Abstract.

4D topographic point clouds contain information on surface change processes and their spatial and temporal characteristics, such as the duration, location, and extent of mass movements. To automatically extract and analyze changes and patterns of surface activity from this data, methods considering the spatial and temporal properties are required. The commonly used M3C2 point cloud distance reduces uncertainty through spatial averaging for bitemporal analysis. To extend this concept into the full spatiotemporal domain, we use a Kalman filter for change analysis in point cloud time series. The filter incorporates M3C2 distances together with uncertainties obtained through error propagation as Bayesian priors in a dynamic model. The Kalman filter yields a smoothed estimate of the change time series for each spatial location in the scene, again associated with an uncertainty. Through the temporal smoothing, the Kalman filter uncertainty is generally lower than the individual bitemporal uncertainties, which therefore allows the detection of more changes as significant. We apply our method to a dataset of tri-hourly terrestrial laser scanning point clouds of around 90 days (674 epochs) showcasing a debris-covered high-mountain slope affected by gravitational mass movements and snow cover dynamics in Tyrol, Austria. The method enables to almost double the number of points where change is detected as significant (from 24.2% to 46.8% of the area of interest). Since the Kalman filter interpolates the time series, the estimated change values can be temporally resampled. This can be critical for subsequent analysis methods that are unable to deal with missing data, as may be caused by, e.g., foggy or rainy weather conditions or temporary occlusion. Furthermore, noise in the time series is reduced by the spatiotemporal filter. By comparison to two other point cloud change methods, namely temporal median smoothing and linear interpolation, we highlight the main advantage of our method, which is the extraction of a smoothed best estimate time series for change and associated uncertainty at each location. A drawback of the Kalman filter is that it is ill-suited to accurately model discrete events of large magnitude. It excels, however, at detecting gradual or continuous changes at small magnitudes. In conclusion, the combined consideration of temporal and spatial information in the data enables a notable reduction in the associated uncertainty of quantified change values for each point in space and time, in turn allowing the extraction of more information from the 4D point cloud dataset.

1 Introduction

25 Near-continuous time series of 3D topographic point clouds have recently become readily available through applications in re-
search (Eitel et al., 2016), industry (Industry 4.0, e.g., Pasinetti et al., 2018), and in the public sector (e.g., disaster management,
Biasion et al., 2005). Commonly, terrestrial laser scanners are installed on surveying pillars to regularly (e.g. hourly) acquire
three-dimensional representations of the surrounding topography. To interpret the data for geographic monitoring, especially
in terms of topographic change processes acting on the surface, information needs to be extracted in the form of movement
patterns (Travelletti et al., 2014), objects, (Anders et al., 2020) or clusters (Kuschnerus et al., 2021). This information can then
30 be used by experts to analyze change patterns and properties concerning their underlying causes, predict future events, and
assess immediate dangers.

However, with any measurement taken in the real world, uncertainties need to be considered. In the case of topographic
laser scanning, uncertainty may result in estimated change values that seemingly correspond to a change in the topography of
the involved surfaces, though no real change has occurred. For example, erosion or accumulation with a low velocity is only
35 confidently detectable after a certain period, when the change magnitude grows larger than the random effects introduced by
the measurement.

Two approaches can be combined to handle uncertainty: Statistical tests, such as a t-Test, allow making statements about
random variables by transforming them into thresholds or interval values using a confidence probability. For example, a change
value of 0.01 m may have a 95% probability to be significantly different from zero. In the remaining 5% of cases, the value of
40 0.01 m would be caused by random errors and result in a false positive detection. The measurand (the quantity being measured)
is seen not only as a singular value but rather as a probability density function. An analysis of the cumulative distribution
function (CDF) then gives the relation between the Type I error probability α , (or the specificity of a test $(1 - \alpha)$) and the
corresponding confidence interval. This moves the problem of change analysis or quantification to one of change detection.
Such approaches have commonly been used, e.g. in tunnel deformation monitoring (Van Gosliga et al., 2006).

45 The other approach, alleviating uncertainty, takes advantage of the fact that no two measurements are completely uncorre-
lated. Generally, the closer they are to each other, the more they are alike. In space, this has been described in Tobler's first law
of Geography (Tobler, 1970) and logically extends into time. In the analysis of dense time series of 3D point clouds, this fact
can be used to reduce uncertainty in change detection. Consequently, lower thresholds for detectable change may be derived
while keeping the same significance probability. Change can therefore be detected as statistically significant at lower change
50 values; or with lower change rates. To achieve this reduction of uncertainty, some sort of averaging or aggregation of multiple
measurements of the same quantity into one value is required. This allows for reducing the influence of random errors, but the
smoothing also reduces high-frequency information contained in the data.

Spatial smoothing, i.e. aggregating points spatially before change analysis, reduces the spatial resolution at which change
can be detected. In the widely employed multiscale model-to-model cloud comparison (M3C2) algorithm, a method to com-
55 pare surfaces represented by two point clouds, a search cylinder is used to select and aggregate points of the two epochs before
measuring the distance between them (Lague et al., 2013). This is beneficial over a simple cloud-to-cloud (nearest neighbor)

distance, because point clouds acquired with a laser scanner never sample the surface with the exact same pattern, and therefore no one-to-one correspondences can be established. Additionally, averaging the point positions reduces uncertainty in the position of the surface. A more simple approach, the creation of digital elevation models of differences, also includes spatial averaging by aggregating all points within a raster cell to a single value, but is restricted to a single direction of analysis and cannot account for complex 3D topography. The variance of point distances to the fitted surfaces is typically used as a measure for the uncertainty in the estimated position in elevation models (Kraus et al., 2006) and M3C2 change values (Lague et al., 2013).

In the time domain, measurement series are often interpreted as signals. Signal smoothing is widely used and a multitude of methods have been established. In many approaches, a moving window is employed to aggregate multiple consecutive measurements or samples to remove or reduce outliers. Depending on the aggregation function, different filters are established, and may be mathematically described as 1D convolutions (e.g., kernel-based smoothing, Kim and Cox, 1996). Alternatively, global methods such as Fourier transform may be applied to eliminate high-frequency elements of the signal, resulting in a low-pass filter (Kaiser and Reed, 1977).

To smooth time series, (B-)splines are commonly employed (Lepot et al., 2017). Splines are piece-wise approximations of the signal by polynomial functions. Depending on the degree n of the polynomials, the continuity of derivatives is guaranteed up to order $n - 1$, resulting in smooth estimates. For example, with commonly used cubic splines, the second derivative is continuous. In general, splines are interpolators, meaning they will pass through every data point. In the presence of noise, this might not be justified, and approximative splines utilizing least-squares methods have been presented (Wegman and Wright, 1983). For time series of 3D point clouds, a moving average filter has been successfully used to reduce daily patterns and random effects in time series (Kromer et al., 2015; Eltner et al., 2017; Anders et al., 2019).

The geostatistical prediction method of Kriging (Matheron, 1963; Goovaerts, 1997) has been applied in the analysis of time series of geospatial data (e.g., Lindenbergh et al., 2008). Kriging allows to estimate the uncertainty of the predicted (interpolated) value to separate change signals from noise (e.g., Lloyd and Atkinson, 2001). For example, if the distance between sampling locations increases, the uncertainty for predictions between these locations will also increase, following the variogram derived in the Kriging process.

4D point cloud analyses have employed both spatial and temporal smoothing separately to increase the signal-to-noise ratio of the change signal (e.g., Eltner et al., 2017; Anders et al., 2020). Kromer et al. (2015) combine both spatial and temporal neighbors of a high-frequency time series in a median filter to remove the influence of noisy observations. In this work, we present an approach that similarly combines spatial and temporal smoothing by employing a Kalman filter. In contrast to a median filter, the Kalman filter is able to consider observations having unique uncertainties, as it optimally combines these observations, and gives an estimate of the uncertainty of the result. Kalman filters are mathematical descriptions of dynamic systems and are commonly used, e.g., in navigation (Cooper and Durrant-Whyte, 1994) or traffic congestion modeling (Sun et al., 2004). Typical applications of Kalman filtering include sensor integration settings, e.g. in the integration of GNSS and IMU (inertial) measurements, when the target trajectory is smooth. A famous application was the guidance computer in the

Apollo missions (Grewal and Andrews, 2010). Kalman filters are commonly used today in trajectory estimation, e.g. for direct georeferencing of airborne laser scanning data (El-Sheimy, 2017).

In our case, the observations are bitemporal point cloud distances. In a Bayesian sense, each observation provides prior information on the system. The Kalman filter combines this information in a joint probability distribution to obtain estimates for the target variables that are, in general, more accurate (less uncertain) than the original observations. When estimates of position, velocity, and acceleration have been made, they can even be propagated into the future, beyond the newest measurement (Kalman, 1960).

We use the Kalman filter on change values between each epoch and a reference epoch, to obtain a smoother, less uncertain time series of change for each spatial location. To obtain accurate uncertainty estimates for the change values, we apply M3C2-EP (Winiwarter et al., 2021), a method that allows the propagation of measurement and alignment uncertainties in bitemporal point cloud analysis to the obtained change values, but different methods of uncertainty quantification can also be imagined. M3C2-EP contains an aggregation step derived from M3C2, where spatial neighbors are collected to create a local planar model of the surface. Using this as an input to Kalman filtering leads to spatial and temporal smoothing, where the spatial smoothing step acts as a Bayesian prior to the temporal smoothing step.

To show the applicability of our method, we analyze a synthetic scene and a dense (tri-hourly) time series of terrestrial Laser Scanning (TLS) point clouds acquired in Vals, Tyrol (cf. Schröder et al., 2022). Permanent TLS surveys were carried out to ensure the safety of workers repairing the road and moving debris after a rockfall in 2017. We showcase how our method allows extracting interpretable information from a large amount of data present in the time series of 674 epochs with about 0.6 - 1.7 million points (after outlier removal and filtering) each.

We further show how the smoothed time series can be used to improve the results obtained with established clustering methods, namely K-Means clustering, which has been applied to 4D point cloud data by Kuschnerus et al. (2021) to identify change patterns on a sandy beach.

The contribution of our research is twofold: First, we combine the existing methods of M3C2-EP point cloud change quantification including the quantification of associated uncertainty with a Kalman filter to take advantage of the temporal domain, resulting in lower detection thresholds and less noise in the change extracted from the time series. Second, we show how different smoothing methods for topographic point cloud time series influence the results of clustering to derive change patterns in the observed scene.

2 Datasets

We investigate the performance of our method on two different datasets: a real scene featuring surface erosion and snow cover changes on a debris-covered slope, and a synthetic scene created from a 3D surface mesh model with known deformation properties.

2.1 Vals

For a real use case, we are using TLS data acquired over approx. three months, totaling 674 epochs from 2021-08-17 at 12:00 to 2021-11-15 at 18:00 (all times are local times) in Vals, Tyrol, Austria (WGS84: 47°02'48" N 11°32'08" E). The scene was monitored in an effort to ensure safety for the valley following a rockfall event that occurred three and a half years prior, namely on 24 December 2017. A road located immediately beneath the rockfall slope was covered in 8 m of debris, and a total rock volume of 116,000 m³ was relocated (Hartl, 2019). Data was recorded using a RIEGL VZ-2000i TLS permanently installed on a survey pillar in a shelter on the opposite slope about 500-800 m from the area affected by the rockfall.

As the point clouds are not perfectly aligned to each other (Schröder et al., 2022), retroreflective survey prisms located around the rockfall-affected area were measured using RIEGL's 'prism fine scan' measurement program. These scans were carried out every hour in between regular, tri-hourly scans (e.g., at 13:00, at 14:00, and then again at 16:00, with point cloud acquisition of the full scene in high resolution at 15:00). The positions of the prisms were extracted following Gaisecker and Schröder (2022), using two amplitude thresholds. The angular position of the prisms was calculated from the points with the highest amplitude, whereas the ranging component was calculated based on a plane fit through the points around these maxima. Comparisons with a total station and an EDM calibration line showed accuracies for this prism detection of a few mm to < 2 cm at ranges of up to 1,200 m (Gaisecker and Schröder, 2022).

We define the epoch 2021-08-17 at 11:00 as global reference (the 'null epoch') and derive transformation parameters using the prism positions. In addition to the parameters for a 7-parameter Helmert transformation, a full covariance matrix is derived through adjustment computation. The transformations are subsequently applied to the full high-resolution scans by using the respective previous prism fine scan (i.e., prism scan one hour before full scan).

During this period, both natural, as well as anthropogenic surface changes, were captured. To investigate the benefits of full 4D point cloud analysis, we focus on relatively small-magnitude and long-duration changes. We, therefore, select an area of interest consisting of the debris-covered slopes excluding the valley, where excavator works lead to sudden and high-magnitude changes (Fig. 1a). For these types of surface changes, simple bitemporal change quantification typically suffices. On 2021-11-05, heavy snowfall occurred in the area, which led to large displacement values in a short time. While most of this snow melted again by 2021-11-15, an avalanche led to an accumulation of snow, which persisted throughout the observation period. This deposition can be seen in Figure 1b on the bottom right in red (marked as i).

The dataset presented here is part of a continuous monitoring campaign, which was in operation in three subsequent setups, one in 2020 and two in 2021, and of which we consider the third setup. It was designed to collect data for various research and development activities regarding the deployment of long-range laser scanners within a remotely controlled, web-based monitoring system from an engineering geodetic perspective. In addition to the laser scanner, inclination sensors on the pillars (PC-IN1-1° from POSITION CONTROL) and various meteorological sensors were used in the shelter. For the first two setups, a total station (LEICA TM30) and additional meteorological sensors placed throughout the area of interest were employed. The additional measurements are used to verify systematic error influences on the result results and align well with the transformation parameters extracted from the prism scans (Schröder et al., 2022).

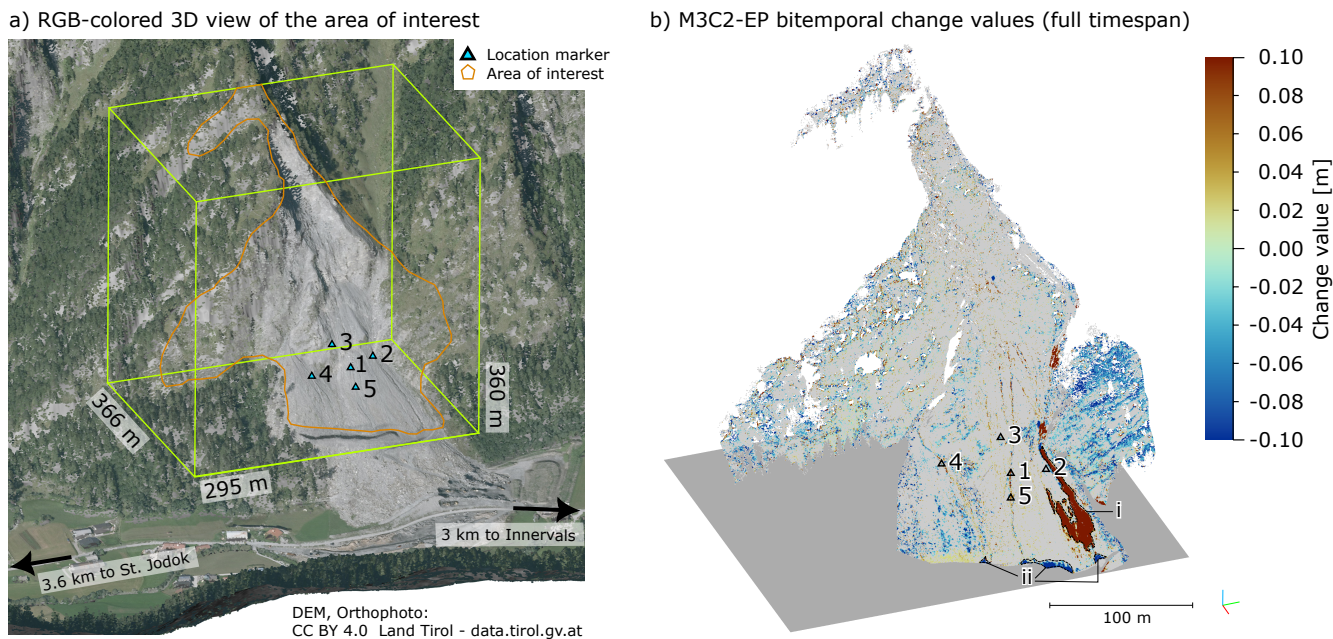

Figure 1. a) 3D perspective view of the study area (WGS84: 47°02'48" N 11°32'08" E). The debris-covered slope can be seen in gray. The point cloud which is used for analysis and which is shown in subsequent plots is outlined in orange, and singular locations investigated later on are labeled as 1-5. b) Bitemporal differences estimated with M3C2-EP over the full timespan. The change of > 0.1 m on the lower right is packed snow after an avalanche (i). The blue edge at the bottom is erosion due to an anthropogenic break line in the terrain (ii).

In addition to dataset alignment, preprocessing consisted of the removal of outliers and vegetation points using the statistical outlier filter ($k=8$, multiplier=10.0; Rusu et al., 2008) and the SMRF filter (cell size=0.5 m, slope=2; Pingel et al., 2013), as well as a filter on the waveform deviation (≤ 50), all implemented in PDAL (PDAL Contributors, 2018). The parameter file is supplied with the code (see *Code availability* statement).

160 In these data, we quantified bitemporal change magnitudes and uncertainties using M3C2-EP (presented in detail in Sect. 3.1). We used the same normal vectors for all epochs, which were calculated using a 5 m search radius on the null epoch. The M3C2 distancing was carried out on a subset of the null epoch (the “core points”) created by distance-based subsampling in Cloud-Compare, reducing the number of points to around 555,000 (min. point spacing: 0.25 m). The projection radius was 0.5 m and the maximum cylinder length was 3.0 m. With a 0.5 m search radius, we ensured that a sufficient number of points were
165 found for the central area of interest (the debris-covered slope). Fig. 2a shows a histogram of the number of points found in the cylinder over all epochs.

To estimate the ranging uncertainty and its variation over time, we again used the prisms installed in the scene. After extracting them from the full high-resolution scans using thresholding on the returned amplitude and approximate locations of the prisms, a planar fit was carried out. The variance of the orthogonal distances to this plane was then extracted for each
170 prism and averaged for each epoch. The resulting precision measure, ranging from 0.004 m to 0.006 m (standard deviation),

a) Distribution of number of points

b) Point count in M3C2-EP search cylinder (r=0.5 m)

Figure 2. a) Histogram over points found in each M3C2 search cylinder for the respective second epoch of all bitemporal comparisons. b) 3D view of the number of points found in the M3C2 search cylinders for Epoch 2021-11-15 18:00. The search radius of 0.5m was chosen such that most areas of interest (especially the debris-covered slope, cf. Fig. 1a) are well-represented in most epochs.

was used as an input for M3C2-EP for each epoch, respectively. Epochs, where no prisms were detected due to precipitation, were assigned the maximum ranging uncertainty value of 0.006 m. For angular uncertainty in azimuth and elevation, we used 0.0675 mrad, derived from the beam divergence as presented in Winiwarter et al. (2021) (again values of single standard deviation respectively).

175 2.2 Synthetic scene

To validate and compare different methods of 4D point cloud processing, we create a synthetic 4D point cloud dataset. A mesh model of a 100 m × 100 m plane is created for 40 epochs by creating points in a regular 1 × 1 m grid and computing a Delaunay triangulation. Different change values are then applied over time. The magnitude of the change values ranges from 0.00 m to 0.05 m (linear gradient), and the temporal pattern is modeled by a sinusoidal function (Eq. 1). This pattern is chosen to obtain
180 a non-uniform yet continuous velocity and acceleration.

$$f(t) = (\sin(t) + 1)/2 \quad \text{for } t \in [-\pi/2, \pi/2], \text{ mapped to days 0 to 40} \quad (1)$$

We apply displacements orthogonally to the mesh surface and rotate the mesh to represent a slope of 60°. Subsequently, we perform virtual laser scanning from a single TLS position located 300 m away from the plane center, using the specifications of

a RIEGL VZ-400 TLS implemented in the HELIOS++ virtual laser scanning simulator (Winiwarter et al., 2022). The resulting point spacing ranges from 0.63 m to 1.04 m. To simulate alignment errors, we draw random transformation parameters for a 7-parameter Helmert transformation from a normal distribution ($\mu = \mathbf{0}, \sigma_x = \sigma_y = \sigma_z = 0.002\text{m}, \sigma_\alpha = \sigma_\beta = 0.001^\circ, \sigma_\gamma = 0.005^\circ, \sigma_m = 0.00001\text{ppm}$). The uncertainty values are derived to be similar to the maximum values encountered in the real dataset.

For each epoch, a different transformation is then applied to the point cloud. Subsequently, M3C2-EP was used to quantify bitemporal surface changes and associated uncertainties, where the same normal distribution parameters were used as covariance information for the transformation. The full point cloud of the null epoch (no deformations) was used as core points, and the normal vector was defined to be the plane normal vector of the original mesh for all points. For M3C2-EP and M3C2 distance calculations, a search radius of 1 m was used, resulting in an average of 10 points falling within the search cylinder.

3 Methods

In this section, we

1. show how measurement uncertainties can be propagated to bitemporal change values using M3C2-EP (Sect. 3.1),
2. present a baseline method of time series smoothing using a temporal median filter (Sect. 3.2),
3. introduce the Kalman filter and the corresponding equations (Sect. 3.3), and
4. use clustering to identify areas of similar change patterns (Sect. 3.4).

The full processing workflow is shown in Figure 3.

3.1 M3C2-EP point cloud change analysis

To enable analysis of the time series, we convert the 4D point cloud into a series of change values at selected locations (the “core points”). As we want to rigorously consider uncertainties in order to separate noise from change signal, we employ multiscale model-to-model cloud comparison using error propagation (M3C2-EP, Winiwarter et al., 2021). This method considers measurement and alignment errors of the laser scanning observations to arrive at an estimate of the uncertainty for obtained change values. In turn, such uncertainties can be used in statistical tests on the significance of change values (Lague et al., 2013). Typically, the test is expressed as a spatially varying Level of Detection, which is a measure of how large a change value has to be in order to be attributed to actual change. The Level of Detection depends on a significance level, which is typically set to 95% (Lague et al., 2013; James et al., 2017). In Winiwarter et al. (2021), we showed how the Level of Detection can be derived from knowledge on the sensor accuracies (e.g. from the sensor data-sheet) and alignment accuracy (using an ICP alignment; Besl and McKay, 1992) by error propagation. In addition, the individual measurements are weighted by their respective uncertainties to arrive at an unbiased estimate for the change values. We refer to this method as M3C2-EP, as it extends the M3C2 algorithm by error propagation.

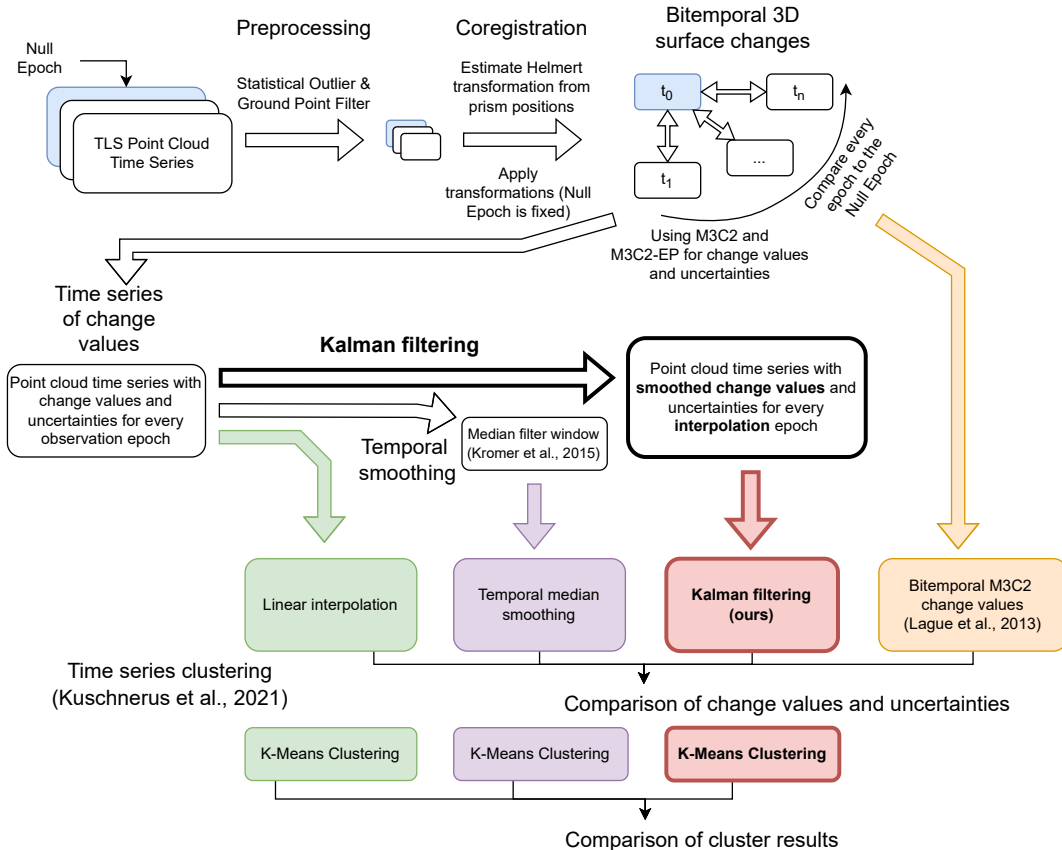

Figure 3. Flowchart of the workflow undertaken in this research. The novel method is highlighted using bold arrows and boxes. Three time series-based and one bitemporal method are compared. Additionally, we use K-Means clustering based on (Kuschnerus et al., 2021) on the multitemporal methods and compare the resulting clusters.

The error propagation is carried out by taking the mathematical model of how point cloud coordinates are obtained from transforming measured quantities (range, azimuth angle, and elevation angle) and computed quantities (transformation parameters). This model is then linearized by a Taylor approximation. Following Niemeier (2001), the uncertainty in the Cartesian target coordinates (C_{xyz}) can then be estimated by multiplying the linear approximation model in the form of the Jacobian matrix A onto the covariance matrix of the input quantities $C_{r\varphi\theta}$ from the right, and the transpose of the Jacobian from the right, respectively (cf. Eq. 2).

$$220 \quad C_{xyz} = A^T \cdot C_{r\varphi\theta} \cdot A \quad (2)$$

While M3C2 itself also quantifies the uncertainty of the estimated bitemporal differences, this estimate is derived from the data distribution and influenced by non-orthogonal incidence angles, and object roughness within the M3C2 search cylinder (Fey and Wichmann, 2017; Winiwarter et al., 2021).

225 The M3C2-EP point cloud distance measure hence allows transferring uncertainty attributed to each of the original measurements, i.e., laser ranges and angular measurements, to uncertainty in point cloud change for every individual core point. Thereby, the obtained M3C2-EP distance and its spatially heterogeneous uncertainty are representing our knowledge of the point cloud change itself, not of the measurements. This property allows us to use the distance for following analyses.

We resample the time series to a regular dataset by using linear interpolation to fill in missing data points, e.g. caused by temporary occlusion in the observed scene.

230 **3.2 Temporal median smoothing**

As a baseline method to compare the Kalman filter result with, we apply a temporal median filter for smoothing the time series, as presented by Kromer et al. (2015). In this 'sliding window' approach, the median function is applied to all change values in a temporal window. The median function has the advantage that the exact points in time when change is measured, will not be altered. Furthermore, outliers can be completely removed, as single spikes in the input time series will not propagate 235 to the smoothed result. However, the median function is not differentiable, nor does it consider different weights in the inputs (which may be derived from measurement uncertainties). Therefore, the error in the quantified differences cannot be easily propagated. Furthermore, a window size needs to be chosen. If chosen too large, temporary surface alterations, such as a deposition of material followed by erosion, will be smoothed out. For too small windows, the benefit of smoothing in terms of noise elimination becomes negligible. To account for this, the window must be chosen smaller than the expected change rates 240 (Kromer et al., 2015) thereby depending on the change process that is investigated.

3.3 Kalman filter and smoother for change analysis

We present the use of a Kalman filter, which can be used to incorporate multiple observations (in our case the change values for each epoch, quantified along the local 3D surface normals using M3C2-EP, cf. Section 2.1) and obtain predictions about the displacement at arbitrary points in the time series, analogous to the median smoothing. A main advantage of the Kalman filter is 245 its potential to consider uncertainties both in the inputs, allowing for observations of different qualities to be combined, as well as in the output. Here, an uncertainty value for each point in time is estimated, allowing for statistical testing of the obtained smoothed change values (as in the M3C2 for bitemporal change values). While the Kalman filter is commonly employed for smooth, continuous time series, not all changes are smooth in our case of 4D point cloud change analysis. The limitations arising thereof are discussed later (Section 5).

250 While the Kalman filter is an "online" method, which allows updates by adding new data points, we consider a post hoc analysis and assume that all measurements are available at the time of analysis. This allows us not only to consider previously observed change values at a given location, but also to incorporate future observations. To that end, we can make use of the full 4D domain of the dataset.

The Kalman filter can be seen as a temporal extension of adjustment computation. It allows the integration of measurements
 255 over time into a *state* vector x_t describing the system at a specific point in time t . This state can contain information on position,
 velocity, acceleration, or other quantities. For the propagation from one state to the next, the so-called state transition matrix
 F is used¹. It is a linear approximation of how the state changes from one point in time to the next, based on all the values in
 the state. The following examples of the matrices and vectors correspond to the implementations in the method presented in
 this paper. For a state vector containing the position, the velocity, and the acceleration of an object, the state transition matrix
 260 is given in Eq. 3:

$$F = \begin{pmatrix} 1 & \Delta t & \frac{\Delta t^2}{2} \\ 0 & 1 & \Delta t \\ 0 & 0 & 1 \end{pmatrix} \quad (3)$$

Here, the next position (at $t_1 = t_0 + \Delta t$) derives from the current position (at t_0), onto which the velocity multiplied by the
 time step and the contribution of the acceleration are added. The diagonal entries of 1 ensure that the current position, velocity,
 and acceleration are transferred to the next point in time. The transition of the state vector from t_0 to t_1 is done using the
 265 prediction update equation (Eq. 4) in the prediction step:

$$x_{t+\Delta t} = F \cdot x_t \quad (4)$$

A measurement may subsequently be introduced in the so-called correction step. For this, a linear approximation of the
 measurement function H is required. A measurement consisting only of the position of the object, or in our case, the change
 magnitude at a position, results in a matrix H as shown in Eq. 5. The velocity and acceleration are not observed, so the second
 270 and third elements are zero. One could also imagine including physical measurements of velocity, e.g., using a Doppler radar
 system, or of acceleration, such as from an inertial measurement unit. In our application of terrestrial laser scanning repeated
 from a fixed position, such measurements are typically not available when investigating geomorphic surface changes.

$$H = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \quad (5)$$

The step size of the update Δt is not necessarily equal to the measurement interval, leading to prediction steps without
 275 correction steps. This allows the estimation of the state for points in time where no measurement was recorded, based on
 previous measurements only. State estimation is not limited to interpolation but also allows extrapolation into the future.

As in adjustment computation, every measurement in the Kalman filter is attributed with uncertainties, herein presented by
 the measurement noise matrix R . In our application, we use the uncertainty in point cloud distance obtained by M3C2-EP for
 each epoch's change value.

¹ we use the nomenclature of the Python package "FilterPy" and the accompanying book "Kalman and Bayesian Filters in Python" (Labbe, 2014)

280 Finally, the process noise matrix Q represents how much uncertainty is introduced in each prediction step, and therefore depends on the time step Δt . By transitioning from t to $t + \Delta t$, the state vector becomes more uncertain, unless new measurements are introduced. Q is representative of the system's ability to change outside of the filter constraints. We can, for example, assume a system with constant acceleration. However, in reality, this is not the case, as, e.g., in gravitational mass movement processes, friction coefficients between topsoil and stable subsurface will change for different temperatures, moisture, and
 285 other parameters, so we allow for an adaptation of the acceleration over time.

A common approach to model process noise is discrete white noise. Here, we define the variance of the highest-order element (e.g., the acceleration) as σ^2 and calculate the effect of this variance on the other elements of the system's state (i.e., velocity and position), cf. Equation 6, following Labbe (2014, Chapter 7). In consequence, the state of the system becomes less certain over a longer time and can be made more certain by introducing a new measurement with adequate uncertainty. For example,
 290 in the case of near-continuous TLS, change can be estimated one day into the future after having acquired one week of hourly measurements. This allows estimating whether a larger interval between the measurements still fully represents the expected changes.

$$Q_{xva} = \begin{pmatrix} \frac{\Delta t^4}{4} & \frac{\Delta t^3}{2} & \frac{\Delta t^2}{2} \\ \frac{\Delta t^3}{2} & \Delta t^2 & \Delta t \\ \frac{\Delta t^2}{2} & \Delta t & 1 \end{pmatrix} \sigma_a^2 \quad (6)$$

The exact choice of this process noise model, especially the choice of the value of σ^2 , is critical to the success of Kalman
 295 filtering. Therefore, we compare different choices for σ^2 , investigate the resulting time series and pick one where the overfitting of the measurement data is reduced while the model still is flexible enough to represent most of the subtle changes apparent in the dataset appropriately. For models where the state vector only includes velocity and displacement, or just the displacement value itself, the white noise models are given in Equations 7 and 8, respectively.

$$Q_{xv} = \begin{pmatrix} \Delta t^2 & \Delta t \\ \Delta t & 1 \end{pmatrix} \sigma_v^2 \quad (7)$$

$$300 \quad Q_x = \sigma_x^2 \quad (8)$$

To initialize the iterative Kalman filter algorithm, starting values for the state and its uncertainty are required. As we start the time series at the null epoch with zero change, we define the initial state vector to be $(0, 0, 0)^T$. Because the change values are quantified with respect to this null epoch, we can be certain that there is no change in the null epoch (by definition) and therefore set the variance of the position to be $\sigma_x^2 = 0 \text{ m}^2$. We allow the velocity and acceleration to take other values, and set
 305 them to $\sigma_v^2 = \sigma_a^2 = 1.0 \text{ m}^2/\text{day}^2 / \text{m}^2/\text{day}^4$. The exact choice of these values is negligible, as long as they are larger than the expected magnitude of velocity and acceleration (Labbe, 2014, Chapter 8).

Running the Kalman filter then results in estimates of the state and its uncertainty for each point in time, based on all previous states and measurements. This is referred to as a "forward pass", as calculation on a time series starts with the first measurement and then continues forward in time (Gelb et al., 1974, p. 156). It is, however, also possible to include consecutive states and measurements, which can decrease uncertainty and lead to a better estimate of the state as, e.g., outliers are much more easily detected compared to just using a forward pass. The Rauch-Tung-Striebel (RTS) smoother is a linear Gaussian method (such as the Kalman Filter itself) to consider consecutive states of the system (Rauch et al., 1965). It operates backward on the time series, starting with the latest Kalman state estimate ("backward pass"). The final result is then a smoothed, estimated time series, making use of all of the available information (Gelb et al., 1974, p. 169). For discrete, instantaneous changes, the backward pass further ensures that the resulting time series will have a change of curvature temporally collocated with the change event, allowing for precise extraction of the event's temporal location. For more detail on the RTS smoother and its alternatives, the reader is referred to in-depth literature (e.g., Gelb et al., 1974; Labbe, 2014). In the results, we always show the RTS smoother estimates.

3.4 Clustering and identification of change patterns

To represent the information contained in the time series in a static map, we use a clustering approach. Here, data points with similar features are aggregated into groups or clusters. Due to its unsupervised nature, no training data is required, which would often be lacking in the case of topographic monitoring of scenes featuring variable, a-priori typically unknown surface dynamics. Instead, the resulting clusters can be analyzed with respect to their size, location, and magnitude, as well as visually by their shape in 3D space, and ultimately attributed to certain process types. We use a K-Means clustering, which has been found to perform well for the identification of change patterns in 4D point clouds by Kuschnerus et al. (2021). As feature space, the estimated time series of change values for each core point, i.e., a list of displacement values over time, is used. The spatial component, i.e., the location of the core point in the scene, is not included in the clustering, meaning that any spatial patterns emerging in the clusters are solely due to similar time series. We investigate how the different time series lead to different cluster results in Section 4.4.

In K-Means, the clustering algorithm iteratively minimizes the total sum of all distances from data points to the centroids of k clusters (Hartigan and Wong, 1979). As the distance is euclidean, all dimensions are expected to be in the same unit and scale. An important parameter is the selection of the number of clusters. We, therefore, create segmentations with 4, 8, 10, and 12 clusters and compare them visually. The goal is to detect all groups of different processes acting on the scene while avoiding splitting up groups of the same processes into subclusters (over-segmentation).

4 Results

We first present the impact of different model and parameter choices on the clustering and change detection results, before comparing our resulting change time series with the ones of linear interpolation, temporal median smoothing, and bitemporal

M3C2-EP (cf. Fig. 3). The results of the synthetic experiment are presented subsequently. Finally, clustering is carried out. The results are then discussed in Section 5.

340 4.1 Impact of model and parameter choice

We tested three different model choices for the Kalman filter and a number of parameters for each model. The different models increase in complexity and dimensions of their state vector: The first model simply tracks the displacement value itself. The assumption for this model is that the allowed variance (σ) representing how the state may change over time is sufficient to explain the displacement changes. The second model adds velocity as a component to the state vector and imposes
345 the restriction of the variance on the velocity component. According to Eq. 7, the variance in the displacement value is then derived via error propagation from the variance in velocity. Finally, a model including displacement, velocity, and acceleration is created. The motivation for this model is a constant, gravitational acceleration, governing the surface erosion processes observed in the scene. However, this motivation assumes that friction coefficients also change continuously throughout the scene.

350 For each of the three models, we experimented with the process noise variance σ . As shown in Fig. 4, larger values lead to a more flexible time series model, whereas smaller values ensure a more smooth temporal trajectory. For discrete events, larger values lead to ringing effects, especially with the higher-order models that include velocity and acceleration. The choice of σ also influences the achievable Level of Detection: With a smaller σ value, the Level of Detection decreases, as subsequent measurements are considered to be more correlated to each other. This is reflected by the width of the error band in the plot.
355 Generally, lower values in σ lead to more smoothing and lower Levels of Detection.

To find appropriate values for σ for each of the models, the following options were investigated: For the displacement-only model (Order 0), values of 0.0002 m, 0.0005 m, 0.001 m, 0.002 m, and 0.005 m were compared (Fig. 4a). The goal was to recover processes exhibiting smooth displacements while avoiding fitting any daily patterns, which we attribute to atmospheric effects in our case. We, therefore, selected 0.0005 m as the value for subsequent analyses of our example application. Similarly,
360 for the velocity-based model (Order 1), we investigated values of $\sigma = 0.002$ m/day, 0.005 m/day, 0.01 m/day, 0.02 m/day and 0.05 m/day (cf. Fig. 4b). Here, we chose $\sigma = 0.02$ m/day to be most appropriate for our use case. In the case of the acceleration-based model (Order 2), we compared values of 0.0005 m/day², 0.001 m/day², 0.002 m/day², 0.005 m/day², 0.01 m/day², and 0.02 m/day² (cf. Fig. 4c), and selected $\sigma = 0.002$ m/day² to be optimal. While Fig. 4 only shows the retrieved trajectories for one specific location, our investigation was carried out for all locations shown in Fig. 5, and similar results were obtained for
365 these locations (always excluding the sudden changes induced by snowfall and avalanche events).

For sudden changes that result in a 'step function'-like trajectory, smaller values of σ strongly smooth out the trajectory of the event. While these trajectories clearly do not represent the actual change happening, the event can still be located temporally by means of the change of curvature. In Figure 4, all estimated trajectories intersect at their change of curvature points on 2021-10-05.

370 With increasing order of the model, the smooth trajectories are more oscillating. For the model of order 2 (Fig. 4c), this can be seen especially after the sudden change on 2021-10-05. Here, a model with a comparatively high dampening ($\sigma =$

Comparison of Kalman filter models

a) Order 0 model (x)

b) Order 1 model (x, v)

c) Order 2 model (x, v, a)

Figure 4. Retrieved Kalman smoother estimates for three different models: a) using only the displacement x , b) using the displacement and the velocity v , and c) using the displacement, the velocity, and the acceleration a in the model. For each model, different choices for the variance σ in the state vector were tested. The final choices, manually picked to have the largest value that does not follow daily signals, are highlighted in bold font. The location of these time series is labeled '1' in Fig. 1. The levels of detection at 95% significance are shown with the thin, dotted lines in the respective colors. Note how lower values of σ lead to lower levels of detection, and more smoothing in the estimated displacement trajectories. The plots are cut off at 2021-11-03, just before the main avalanche event, as this event's magnitude exceeds the axes limits.

0.002 m/day²) is required to avoid the oscillations, in turn limiting the ability to adapt to actual changes in the data. To further showcase the suitability of different models for different locations and corresponding change types, we present the trajectories obtained with the models of orders zero, one, and two and the respective choices of state variance σ for selected locations in the scene in Figure 5. The locations are highlighted in Figure 1. For subsequent analyses, we focus on the order 1 model, as the order 2 model exhibits ringing artifacts at the discrete events, and the order 0 model does not follow the change signal sufficiently well.

4.2 Comparison with other methods

To investigate the performance of the Kalman filter within the field of 4D change analysis methods, we ran analyses using two other methods on our dataset (cf. Fig. 3). In Figure 6, we present the trajectories obtained by (i) linear interpolation of subsequent M3C2 distances, (ii) temporal median smoothing following Kromer et al. (2015) with two different window sizes, and (iii) our method for selected locations, which are marked in Figure 1.

An important result of the Kalman filter is the quantification of the Level of Detection, which we compare to the Level of Detection of the bitemporal M3C2 with error propagation. In Fig.7, we show the relative number of observations (for epoch-wise bitemporal M3C2-EP) respectively the relative amount of time over the full interpolated Kalman filter result where the displacement magnitude is larger than the associated Level of Detection for each core point. Generally, larger values mean earlier detection of change of any type. It can be clearly seen that the Kalman filter shows more changes as significant than the bitemporal approach, comparing each epoch individually to the null epoch.

We show the locations of points where change is detected with only the bitemporal approach, where it is detected with multitemporal Kalman filtering, and where it is detected with both in Figure 8b. Approximately 26.92% of the core points in the study area were attributed with significant change when using the multitemporal approach but not with the bitemporal approach. This mostly concerns areas on the lower slope (colored in blue), where the magnitudes are between 0.02 and 0.06 m from deposited snow. In contrast, about 4.26% of the core points were attributed with significant change in the bitemporal analysis, but not for the multitemporal case. Figure 1b shows the change values obtained with bitemporal M3C2-EP, when not making use of the full time series, for comparison.

4.3 Results on synthetic data

For the real dataset, there is no validation data or other area-wide reference data with a much higher accuracy available, as TLS is considered to be the “gold standard”. This means that we cannot investigate whether the detected change is actual change. We, therefore, employed a synthetic scene with exactly known displacement to study the behavior of our method. For the analysis, we followed the same approach as with the real data, i.e., selecting a proper value of σ for the Kalman models of zeroth, first, and second order based on visual interpretation of the estimated trajectories. Additionally, for the synthetic data, we can quantify the residuals to the true displacement. Table 1 shows these mean residuals for different order models and different choices of σ , which are compared with the residuals from temporal median smoothing (higher by approx. a factor of 2) and linear interpolation (higher by a factor of 3)

Comparison of Kalman models of different order

Figure 5. Estimated Kalman smoother trajectories for models of different order: Order zero (displacement only) in blue, order one (displacement and velocity) in red, and order two (displacement, velocity, and acceleration) in yellow. The scale of the y-axes is adapted to the change magnitudes at the respective locations, but the horizontal grid lines are always spaced by 0.01 m to facilitate comparison. The locations shown represent different combinations of surface change-inducing processes. The levels of detection at 95% significance are shown with the thin, dotted lines in the respective colors. To avoid over-representation due to the high magnitude, the snowfall period and subsequent avalanche event on 2021-11-04 are excluded from display. In subfigures a, b, d, and e, the onset of this event in the Kalman smoother estimate can be seen at the very right. Subfigure c represents a location at an almost vertical rock face, where no snow is accumulated. The subfigures correspond to the following numbers in Fig. 1: a - 1, b - 2, c - 3, d - 4, and e - 5.

Comparison of multitemporal change quantification

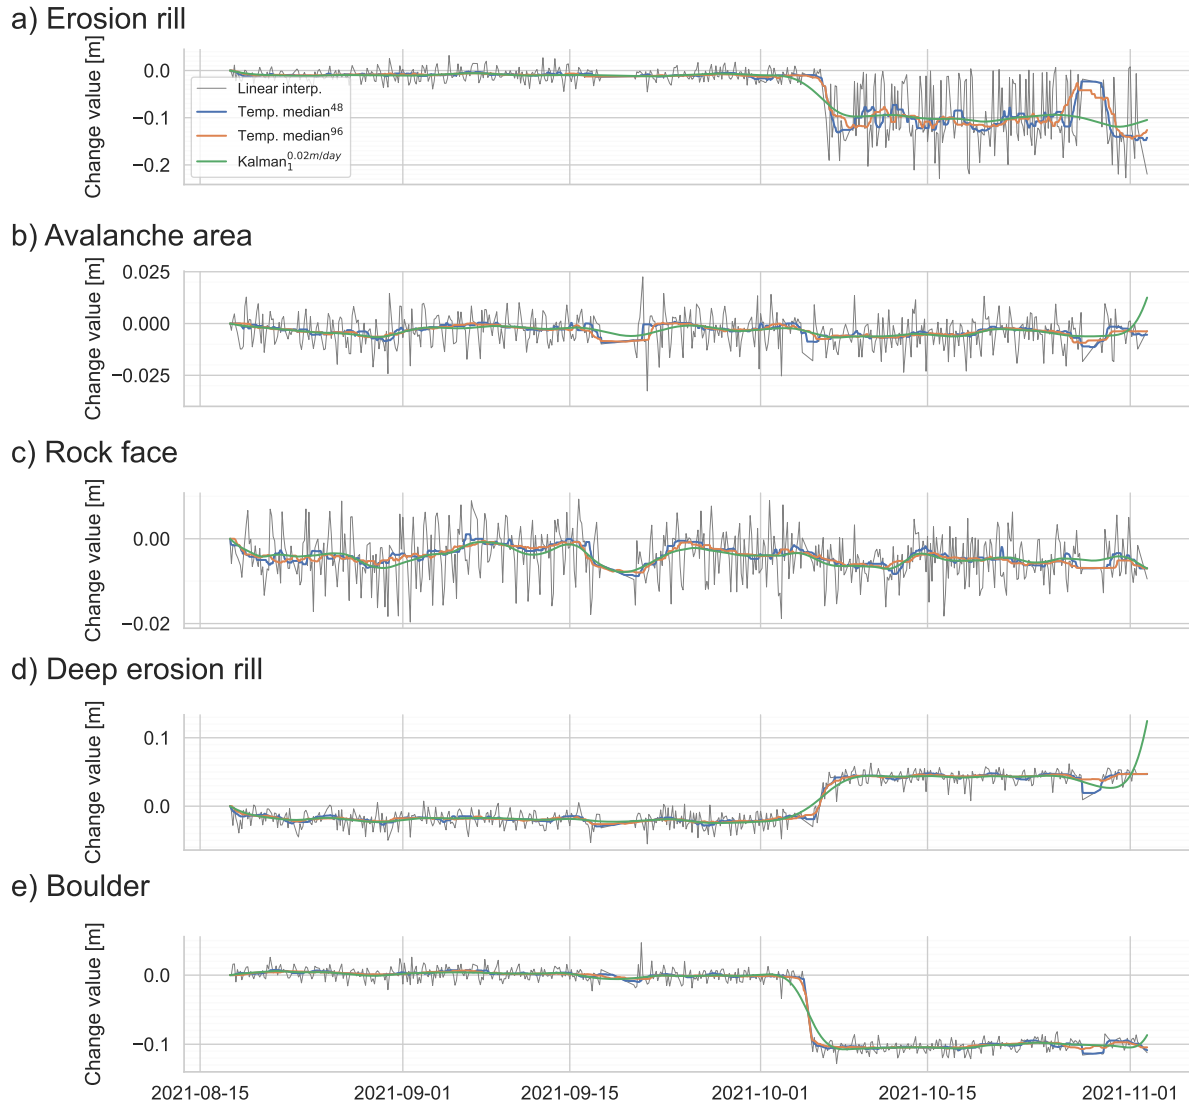

Figure 6. Comparison of different temporal smoothing methods: Linear interpolation (grey), temporal median with 48 hours (blue) and 96 hours (orange) filter size, and an order 1 Kalman model (green). To avoid over-representation due to the high magnitude, the snowfall period and subsequent avalanche event on 2021-11-04 are excluded from display as in Figure 5. The subfigures correspond to the following location numbers in Fig. 1: a - 1, b - 2, c - 3, d - 4, and e - 5.

a) Bitemporal M3C2-EP change detection

b) Multitemporal Kalman-filter change detection

Figure 7. Percentage of time over the full timespan where change was detected (displacement value larger than the respective level of detection). The results from the bitemporal detection (a) show most points with only minimal detected change (<10%), with a few exceptions at the bottom edge and in the avalanche-affected area on the bottom right. In comparison, the multitemporal change (b) lowers the level of detection so that many points, especially close to the erosion rills in the lower part of the slope, show significant change over >50% of the full timespan (in shades of green).

405 In addition, we show the alternative models of linear interpolation and temporal median smoothing for two locations at the extremes (zero displacement and maximum positive/negative displacement) in Figure 9. The detected change at the end of the simulated 40-day change process is shown in Figure 10, where the different levels of detection result in a large difference in terms of detectable change.

4.4 Clustering of change signal

410 To assess the influence of filtering on subsequent analyses, we use the estimated time series of change values to cluster the core points following the approach by Kushnerus et al. (2021). As the number of clusters is an important parameter in any clustering approach, we visually inspect the results of clustering the Kalman smoothed time series (order 1 model) for 4, 8, 10, and 12 clusters (Figure 11). As the number of clusters increases, a larger number of patterns become visible. For our use case, we choose a cluster number of 10, and compare the results of clustering from different time series analysis methods in
 415 Figure 12. Additionally, we include the Kalman models of orders 0 and 2 for comparison. Comparing Figures 12a and b to Figure 11c shows the clusters resulting from the Kalman models of different order. The most apparent difference is that the order 0 model (Fig. 12a) assigns the lower slope to cluster 8, while the other two models assign it to cluster 9. As the clusters

Figure 8. a) Change magnitudes resulting from multitemporal analysis (smoothed Kalman estimates using the order 1 model). The values displayed are the magnitudes at the end of the investigation period. Points where the magnitude is lower than the $LoDetection_{95\%}$ are coloured in grey. b) Differences between bi- and multitemporal change detection. Yellow points represent locations where change has been detected as significant by both bi- and multitemporal analysis, red points are locations where change has only been detected in the bitemporal comparison, and blue points show where the multitemporal analysis enabled to detect significant change that was not detected by the bitemporal method. Subfigure b is a comparison of Subfigure a with Fig. 1b (bitemporal changes for the last to the first epoch in the time series).

are ordered by size, we can conclude that more points are grouped with the lower slope in the order 1 and 2 models than in the order 0 model. In terms of the other clusters, the results are quite similar. All of them clearly show the areas of snow deposit
 420 after the avalanche event in two shades of blue, and pick up the central erosion rill in green. Furthermore, the lower slope is clearly separated from the upper slope, where snow did not accumulate.

Comparing the results from the temporal median model (using a window size of 96 hours) to the Kalman filter, a less clear segmentation is observed for the temporal median model on the central slope (cluster 8) where two erosion rills cross the segment. In the Kalman model, especially of order 1, this segment is much more clearly represented. This behavior is even
 425 more pronounced when comparing the Kalman model results to the ones obtained from linear interpolation: Here, clusters 8 and 9 are much more mixed than in the Kalman results. Additionally, more noise appears especially in the upper half of the study site, where many green points (clusters 6 and 7) appear. The erosion rill on the central lower slope is also less pronounced than in the other models. Still, the areas of snow accumulation are clearly segmented as clusters 2 and 3. Note that
 430 these clusters have been created without any spatial components, i.e., spatially contiguous areas are solely the result of similar change behavior.

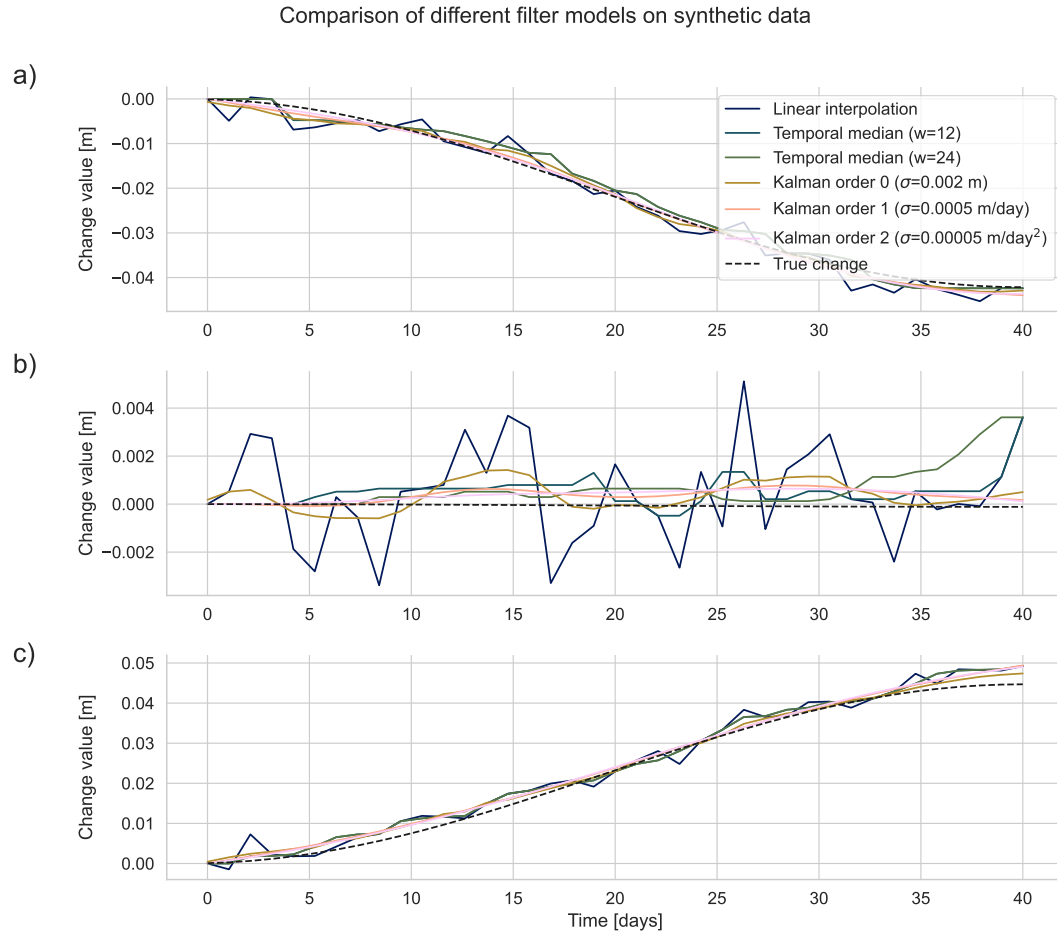

Figure 9. Timelines for different models representing change values in the synthetic scene. a) and c) show locations at the negative and positive maxima, respectively, and b) shows a core point at the center line of the scene, where the true displacement (black dashed line) is zero. This true displacement is calculated from the y -coordinate of the core point using the displacement formula (Equation 1).

| Model | σ [m] / [m/day] / [m/day ²] | Sum of squared residual [m ²] |
|----------------------|--|---|
| Kalman | 0.001 | 3.636 |
| order 0 | 0.002 | 3.154 |
| (x) | 0.005 | 4.323 |
| Kalman | 0.0002 | 3.067 |
| order 1 | 0.0005 | 2.686 |
| (x, v) | 0.0010 | 2.923 |
| Kalman | 0.00002 | 2.864 |
| order 2 | 0.00005 | 2.683 |
| (x, v, a) | 0.00010 | 2.797 |
| Temporal median | window size 24 | 4.297 |
| Temporal median | window size 12 | 4.435 |
| Linear interpolation | – | 8.425 |

Table 1. Sum of squared residuals (estimated - true) for the synthetic change aggregated for all core points over the full time series. The true displacement is calculated by using the y-coordinate of the core point using the model presented in Section 2.2. The minimum value is highlighted.

5 Discussion

Kalman filtering is an alternative method for time series analysis of 3D point clouds, which, compared to simple linear interpolation or moving median windows, rigorously considers uncertainties. As such, each observation input to the Kalman filter is attributed with an uncertainty, e.g., stemming from bitemporal change quantification using M3C2 with error propagation.

435 This uncertainty is then combined with a system state variance, a measure of how much change is expected in subsequent time periods. The result is (a) a smoothed time series and (b) associated uncertainties. These uncertainties are not only quantified for the observation points, but also for interpolated displacement values. Quantification of uncertainties allows for statistical tests of significance, in turn used to separate change from noise. By analyzing the full time series instead of epoch-wise bitemporal analyses, we were able to increase the number of points where change was detected confidently at a given point in time, e.g.

440 at the end of the time series. In our study site, the number of core points attributed with significant change was almost doubled (cf. Fig. 7). The result is confirmed by the analysis of a synthetic scene (cf. Fig 10). The value of 4.26% of locations that were detected using the bitemporal M3C2-EP method, but not when using the multitemporal approach, is close to the theoretical number of false positives (5% when using a level of significance of 95%), when considering that of these 5% of false positives, some will again be incorrectly identified as false positives by the multitemporal method using the same level of significance.

445 We compare different models by visually inspecting the estimated trajectories at sample locations (Figs. 4 and 5). In the case of the synthetic dataset, we can quantify a residual, as the actual change is known, and use this to select a model order and state variance value. Here, we also showed that a properly chosen Kalman model results in a lower sum of squared residuals than the temporal median model (cf. Tab. 1). Note, however, that the synthetic change used a sinusoidal function as a model,

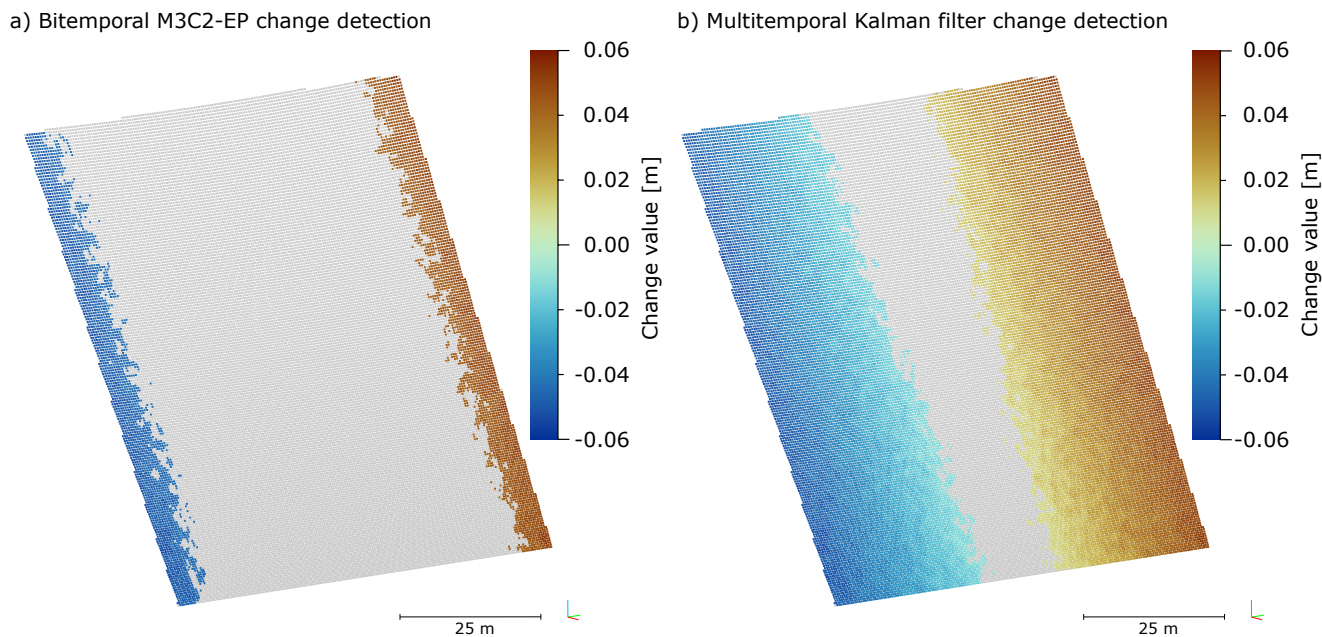

Figure 10. Comparison of detected synthetic change at the end of the 40-day period with a maximum displacement of 0.05 m at the edges of the scene. The bitemporal M3C2-EP method (a) picks up changes above approx. 0.04 m, whereas the Kalman-smoother method allows to detect changes in the time series larger than 0.008 m. Note that these changes and the error budget include a random transformation error. From the image, it can be seen that the quantified changes are still reliable, i.e., there are no changes with reversed signs on the wrong side of the plane.

which ensures that the changes and their derivatives in time are continuous. The Kalman filter is ill-suited to represent sudden
 450 changes, as caused by discrete events of mass movement. However, gradual motions such as rockfall precursors as studied
 by Abellán et al. (2009), could be detected well even without the backward pass of the RTS smoother, given that repeated
 observations show such a trend. In such use cases, the reduction in the Level of Detection is especially crucial.

A major challenge in the application of our method for different geographic settings is the choice of the model order (i.e.,
 the physical basis) and the state variance. As no control data were available for the real dataset, we chose models by visual
 455 interpretation. We selected models that effectively reduce daily patterns, which in our data can be attributed to remaining
 atmospheric effects, yet do not smooth out real surface changes too much. In this study area, we select a model of order 1
 for further investigations. The exact choice of model and state variance depends on the types of change processes that are
 being investigated. Even a spatially and temporally varying state variance could be applicable and is possible with the existing
 mathematical model. This would, however, require a-priori knowledge of the processes acting on the surface.

460 In comparing the estimated trajectories to ones obtained from temporal median smoothing or linear interpolation, we demon-
 strate that especially with data gaps, the Kalman filter estimates often provide a more realistic interpolation trajectory (e.g.
 Fig. 6c on 2021-09-18). The Kalman filter works especially well for continuous changes, and less so for discrete events. For

Result of time series clustering for different numbers of clusters

a) K-Means: 4 clusters (Order 1 Kalman model)

b) K-Means: 8 clusters (Order 1 Kalman model)

c) K-Means: 10 clusters (Order 1 Kalman model)

d) K-Means: 12 clusters (Order 1 Kalman model)

Figure 11. Comparison of different numbers of cluster centroids used in K-Means clustering of the Kalman smoothed time series (Model of order 1, $\sigma=0.02$ m/day). The clusters are ordered by the number of points they contain, which results in the largest class always appearing in subtle off-white. With the addition of more clusters, patterns emerge, e.g., in the case of 10 clusters (c), the avalanche-affected area (bottom right, blue) is split into two separate segments. One of these segments (light blue) has a mean amplitude of around 0.5 m, whereas the more central one (dark blue) has a mean amplitude of 1.2 m in the Kalman filter. The segmentation further increases with 12 clusters (d).

Result of time series clustering for different models

a) Order 0 Kalman model (K-Means: 10 clusters)

b) Order 2 Kalman model (K-Means: 10 clusters)

c) Temporal median model (K-Means: 10 clusters)

d) Linear interpolation model (K-Means: 10 clusters)

Figure 12. Comparison of clustering results from time series estimated using different methods. a) Kalman-smoothed time series with an order 0 model, b) Kalman-smoothed time series with an order 2 model, c) Temporal median model (window size of 96 hours), and d) linear interpolation. The cluster numbers are assigned by point count, cluster 10 being the largest cluster.

example, in Fig. 6a, d, and e, a discrete change occurs on 2021-10-05. The onset of this change is shifted to approx. 2021-10-03, and the target amplitude is only recovered on 2021-10-06 in the selected Kalman model. The temporal median models recover the step function much more accurately here. Nevertheless, for an exact localization in time, the change of curvature of the smoothed Kalman trajectory is still useful – in fact, irrespective of the choice of state variance. This can be seen in Figure 4, where all estimated trajectories intersect at this point in time.

Higher order models, especially the order 2 model, tend to overfit on step functions, resulting in ringing artifacts (blue line in Fig. 4c). The assumption for the order two model is that the acceleration value changes continuously, which is not fulfilled in the case of sudden, discrete change events. In the case of the order 0 model, too large choices for the state variance result in the model replicating the measurement noise (blue line in Fig. 4a). Additionally, with larger choices for the state variance, the associated uncertainties increase. A smoother model, therefore, corresponds to a lower level of detection. Changes that result from continuous processes acting on the surface can then be detected earlier.

As an application example, we showed how the smoothed Kalman time series can be used in K-Means clustering as presented on topographic time series by Kuschnerus et al. (2021). While there are slight differences in the results for different inputs, the main clusters are very similar for the Kalman filter methods and the temporal median smoothing. The linear interpolation model, however, shows a lot more noise in the clustering, exhibiting less pronounced spatially contiguous clusters. We conclude that while there are discrete changes occurring in the scene (snowfall, avalanche), which are not well represented by the Kalman filter trajectory, this does not necessarily affect the resulting clusters.

Future research could investigate how discrete change events can be identified and modeled appropriately by re-initializing the Kalman filter just after such an event. Such a re-initialization resets the estimated displacement, velocity, and acceleration (depending on the chosen order of the model), which increases the uncertainty until more observations become available and the filter converges again. In line with this consideration is the choice of uncertainty at the beginning of the process. At the start of the time series, the displacement must be – by definition – zero, and we, therefore, assign an uncertainty of zero to this initialization. This also ensures that all trajectories pass through the point at 0 at the beginning of the timespan. For subsequent initializations, this argument does not hold, and a larger uncertainty (e.g., derived from the bitemporal comparison) should be assumed.

6 Conclusions

We presented a novel method for the analysis of 4D point clouds for monitoring Earth's surface dynamics. The application of a Kalman filter allows informed temporal smoothing, which decreases uncertainty and enables interpolation of the time series. As M3C2-EP, which spatially aggregates and smoothes data, is used to compute point cloud change values, the full 4D domain is exploited to find optimal estimates for change values, velocities, and accelerations. Our work can be used to detect locations and points in time where significant change occurs throughout the near-continuous 3D observation, and to group these locations into areas or subsets with similar properties. The extraction of the smoothed time series then allows the interpretation of individual trajectories where the influence of random noise is largely suppressed, which in turn allows more

precise statements about the significance of quantified change values and the properties of this change. 4D point cloud analysis using a Kalman filter and clustering techniques facilitate interpretation and allows extraction of the relevant information from the topographic point cloud time series.

500 The rigorous treatment of uncertainty follows a statistical approach to identify significant change and to separate it from noise resulting from sensing uncertainty and processing steps. The use of the Kalman filter allows propagating uncertainties from bitemporal differencing into the time series and reduces the associated Level of Detection.

Many real-world time series datasets contain gaps or are (by design) irregular. With our approach, the time series can be both temporally interpolated and resampled. The regularity can subsequently be utilized by algorithms relying on a constant time step in the time series. We showed this by performing clustering of the spatial locations using the estimated change values
505 as a feature vector, yielding groups of similar surface change history.

Overall, smoothing time series while fully considering associated uncertainties is an important tool for the interpretation of topographic 4D point clouds, especially for small-magnitude changes. Such changes become increasingly important with increasing observation frequencies, a common trend in recent near-continuous laser scanning survey setups.

Code and data availability. The code used for processing the point clouds, including M3C2-EP and the Kalman filter, is available on GitHub
510 (<https://github.com/3dgeo-heidelberg/kalman4d>, v0.0.3) and is indexed with Zenodo (cf. Winiwarter, 2022). The data of the Vals rockfall is available upon reasonable request to Daniel Schröder at <daniel.schroeder@dmr-group.com>.
