulder bars' upstream edges are mainly in siltation states. The
428 boulder bars' lengths increase with failure time, mainly caused by boulder bars'
429 upstream edges move upstream. The downstream edges develop slowly and basically
430 near the initial positions. And the developments of boulder bars' downstream edges are
431 much smaller than the developments of boulder bars' upstream edges.

432 (2) During the dam failure process, the lengths varied faster than the widths and

heights of boulder bars. And the boulder bars' lengths along the river are the largest, followed by widths, and lastly the heights when the dam completed failed. The volumes of the boulder bars increase with dam failure, and boulder bars' volume characteristics are consistent with boulder bars' lengths characteristics.

(3) In the experiments, the ratio (R) of boulder bar length to width falls at the range of 8 to 14. There is a nonlinearly relationship between length to width ratio (R) and the dimensionless length of boulder bar (L^*), which could be described as a hyperbolic equation. The dimensionless area (A_1^*) of boulder bar has a linear relationship with the dimensionless area (A_2^*) of the channel cross section, whose slope is about 0.5.

(4) In this paper, 38 boulder bars in the field triggered by four landslide dams' failures were investigated. By comparing the data of boulder bars in field with the boulder bars in the experiments, the distribution and geometric size characteristics of the boulder bars in the field are more consistent with the boulder bars in the experiments, indicating that the experimental results are more reliable.

Author contribution

Xiangang Jiang was responsible for the experiments, article thinking, and writing. Haiguang Cheng was responsible for calculating the article parameters. Lei Gao was responsible for the article's pictures, and Weiming Liu was responsible for checking the full article.

Competing interests

The authors declare that they have no known competing financial interests or
