41 **Abstract**

42 Burrowing animals influence surface microtopography and hillslope sediment redistribution, but changes often
43 remain undetected due to a lack of automated high resolution field monitoring techniques. In this study, we
44 present a new approach to quantify microtopographic variations and surface changes caused by burrowing
45 animals and rainfall-driven erosional processes applied to remote field plots in arid and mediterranean Chile.
46 We compared the mass balance of redistributed sediment between burrow and burrow embedding area,
47 quantified the cumulative sediment redistribution caused by animals and rainfall, and upscaled the results to a
48 hillslope scale. The newly developed instrument, a Time-of-Flight camera, showed a very good detection
49 accuracy. The animal-caused cumulative sediment redistribution was $8.52 \text{ cm}^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$ in the
50 mediterranean and $9.57 \text{ cm}^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$ in the arid climate zone. The rainfall-caused cumulative sediment
51 redistribution within burrow was higher ($-6.09 \text{ cm}^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$) in the mediterranean than the arid climate
52 zone ($-0.82 \text{ cm}^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$). Daily sediment redistribution during rainfall within burrows were up to 350% /
53 40% higher in the mediterranean / arid zone compared to burrow embedding area, and much higher than
54 previously reported in studies not based on continuous microtopographic monitoring. Furthermore, 38% of the
55 sediment eroding from the burrows accumulated within the burrow entrance while 62% was incorporated into
56 overall hillslope sediment flux. The animals burrowed between on average 1.2 – 2.3 times a month and the
57 burrowing intensity increased after rainfall. Our findings can be implemented into long-term soil erosion models
58 that rely on soil processes but do not yet include animal-induced surface processes on microtopographical
59 scales in their algorithms.

84

85 1. Introduction

86 Animal burrowing activity affects surface microtopography (Kinlaw and Grasmueck, 2012; Reichman
87 and Seabloom, 2002), surface roughness (Hancock and Lowry, 2021; Jones et al., 2010; Yair, 1995) and soil
88 physical properties (Coombes, 2016; Corenblit et al., 2021; Hall et al., 1999; Hancock and Lowry, 2021; Larsen
89 et al., 2021; Reichman and Seabloom, 2002; Ridd, 1996; Yair, 1995). Previous studies estimated both positive
90 as well as negative impacts of burrowing animals on sediment redistribution rates. The results were obtained
91 by applying tests under laboratory conditions using rainfall simulators, conducting several field campaigns
92 weeks to months apart, or by measuring the volume of excavated or eroded sediment in the field using methods
93 such as erosion pins, splash boards, or simple rulers (Chen et al., 2021; Imeson and Kwaad, 1976; Le Hir et
94 al., 2007; Li et al., 2019b; Li et al., 2019a; Li et al., 2019c; Li et al., 2018; Reichman and Seabloom, 2002;
95 Übernicketl et al., 2021b; Voiculescu et al., 2019; Wei et al., 2007). Although burrowing animals are generally
96 seen as ecosystem engineers (Gabet et al., 2003; Wilkinson et al., 2009), their role in soil erosion, in general,
97 and for numerical soil erosion models, in particular, is, to date, limited to predictions of the burrow locations
98 and particle mixing at these locations (Black and Montgomery, 1991; Meysman et al., 2003; Schiffers et al.,
99 2011; Yoo et al., 2005). The complex interaction of sediment excavation and accumulation, and erosion
100 processes at the burrow and hillslope scales are not yet included in the modelling, as for this, a suitable method
101 capable of measuring all occurred redistribution processes is needed.

102 The reason for this knowledge gap is that previous studies have not provided data on low magnitude
103 but frequently occurring sediment redistribution due to the specific limitations of their approaches. Field
104 experiments with, for example, rainfall simulators can unveil processes but cannot cover the time-dependant
105 natural dynamics of sediment redistribution. For data samplings that used methods such as erosion pins or
106 splash boards, the sites had to be revisited each time and the data were thus obtained only sporadically
107 (Hazelhoff et al., 1981; Imeson and Kwaad, 1976; Richards and Humphreys, 2010). Similarly, estimations of
108 the excavated sediment volume are currently limited to one-time measurements or studies conducted several
109 months apart (Black and Montgomery, 1991; Hall et al., 1999; Yoo et al., 2005). We expect that non-
110 continuously conducted measurements do not include all frequently occurring excavation and erosion
111 processes. For this, a spatio-temporally high-resolution and continuous monitoring of sediment redistribution
112 is needed.

113 High-resolution, ground-based imaging sensing techniques might overcome such aforementioned
114 problems. Terrestrial laser scanner systems have shown to be a suitable tool for estimation of sediment
115 redistribution and erosion processes (Afana et al., 2010; Eltner et al., 2016a; Eltner et al., 2016b; Longoni et
116 al., 2016; Nasermoaddeli and Pasche, 2008). However, they are expensive and labour-intensive. A
117 continuous, automated monitoring of many mound areas in parallel is for this reason not possible. An already
118 applied low-cost (up to 5000 USD) topographic monitoring technique is time-lapse photogrammetry which can
119 be applied at variable observation distances and scales (e.g. (Blanch et al., 2021; Eltner et al., 2017; Galland
120 et al., 2016; James and Robson, 2014; Kromer et al., 2019; MALLALIEU et al., 2017). For this technique, the
121 surface has to be monitored under various angles for which several devices are needed to be installed in the
122 field.

123 In contrast, The Time-of-Flight (ToF) technology exhibits lower spatial resolution and aerial coverage
124 compared to time-lapse photogrammetry. However, as an active remote sensing tool it can also be used at
125 night. Additionally, the processing is less complex compared to photogrammetry because the distance values
126 are immediately received in a local coordinate system. ToF offers here a new possibility for surface monitoring,

127 as a technique for a cost-effective high-resolution monitoring of sediment redistribution (Eitel et al., 2011;
128 Hänsel et al., 2016) which can be achieved by a simple installation of one device in the field. ToF-based
129 cameras illuminate the targeted object with a light source for a known amount of time and then estimate the
130 distance between the camera and the object by measuring the time needed for the reflected light to reach the
131 camera sensor (Sarbolandi et al., 2018).

132 In our study we developed, tested and applied a cost-effective Time-of-Flight camera for automated
133 monitoring of the rainfall and animal-driven sediment redistribution burrows and burrow embedding areas by
134 burrowing animals with high temporal (four times a day) and spatial (6 mm) resolution. For this, we equipped
135 several plots in remote study sites in the Chilean arid and mediterranean climate zone. We selected these
136 sites in order to analyse sediment redistribution by burrowing activity of vertebrates under different rainfall
137 regimes and as these sites have been shown to be particularly strongly affected by burrowing activity
138 (Grigusova et al., 2021). We estimated the burrowing intensity and its dependence on rainfall. Then, we
139 quantified the daily sediment redistribution within burrow and burrow embedding area. We analysed the
140 impacts of animal burrowing activity and rainfall on the sediment redistribution and quantified the volume of
141 sediment which is additionally incorporated to the hillslope sediment flux due to the presence of burrows.
142 Finally, we estimated sediment redistribution on a burrow scale and upscaled sediment redistribution rates to
143 the entire hillslopes.

144

145 **2. Study sites**

146 Our study sites were located in the Chilean Coastal Cordillera in two climate zones (Fig. 1): in the National
147 Park Pan de Azúcar (further as Pan de Azúcar or PdA) and the National Park La Campana (further as La
148 Campana or LC). The Las Lomitas site in PdA is located in the arid climate zone of the Atacama Desert with a
149 precipitation rate of 12 mm year⁻¹, and it has a mean annual temperature of 16.8 °C (Übernicket et al., 2021a).
150 Here, the vegetation cover is below 5%, and it is dominated by small desert shrubs, several species of cacti
151 (*Eulychnia breviflora*, *Copiapoa atacamensis*) and biocrusts (Lehnert et al., 2018). LC is located in the
152 mediterranean climate zone with a precipitation rate of 367 mm year⁻¹ and a mean annual temperature of
153 14.1 °C (Übernicket et al., 2021a). LC is dominated by an evergreen sclerophyllous forest with endemic palm
154 trees, *Jubaea chilensis*. Both research sites have a granitic rock base, and the dominating soil texture is sandy
155 loam (Bernhard et al., 2018). In PdA, the study setup consisted of one north-facing and one south-facing
156 hillslope. The hillslope inclinations were ~20°, and a climate station was located ~15 km from the camera sites.
157 In LC, the setup consisted of two north-facing and one south-facing hillslopes. The hillslope inclinations were
158 ~25°, and a climate station was located ~250 m from the south-facing hillslope (Übernicket et al., 2021a).
159 Among the most common vertebrate burrowing animals are in PdA carnivores (*Lycalopex culpaeus*, *Lycalopex*
160 *griseus*); marsupials and rodents (*Phyllotis xanthopygus*, *Phyllotis limatus*, *Abrothrix andinus*) (Cerqueira,
161 1985; Jimenez et al., 1992) and in LC rodents (*Octodon degus*, *Rattus norvegicus* and *Phyllotis darwini*) and
162 carnivores (*Lycalopex griseus*) (Muñoz-Pedrerros et al., 2018)

163

 169 created from WorldView-2 data from 19 July 2019. For exact latitude and longitude see Table A2.

170
 171 **3. Methodology**

172 **3.1 Time-of-Flight (ToF) principle**

173 A Time-of-Flight-based camera illuminates an object with a light source, usually in a non-visible
 174 spectrum, such as near-infrared, for a precise length of time. ToF cameras rely on the principle of measuring
 175 the phase shift, with different options to modulate the light source to be able to measure the phase shift. The
 176 here employed cameras used pulse-based modulation, meaning the light pulse was first emitted by the
 177 camera, then reflected from the surface, and finally measured by the camera using two temporary windows.
 178 The opening of the first window is synchronized with the pulse emission i.e. the receiver opens the window
 179 with the same Δt as the emitted pulse. Then, the second window is opened, for the same duration Δt , which is
 180 synchronised with the closing of the first window. The first temporary window thus measures the incoming
 181 reflected light while the light pulse is also still emitting from the camera. The second temporary window
 182 measures the incoming reflected light when no pulse is emitting from the camera. The captured photon number
 183 (i.e. measured by electrical charge) in both windows can be related according to equation 1 and the distance
 184 from the camera to the object can then be calculated as follows:

$$185 \quad d = \frac{1}{2} * c * t * \left(\frac{g_1}{g_1 + g_2} \right) \quad . \quad (1)$$

186 In Eq. (1), d (m) is the distance from the camera to the object, c (m s^{-1}) is the speed of light ($299,792,458 \text{ m s}^{-1}$),
 187 t (s) is the overall time of the illumination and measurement, g_1 is the ratio of the reflected photons to all
 188 photons accumulated in the first window, and g_2 the ratio of the reflected photons to all photons accumulated
 189 in the second window (Li, 2014; Sarbolandi et al., 2018).

190 The sensor in our camera came from Texas Instruments and the data scan contained information on
 191 320 x 240 points. The camera field of view (FOV) and the spatial resolution of the scans depended on the
 192 height of the camera above the surface and camera orientation. The distance was calculated for every point,
 193 and the object was saved in binary format as a collection of 3D points with x-, y- and z-coordinates. The point
 194 clouds taken by the camera were transformed from the binary format to an ASCII format. Each point in the
 195 point cloud was assigned to an x-, y- and z-coordinate. The coordinates were distributed within a three-
 196 dimensional Euclidian space, with the point at the camera nadir (the centre of the camera sensor) being the
 197 point of origin of the 3D Cartesian coordinate system. x- and y-coordinates describe the distance to the point
 198 of origin (m). z-coordinate describes the distance (m) from the object to the camera. The lowest point of the
 199 scanned surface thus has the highest z-coordinate value.

200

201 3.2 Data processing

202 The distortion caused by the hillslope and the camera angle was corrected for each point cloud as
 203 follows:

$$204 z_{cor} = z_{uncor} - \tan(\alpha + \beta) * (y_1 - y_i) \quad . \quad (2)$$

205 In Eq. (2), z_{cor} is the corrected distance (m) between the camera and surface (m), z_{uncor} is the uncorrected z-
 206 coordinate (m), α is the tilt angle of the camera ($^{\circ}$), β is the surface inclination ($^{\circ}$), and y_i (m) is the distance
 207 between each point, and the point with i) an y-coordinate = 0 and ii) the same x-coordinate as the respective
 208 point. The most frequent errors were identified and treated as follows. Due to the ambient light reaching the
 209 camera sensor, the z-coordinate values of some of the points were incorrect (scattering error). To remove this
 210 error, a threshold value was calculated for each point cloud:

$$211 \Omega = mean_{z_{cor}-coordinate} \pm sd_{z_{cor}-coordinate} \quad . \quad (3)$$

212 In Eq. (3), Ω is the threshold value, $mean_{z_{cor}-coordinate}$ is the average value, and $sd_{z_{cor}-coordinate}$ is the standard
 213 deviation of the corrected z-coordinates (m). Then, all points with a z-coordinate above and below this value
 214 were deleted. Point clouds with more than 50% of points above the threshold value Ω were also not considered
 215 for further processing. A drift error occurred when the z-coordinate values of around one-third of the point
 216 clouds decreased by several centimetres from one point cloud to another. Here, the average z-coordinate of
 217 ten point clouds before and after the drift were calculated, and the difference was added to z-coordinates of
 218 the points affected by the drift. The corrected height values were then transformed into a digital surface model
 219 (DSM).

220

221 3.3 Accuracy of the ToF cameras

222 The accuracy of the ToF camera was tested under laboratory conditions by recreating similar surface
 223 conditions as in the field (sloping surface, covered by sediment). An artificial mound using sediment extracted
 224 from a riverbank in central Germany was used, mimicking a mound created by a burrowing animal. During the
 225 test, the camera was installed 100 cm above the surface. The camera FOV was 3 m² and the scan spatial
 226 resolution was 6 mm. The surface was scanned twice by the ToF camera. Then 100 – 450 cm³ of sediment
 227 was manually extracted from the mound. The volume of the extracted sediment was measured by a measuring
 228 cup. After extraction, the surface was again scanned twice by the camera. The experiment was repeated 45
 229 times with varying amounts of extracted sediment. The scans were transformed to point clouds in VoxelViewer-
 230 0.9.10, and the point clouds were corrected according to Eq. (2) and (3). The z-coordinates of the two point
 231 clouds before and two point clouds after the extraction were averaged. The standard deviation of the z-

232 coordinate of the two scans was 0.06 cm. Figure A1 shows the spatially distributed standard deviation. The
 233 deviation increases from the centre towards the corners of the scan. The mound was outlined and only the
 234 points representing the mound were used in the further analysis. The point clouds were then transformed into
 235 DSMs, and the differences between the time steps were calculated. A scan was taken of a smooth surface
 236 (linoleum floor) and a point cloud was created from the data. Then, we fitted a plane into the point cloud and
 237 calculated the distance between the plane and the camera sensor. The standard variation (0.17 cm) in the
 238 distance measurements was saved. Solely, the differences between the DSMs below this variation were
 239 considered in the calculation of the detected sediment extraction. The detected extracted sediment volume
 240 was then calculated for each experiment as follows:

$$241 \text{Vol}_{detected} = \sum_p^1 (DSM_{before} - DSM_{after}) * res^2 \quad , \quad (4)$$

242 In Eq. (4), $\text{Vol}_{detected}$ is the volume of the extracted sediment as detected by the camera (cm^3), p is the number
 243 of pixels, DSM_{before} (cm) is the DSM calculated from the scan taken before the extraction, DSM_{after} (cm) is the
 244 DSM calculated from the scan taken after the extraction, res (cm) is the resolution of the scan, which was 0.6
 245 cm. To evaluate the camera's accuracy, the measured volume of the extracted sediment was compared to the
 246 volume detected by the camera. The camera's accuracy was estimated between the detected volume and
 247 measured volume as follows:

$$248 MAE = \sum_1^n \frac{(\text{Vol}_{detected} - \text{Vol}_{measured})}{area} \quad . \quad (5)$$

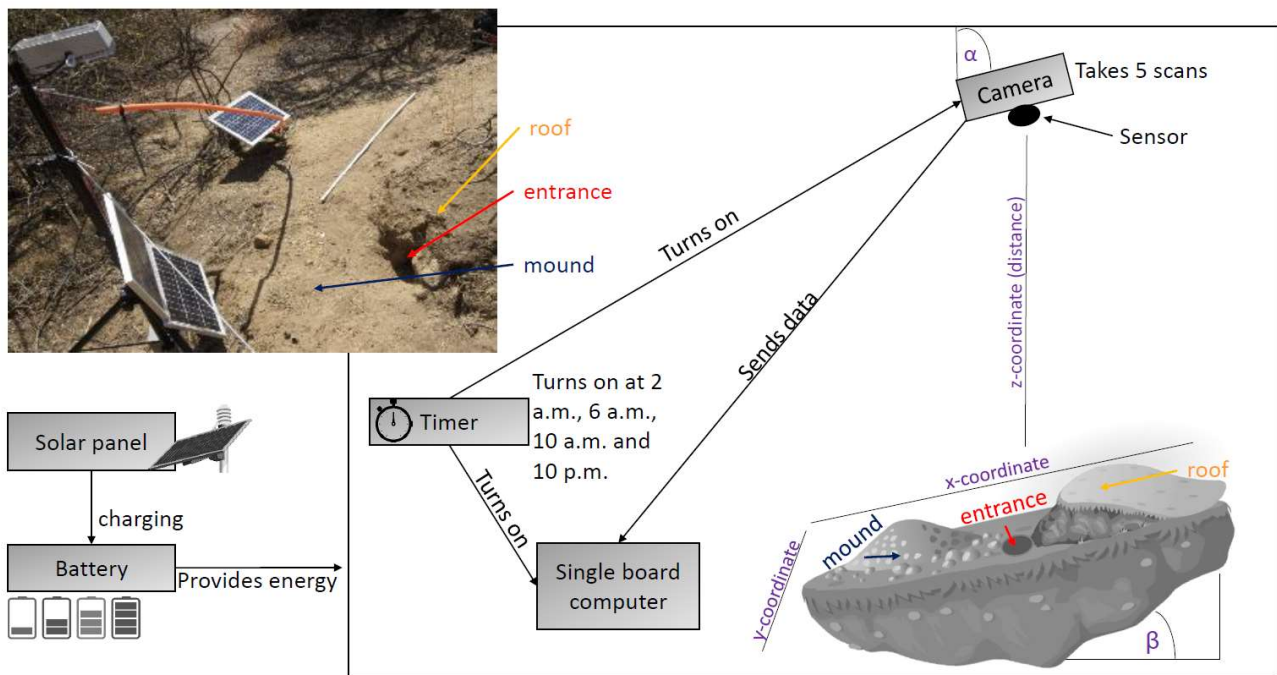

249 In Eq. (5), MAE (cm^3/cm^2) is the mean absolute error, n is the number of scans, $\text{Vol}_{measured}$ (cm^3) is the volume
 250 of the extracted sediment measured by the measuring cup, and the area is the total surface area monitored
 251 by the camera (cm^2).

252

253 3.4 Installation of the cameras in the field

254 We installed 8 custom-tailored ToF-based cameras on 4 hillslopes in two climate zones in areas
 255 including visible signs of bioturbation activity (burrows) and areas without visible signs of bioturbation (Fig. 2).
 256 The cameras were installed in LC on the north-facing upper hillslope (LC-NU), north-facing lower hillslope (LC-
 257 NL), south-facing upper hillslope (LC-SU) and the south-facing lower hillslope (LC-SL); in PdA on the north-
 258 facing upper hillslope (PdA-NU), north-facing lower hillslope (PdA-NL), south-facing upper hillslope (PdA-SU)
 259 and south-facing lower hillslope (PdA-SL). The custom-tailored cameras were installed during a field campaign
 260 in March 2019, the monitoring took place for seven months, and the data were collected in October 2019. The
 261 construction consisted of a 3D ToF-based sensor from Texas Instruments (Li, 2014), a RaspberryPi single board
 262 computer (SBC), a timer, a 12 V 12 Ah battery and three 20 W solar panels for unattended operation (Fig. 2).
 263 Solar panels were located at the camera pole and were recharging the battery via a charge controller. The
 264 camera was located approximately one meter above the surface, facing the surface with a tilt angle of 10
 265 degrees. The timer was set to close the electric circuit 4 times a day: at 1 a.m., 5 a.m., 8 a.m. and 10 p.m. At
 266 these times, the camera and the computer were turned on for 15 minutes. The camera turned on and took five
 267 scans delayed one second from each other and sent them to the SBC. Each camera had its own WiFi (Wireless
 268 Fidelity) and the data could be read from the SBC via Secure Shell (SSH). The cameras collected the data for
 269 the time period of 7 months.

270

271

272 **Figure 2.** Scheme and photo example of a Time-of-Flight-based camera installation in the field. The photo
 273 example is from upper north-facing hillslope in La Campana. Black boxes describe single installation parts.
 274 Purple descriptions are the variables needed for the correction of the scans. Roof, entrance and mound
 275 describe parts of the burrow. The x-, y- and z-coordinates are 3D coordinates identifying the position of each
 276 point in space, where the x-coordinate is the length, y-coordinate is the width and the z-coordinate is the
 277 distance between the camera sensor and the surface. α is the inclination of the camera, and β is the surface
 278 inclination.

279

280 3.5 Delineation of burrows and burrow embedding areas

281 The surface area scanned by the cameras was divided by a delineation scheme into burrows (B) and
 282 burrow embedding areas (EM). The burrows included three sub-areas: (i) mound (M), (ii) entrance (E) and (iii)
 283 burrow roof (R). “Mound” describes the sediment excavated by the animal while digging the burrow. “Entrance”
 284 describes the entry to the animal burrow up to the depth possible to obtain via the camera. “Burrow roof”
 285 describes the part of the sediment above and uphill the burrow entrance (BANCROFT et al., 2004). During the
 286 burrow’s creation, sediment was not only excavated but also pushed aside and uphill the entrance, which
 287 created the burrow roof. We assume that this elevated microtopographical feature then forms an obstacle for
 288 sediment transported from uphill, which leads to its accumulation in this area. The remaining surface within
 289 the camera’s FOV was burrow embedding area. Please note, that this area may still be affected by the
 290 burrowing activity of the animal and is not completely unaffected by the animal.

291 For the delineation, we used the DSM calculated from the point cloud, and a slope layer calculated
 292 from the DSM (Horn, 1981). The DSM had a size of 4 m² a resolution of 0.6 cm. Entrance was assigned to an
 293 area determined by a search algorithm starting at the lowest point of the DSM (pixel with the highest z-
 294 coordinate value). We increased the circular buffer around the starting point by one pixel until the average
 295 depth of the new buffer points was not higher than the height of the camera above the surface, or until the
 296 slope of at least 50% of the new buffer points was not 0. Then, we masked all pixels within the buffer with a
 297 depth lower than the average depth of the points within the buffer, which had a slope that was 0. The remaining
 298 pixels belonged to the entrance area. Then, the surface scan was divided into an uphill and downhill part with

299 regards to the entrance position. Both the uphill and the downhill parts were subdivided into 16 squares, so
300 that each of the four quadrants within the 2D grid (x- and y-axis) contained four squares. The squares had size
301 of 0.5 m².

302 To delineate the mound in the downhill part, we first identified the highest points (pixel with the lowest z-
303 coordinate value) within all 16 squares. We then calculated the distance of these maxima to the entrance, and
304 the pixel located nearest to the entrance was identified as the highest point of the mound (i.e., seed point).
305 Consecutively, we increased the circular buffer around the seed point by one pixel until the average depth of
306 the new buffer points was not lower than the height of the camera above the surface, or until the slope of at
307 least 50% of the new buffer points was not 0. Then, we masked all pixels within the buffer with a depth higher
308 than the average depth of the points within the buffer, which had a slope that was 0. The remaining pixels were
309 classified as mound area. To delineate burrow roof, we used the same approach as for the delineation of
310 mound and applied it on the uphill part of the surface scan. We used the DEM and slope layers for the
311 delineation for several reasons. The distance from the surface to the camera was the most important parameter
312 to derive (i) the deepest point of the entrance and (ii) the highest point of the mound or burrow roof, as this
313 was (mostly) the closest point to the camera. After the angle correction of the z-coordinate according to chapter
314 3.2., the surface inclination of the areas without burrow was 0°, while the angle between the border of the
315 burrow entrance or mound and the burrow embedding surface was above 0°. Because neither the entrance
316 nor the mound have a perfect circular form, we would largely overestimate or underestimate the entrance or
317 mound size. Overestimate by not stopping the search algorithm until the angle between all new points of the
318 buffer to the rest of the buffer was 0°. Underestimate by stopping the algorithm when the angle of one point of
319 the buffer to the nearest point of the buffer was 0°. The value of 50% thus minimized the error. All pixels that
320 were not classified during the entire delineation process were treated as burrow embedding areas.

321 The position and the boundaries of entrance, mound and burrow roof were validated visually (Fig. 3 and A2).

322
323 **Figure 3.** Corrected digital surface model of the camera on the upper north-facing hillslope in La Campana
324 with delineated areas. The point of origin of the coordinate system is at the camera nadir. Distance refers to
325 the distance between surface and camera. The red line delineates the burrow entrance, blue the mound and
326 orange the burrow roof. The area which was outside of any delineated area was classified as burrow
327 embedding area. The arrow indicates a downhill direction of the hillslope.

328
329 In LC, the burrows always consisted of an entrance, mound and burrow roof. In PdA, there was no
330 burrow roof on the upper hillslopes. Burrows without a burrow roof were located on shallower parts of the

331 hillslopes (up to an inclination of 5°), and the angle of the burrow entrance to the ground was ~90°. Burrows
332 with a burrow roof were located on steeper parts of the hillslopes (with an inclination above 5°), and the angle
333 of the burrow entrance to the ground was ~45°.

334

335 **3.6 Calculation of animal-caused and rainfall-caused sediment redistribution**

336 We pairwise compared the DSMs of each scan with the scan saved before and identified 3 types of
337 sediment redistribution which occurred in the time period between these images. The 3 types of redistribution
338 were: a) animal caused; b) rainfall-caused; c) both animal and rainfall caused.

339 The animal-caused sediment redistribution occurred when the animal actively reworked sediment
340 within its burrow. Following five prerequisites had to be met when the sediment redistribution was caused
341 solely by the animal: (i) as the animal excavates sediment from the entrance, the depth of the entrance must
342 increase in the second scan; (ii) as the excavated sediment accumulates on the mound, the height of the
343 mound must increase in the second scan; (iii) as the burrowing might lead to an expansion or a collapse of the
344 burrow roof, an increase or decrease of the burrow roof must occur between the scans; (iv) as the animal only
345 digs within his burrow, no changes must occur between the two scans within the burrow embedding area by
346 the animal; (v) no rainfall occurred during this period.

347 The rainfall-caused sediment redistribution was calculated as follows: From the data from the climate
348 stations (Übernicker et al., 2021a), we calculated the daily precipitation in mm. The sediment redistribution
349 recorded immediately and within five scans before and after a rainfall event is defined to be the result of the
350 rainfall event. This was necessary as the climate stations are located up to a 15 km distance from the cameras
351 (Fig. 1). To attribute sediment redistribution to rainfall event, three preconditions had to be met: (i) A rainfall
352 event occurred; (ii) sediment is eroded from burrow roof, mound and the embedding area; (iii) sediment is
353 accumulated within the burrow entrance.

354 To attribute sediment redistribution to a combination of animal activity and rainfall, four preconditions
355 had to be met: (i) A rainfall event occurred; (ii) sediment is eroded from embedding area; (iii) the height of
356 burrow roof and mound decreased or increased; (iv) the depth of burrow entrance increased.

357 The animal-caused sediment redistribution was calculated as the sediment volume excavated from
358 the entrance. Animal excavation always increased depth of the burrow entrance. The rainfall-caused sediment
359 redistribution was calculated as the sediment volume which eroded from the burrow roof and mound. During
360 a rainfall event, sediment eroding from burrow roof might accumulate within burrow entrances. In this case,
361 the depth of the burrow entrance decreased. No sediment could erode from the entrance during a rainfall
362 event. Decreased depth of a burrow entrance always points to sediment redistribution caused by rainfall,
363 increased depth of burrow entrance always means redistribution by animals. Rainfall-caused redistribution
364 always occurred before animal-caused redistribution, as without erosion caused by rainfall, the animals did not
365 need to reconstruct their burrows.

366

367 **3.7 Calculation of daily sediment mass balance budget**

368 The volume of the redistributed sediment was calculated daily and was then cumulated from the first
369 day of monitoring. For the calculation of the daily sediment redistribution, the change in the surface level
370 detected by the camera was calculated first. For each day, the scans from the day before and after the
371 respective day were averaged and subtracted. The average standard deviation of the z-coordinate of these
372 scans was 0.06 cm. As described in Section 2.2., all values with a difference below and above the threshold

373 value of 0.2 cm were set to 0. The redistributed sediment volume was then calculated from the surface change
 374 for each pixel as follows:

$$375 \text{ } Vol_{redistributed} = (S_b - S_a) * res^2 \quad (6)$$

376 In Eq. (6), $Vol_{redistributed}$ ($cm^3 \text{ pixel}^{-1}$) is the volume of the calculated redistributed sediment, S_b (cm) the scan
 377 before, S_a (cm) the scan after the rainfall event and res is the spatial resolution (cm). Using the daily volume
 378 of the redistributed sediment per pixel, we calculated the daily mass balance budget by summing the volume
 379 of sediment eroding or accumulating within each delineated area.

380

381 **3.8 Calculation of the overall volume of redistributed sediment after the period of 7 months**

382 From the camera data, we calculated the average cumulative volume of redistributed sediment for the
 383 period of 7 months within burrows ($Vol_{burrows}$ ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$)) and burrow embedding ($Vol_{embedding}$ (cm^3
 384 $cm^{-2} \text{ 7 months}^{-1}$)) areas and the average sediment volume redistributed (excavated) by the animal (Vol_{exc} (cm^3
 385 $cm^{-2} \text{ 7 months}^{-1}$)), separately for each site. We estimated the volume of sediment that was redistributed during
 386 rainfall events due to the presence of the burrow (Vol_{add} ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$)). Vol_{add} was calculated as the
 387 difference in the redistributed sediment volume between burrows and burrow embedding areas according to
 388 Eq. (7).

$$389 \text{ } Vol_{add} = (Vol_{affected} - Vol_{unaffected}) \quad (7)$$

390 Additionally, we calculated the average volume of the redistributed sediment per burrow ($Vol_{per \text{ burrow}}$ [cm^3
 391 $burrow^{-1} \text{ 7 months}^{-1}$]).

$$392 \text{ } Vol_{per \text{ burrow}} = (Area_{burrow} * Vol) \quad (8)$$

393 In Eq. (8), $Area_{burrow}$ (cm^2) is the average size of the burrows that are monitored by the cameras; Vol is Vol_{burrow}
 394 ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$), Vol_{exc} ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$) or Vol_{add} ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$).

395 We then upscaled the Vol_{burrow} ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$), Vol_{exc} ($cm^3 \text{ cm}^{-2} \text{ 7 months}^{-1}$) and Vol_{add} (cm^3
 396 $cm^{-2} \text{ 7 months}^{-1}$) to the hillslope using the following approach. Hillslope-wide upscaling of the results
 397 generated in this study was performed by using a previous estimation of vertebrate burrow density (Grigusova
 398 et al., 2021). In this study, the density of burrows was measured in situ within eighty 100 m^2 plots and then
 399 upscaled to the same hillslopes on which the cameras were located by applying machine-learning methods,
 400 using the UAV-data as predictors. For upscaling, we applied a random forest model with recursive feature
 401 elimination. The model was validated by a repeated Leave-One-Out cross validation. The density of vertebrate
 402 burrows was between 6 and 12 100 m^2 in LC and between 0 and 12 100 m^2 in Pan de Azúcar. Using the
 403 hillslope-wide predicted vertebrate burrow densities ($Dens_{burrow}$ (number of burrows 100 m^{-2})) from Grigusova
 404 et al. 2021, we estimated the volume of redistributed sediment for each pixel of the raster layers ($Vol_{per \text{ pixel}}$
 405 ($cm^3 \text{ m}^{-2} \text{ 7 months}^{-1}$)) according to Eq. (9):

$$406 \text{ } Vol_{per \text{ pixel}} = Vol_{per \text{ burrow}} * Dens_{burrow} \quad (9)$$

407 The average hillslope-wide volume of redistributed sediment ($Vol_{hillslope-wide}$ ($m^3 \text{ ha}^{-1} \text{ 7 months}^{-1}$)) was
 408 then estimated as follows:

$$409 \text{ } Vol_{hillslope-w} = \sum_1^m Vol_{per \text{ pixel}} * 0.001 \quad (10)$$

410 In Eq (10), m is the number of pixels.

411

412 **4. Results**

413 **4.1 Camera accuracy and data availability**

414 The accuracy between the measured extracted sediment volume and sediment volume calculated
415 from the camera scans was very high (MAE = 0.023 cm³ cm⁻², R² = 0.77, SD = 0.02 cm³ cm⁻², Fig. A3). The
416 accuracy between the calculated and measured extracted sediment was higher when the two scans taken
417 before as well as after the extraction of the sediment were averaged and the sediment volume was estimated
418 using these averaged scans. When calculating the redistributed sediment from solely one scan before and
419 after extraction, the accuracy slightly decreased (MAE = 0.081 cm³ cm⁻², R² = 0.64). The cameras tended to
420 overestimate the volume of redistributed sediment. Six out of eight custom-tailored cameras collected data
421 over the seven-month period (Table A2). One camera collected data for a period of three months and one
422 camera stopped working a few days after installation. The quantity of usable point clouds taken at 1 a.m., 5
423 a.m. and 10 p.m. was higher than of point clouds taken at 8 a.m. Approximately 20% of points was removed
424 from the point clouds before final analysis due to the high scattering at the point cloud corners. After data
425 filtering (see Section 3.2.), 1326 scans were usable and for 86% of the days, at least one usable scan was
426 available. The usable scans were distributed continuously within the monitoring period.

427

428 **4.3 Mass balance of redistributed sediment**

429 The cameras detected (i) sediment redistribution directly following rainfall events and (ii) due to the
430 burrowing activity in times without rainfall (Fig. 3, A4 and A5). In all cases, burrows (entrance, burrow roof and
431 mound) exhibited higher sediment redistribution rates than burrow embedding areas. In addition, the volume
432 of redistributed sediment by animal activity was higher after a rainfall event occurred.

433 In the following, the dynamics are exemplary explained for four cameras. Animal burrowing activity
434 was detected seven times by the camera LC NU (Fig. 4a, A4, A5) during the monitoring period, by an increase
435 in sediment volume in the area delineated as mound. Simultaneously, the burrow entrance showed signs of
436 modification and sediment accumulation, but these changes were less clear. Overall, the volume of the
437 excavated soil varied. From April until June, up to 0.5 cm³ cm⁻² of sediment was excavated by the animal and
438 accumulated on the mound. From June until September, animal burrowing activity was detected at four time
439 slots (5 June 2019, 9 June 2019, 1 July 2019 and 18 August 2019) and sediment volume of up to 2 cm³ cm⁻²
440 accumulated each time on the mound, burrow roof and within the entrance. During the rainfall events of up to
441 20 mm day⁻¹ on 16 June 2019, 27 mm day⁻¹ on 29 June 2019 and 7 mm day⁻¹ on 13 July 2019, sediment
442 volume of up to 4 cm³ cm⁻² eroded, especially from the burrow roof and the mound while a sediment volume
443 of up to 1 cm³ cm⁻² accumulated within the entrance during each rainfall event. Camera LC-SL (Fig. A4, A5)
444 showed burrowing activities eight times and sediment volumes of up to 3 cm³ cm⁻² accumulated within the
445 entrance and burrow roof. The camera detected sediment erosion of up to 2 cm³ cm⁻² after a rainfall event of
446 27 mm day⁻¹ on 27 July 2019. On the south-upper hillslope, the camera detected animal burrowing activity six
447 times, with a sediment accumulation of up to 3 cm³ cm⁻² (Fig. A2 and A3).

448 In contrast, camera PdA-NU pointed to animal burrowing activity up to 15 times where up to 1 cm³ cm⁻²
449 of sediment volume was redistributed from the entrance to the mound (Fig. 4b, A4, A5). At the end of June
450 on 27 June 2019, a rainfall event of 1.5 mm day⁻¹ occurred and up to 2 cm³ cm⁻² of sediment eroded from the
451 burrow roof and accumulated within the burrow entrance. We observed increased sediment redistribution by
452 the animal after the rainfall events. Camera PdA-SL evenly revealed animal burrowing activity up to 15 times
453 ((Fig. A4, A5)). The burrowing had a strong effect on the sediment redistribution. The rainfall event of 1.5 mm
454 day⁻¹ on 27 June 2019 did not cause any detectable surface change.

455

456

457 **Figure 4.** Examples of the mass balance of redistributed sediment for burrows and burrow embedding areas
 458 (a) The record of the camera on the upper north-facing hillslope in La Campana showed that larger rainfall
 459 events cause a negative sediment balance (sediment loss), followed by a phase of positive sediment mass
 460 balance after approximately 3 days due to sediment excavation; (b) The record of the camera on the upper
 461 north-facing in Pan de Azúcar hillslope showed a similar pattern to the camera on the upper north-facing
 462 hillslope, but the phase of positive mass balance was delayed in comparison. The blue line is the daily
 463 precipitation in mm day⁻¹, and “X” marks the days at which animal burrowing activity was detected. Mass
 464 balances for all cameras are displayed in Fig. A2 and A3.

465

466 The analysis of cumulative volume of the redistributed sediment caused by burrowing animal activity
 467 and rainfall over the monitored period of seven months for all eight cameras showed a heterogeneous pattern.

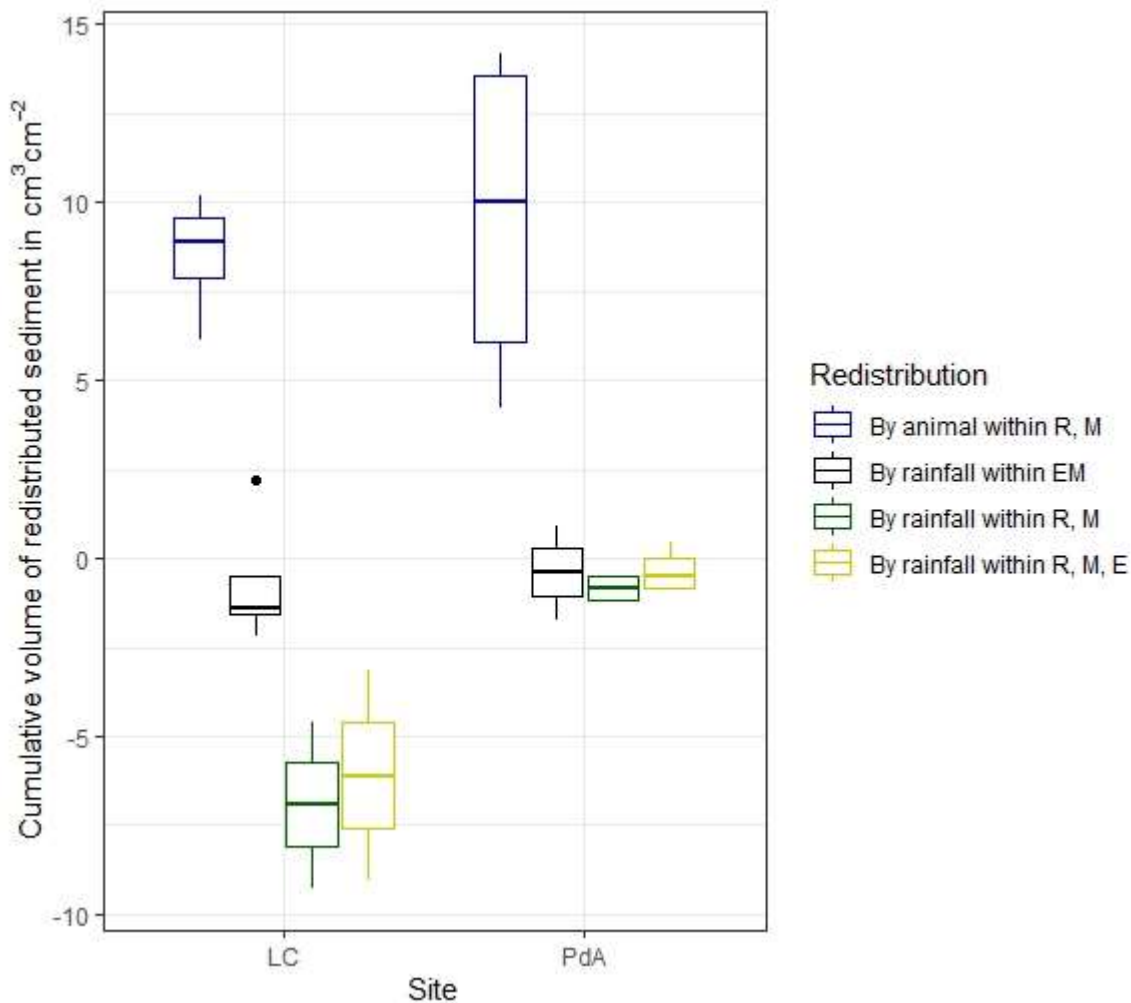

468 In LC, the cumulative volume of the sediment excavated by the animal within the burrow roof and
 469 mound increased continuously (Fig. 5, A7). Especially between the rainfall events from June until August, a
 470 cumulative volume of on average 6.5 cm³ cm⁻² was excavated by the animal. We calculated that, on average,
 471 8.53 cm³ cm⁻² cumulatively eroded from the burrow roof and mound; while 2.44 cm³ cm⁻² sediment volume
 472 accumulated within the entrance (Fig. 5, A7). These results indicate that 28% of sediment eroding from the
 473 burrow roof accumulated within the entrance, while over 62% of sediment eroded downhill. Averaged over all

474 camera scans, 338% more sediment was redistributed by rain within burrow compared to the burrow
475 embedding area (Fig. 6).

476 In PdA, cameras continuously detected animal burrowing activity and excavation of the sediment (Fig.
477 A7). The volume of the detected excavated sediment increased steadily within all cameras. The cumulative
478 sediment accumulation surpasses the sediment eroded due to the rainfall. The volume of the sediment eroded
479 within the burrows was 40% higher than within the burrow embedding areas. The results show that
480 approximately 50% of the eroded sediment accumulated within the entrance (Fig. 6).
481

482
483 **Figure 5.** Examples of the cumulative volume of redistributed sediment within burrows and burrow embedding
484 areas caused by animal burrowing activity or rainfall in mediterranean La Campana: (a) Upper north-facing
485 hillslope; (b) Lower south-facing hillslope. Positive values indicate sediment accumulation. Negative values
486 indicate sediment erosion. E is the burrow entrance; M is the mound; R is burrow roof; EM is the burrow
487 embedding area. Cumulative volumes for all cameras are in Fig. A7.

488

489 **Figure 6.** Cumulative volume of the redistributed sediment for all cameras. Positive values indicate sediment
 490 accumulation. Negative values indicate sediment erosion. Whiskers indicate the median of sediment
 491 redistribution. E is the burrow entrance; M the mound; R is the burrow roof; EM is burrow embedding area; LC
 492 stands for National Park La Campana in the mediterranean climate zone; PdA stands for National Park PdA in
 493 the arid climate zone.

494

495 **4.4 Volume of redistributed sediment**

496 The average size of the burrows was 84.36 cm^2 (SD = 32.54 cm^2) in LC and 91.35 cm^2 in PdA (SD = 8.53
 497 cm^2). The animals burrowed on average $1.2 \text{ times month}^{-1}$ in LC and $2.33 \text{ times month}^{-1}$ in PdA. The volume
 498 of the excavated sediment was $102.22 \text{ cm}^3 \text{ month}^{-1}$ in LC and $124.89 \text{ cm}^3 \text{ month}^{-1}$ in PdA. Each time the
 499 animals burrowed, they excavated 42 cm^3 sediment volume in LC and 14.33 cm^3 sediment volume in PdA.
 500 The burrowing intensity increased in winter after the rainfall occurrences in LC and stayed constant during the
 501 whole monitoring period in PdA. The burrows deteriorate after rainfall events with a rate of $73.03 \text{ cm}^3 \text{ month}^{-1}$
 502 or $63.90 \text{ cm}^3 \text{ event}^{-1}$ in LC and $10.53 \text{ cm}^3 \text{ month}$ or $24.57 \text{ cm}^3 \text{ event}^{-1}$.

503

504 The overall volume of the sediment excavated by the animal and redistributed during rainfall events
 505 varied between the sites (Table 1). The volume of the sediment redistributed by the animal was lower in LC
 506 than in PdA. However, on the hillslope scale, a higher total area-wide volume of excavation was calculated for
 LC compared to PdA, due to the higher burrow density in LC. The volume of the sediment redistributed within

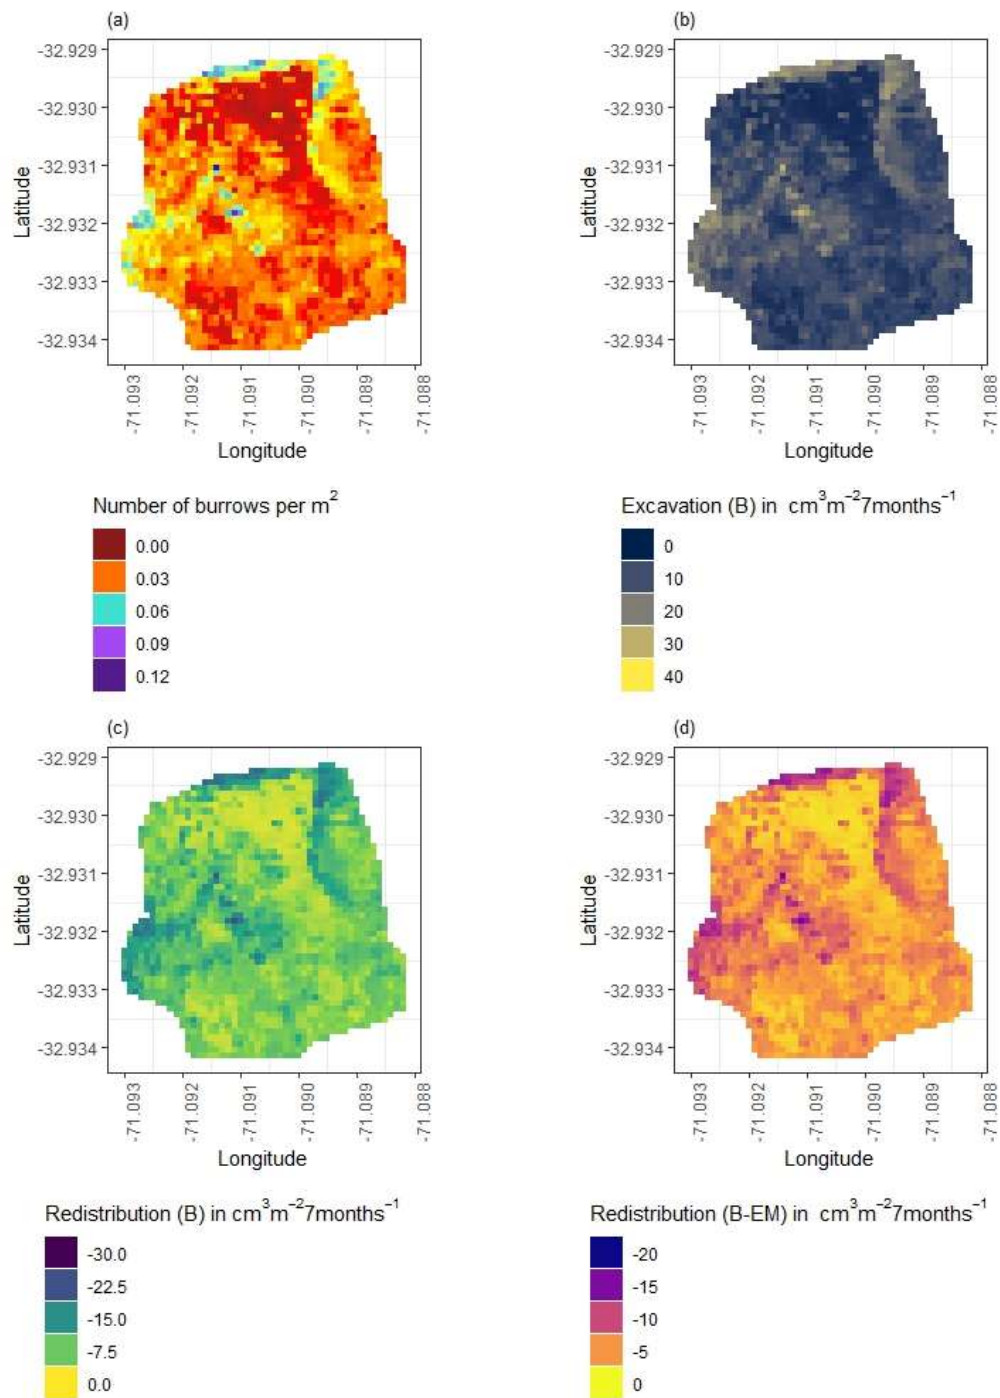

507 burrows during rainfall events was higher in LC than in PdA. The volume of additionally redistributed sediment
 508 due to the presence of burrows was higher in LC than in PdA (Table 1, Fig. 7).

509

510 **Table 1.** Summary of the volume of redistributed sediment, according to area and disturbance type. Vol_{exc}
 511 describes volume of the sediment excavated by the animals. Vol_{burrow} describes volume of the sediment
 512 redistributed during rainfall events within burrows. Vol_{add} describes the difference in redistributed sediment
 513 volume within burrows and burrow embedding areas during rainfall.

Disturbance	Area	PdA	LC
Vol_{exc}	Burrow	9.57 cm ³ cm ⁻² 7 months ⁻¹	8.53 cm ³ cm ⁻² 7 months ⁻¹
	Per burrow	874.22 cm ³ burrow ⁻¹ 7 months ⁻¹	715.52 cm ³ burrow ⁻¹ 7 months ⁻¹
	Hillslope-wide	0.11 m ³ ha ⁻¹ 7 months ⁻¹	0.39 m ³ ha ⁻¹ 7 months ⁻¹
Vol_{burrow}	Burrow	-1.15 cm ³ cm ⁻² 7 months ⁻¹	-6.09 cm ³ cm ⁻² 7 months ⁻¹
	Per burrow	-73.71 cm ³ burrow ⁻¹ 7 months ⁻¹	-511.22 cm ³ burrow ⁻¹ 7 months ⁻¹
	Hillslope-wide	-0.03 m ³ ha ⁻¹ 7 months ⁻¹	-0.28 m ³ ha ⁻¹ 7 months ⁻¹
Vol_{add}	Burrow	-0.69 cm ³ cm ⁻² 7 months ⁻¹	-4.30 cm ³ cm ⁻² 7 months ⁻¹
	Per burrow	-28.21 cm ³ burrow ⁻¹ 7 months ⁻¹	-361.20 cm ³ burrow ⁻¹ 7 months ⁻¹
	Hillslope-wide	-0.01 m ³ ha ⁻¹ 7 months ⁻¹	-0.2 m ³ ha ⁻¹ 7 months ⁻¹

Figure 7. Example of the hillslope-wide volume of redistributed sediment for a time period of 7 months on the south-facing hillslope in La Campana: (a) Density of burrows as estimated by Grigusova et al. (2021); (b) Volume of the sediment excavated by the animals; (c) Volume of the sediment redistributed during rainfall events within burrows; (d) Volume of additionally redistributed sediment during rainfall events due to the presence of the burrows. The values were calculated per burrow as stated in Section 3.7. by subtracting the sediment volume redistributed within burrows from the sediment volume redistributed within burrow embedding area and then upscaled. The letters in brackets indicate if the upscaling was conducted using data from burrows or burrow embedding areas. “B” stands for burrow. By “EM-B”, the redistribution calculated within burrow embedding areas was subtracted from the redistribution calculated within burrows to obtain the additional volume of redistributed sediment due to the burrows’ presence.

527

528 **5. Discussion**

529 Our results showed that the custom-made ToF device is a suitable tool for high-resolution, automated
530 monitoring of surface changes, applicable also in remote areas. The ability of a continuous observation of
531 sediment redistribution over a longer time during our study provided new insights into the importance of
532 burrowing animals for sediment redistribution. Our research reveals that the presence of vertebrate burrows
533 increases hillslope sediment redistribution rates much more than previously assumed (up to 208%). We
534 showed that the quantity of animal-related sediment redistribution, however, varied with rainfall occurrence,
535 with an increase in sediment redistribution between 40% in the arid research area and 338% percent in the
536 mediterranean research area.

537

538 **5.1 Suitability of the ToF method for surface monitoring**

539 The here proposed monitoring technique enables an automatic monitoring of surface changes on a
540 microtopographic scale, and its measurement continuity allows for the analysis of ongoing
541 biogeomorphological processes in high temporal resolution.

542 With regard to the costs, measurement frequency and sampling autonomy, the custom-made ToF
543 device stands in contrast to earlier studies that used laser scanning technology to monitor microtopographic
544 changes (Table A5). Previous studies mainly applied expensive laser scanning for the estimation of sediment
545 redistribution, and the research sites had to be personally revisited for each of the measurements (Eltner et
546 al., 2016a; Eltner et al., 2016b; Hänsel et al., 2016; Nasermoaddeli and Pasche, 2008). The estimated costs
547 in studies using time-lapse photogrammetry were similar to our study (up to 5000 USD) (Blanch et al., 2021;
548 Eltner et al., 2017; Galland et al., 2016; James and Robson, 2014; Kromer et al., 2019; Mallalieu et al., 2017).
549 However, for time-lapse monitoring, several devices needing different viewing angles increases installation
550 efforts significantly.

551 In terms of data quality, our ToF device is more precise or comparable to those employed in other
552 studies. The accuracy of the camera ($R^2 = 0.77$) was in the range of previous studies ($R^2 = 0.26$ – 0.83 (Eitel et
553 al., 2011), Table A5). The horizontal point spacing of our cameras was 0.32 cm, and the maximum number of
554 points per cm^2 was 8.5. These values are similar to previous studies in which the used devices had a horizontal
555 point spacing in the range of 0.25–0.57 cm (Kaiser et al., 2014; Nasermoaddeli and Pasche, 2008)) (Table
556 A5), and the maximum number of points per cm^2 in a range of 1 point–25 points cm^{-2} (Eitel et al., 2011; Longoni
557 et al., 2016) (Table A5).

558 Our cameras tended to slightly overestimate or underestimate the volume of redistributed sediment.
559 This error occurs when the pulse reflects from several vertical objects such as walls or, in our case, branches
560 or stones and then enters the camera sensor. This phenomenon was also observed in previous studies
561 applying laser scanners and is inevitable if the goal is to study surface changes under natural field conditions
562 (Ashcroft et al., 2014; Kukko and Hyypä, 2009). During operation of the cameras, we learnt that our newly
563 developed instruments are particularly capable of delivering usable scans at night. This is likely due to the
564 strong scattered sunlight reaching the camera sensor during the day, blurring the data (Li, 2014). Thus, in
565 future studies, we recommend focusing on nocturnal operation to prevent light contamination from the
566 surroundings.

567 We could thus prove that ToF cameras are a suitable and cost-effective method for a continuous
568 monitoring of sediment redistribution at a microtopographic scale without the need of time, labour and cost
569 intensive laser scanning/time-lapse photogrammetry campaigns.

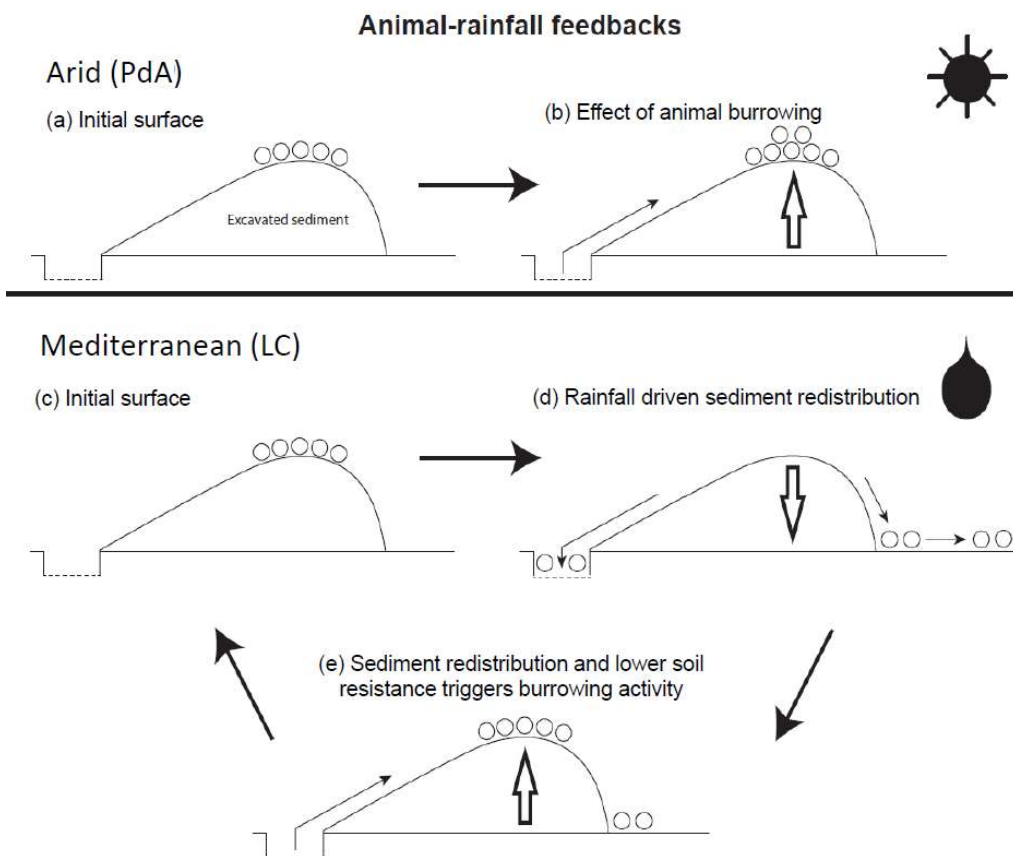

570

571 5.2. Sediment Redistribution

572 Our research reveals that the presence of vertebrate burrows generally increases hillslope sediment
573 redistribution. We show, however, that the ratio between the sediment redistribution caused by rainfall within
574 burrow and burrow embedding areas varies between climate zones. Sediment redistribution within burrow
575 areas was 40% higher at the arid research site, and at the mediterranean research site, it was 338% higher
576 when compared to burrow embedding area (Table A6).

577 By monitoring microtopographical changes in a high spatio-temporal resolution, we found that the
578 occurrence of larger rainfall events played a two-fold, accelerating role in influencing sediment redistribution
579 (Fig. 5, A4). Firstly, rainfall-runoff eroded burrow material caused increased sediment loss. This was followed
580 by animal burrowing activity after the rainfall. This means that rainfall triggered animal burrowing activity which
581 was very likely related to a lower burrowing resistance of the soil due to the increased soil moisture (Herbst
582 and Bennett, 2006; Romañach et al., 2005; Rutin, 1996). This double feedback led to frequently occurring but
583 small redistribution rates. However, cumulatively, the mechanism increased downhill sediment fluxes. Previous
584 studies most likely missed this low magnitude but frequent surface processes due to a lower monitoring
585 duration and frequency, or artificial laboratory conditions, and thus, did not quantify the full volume of
586 redistributed sediment associated with burrowing activity. To quantify all occurred sediment redistribution
587 processes, a continuous surface monitoring, like the here presented, is needed.

588

589

590 **Figure 8.** Scheme of animal-driven and rainfall-driven sediment redistribution processes in both investigated
591 climate zones: (a) Describes the initial surface of the burrow before the start of a sediment redistribution
592 process, and (b) the animal excavation process in the arid climate zone. Here, due to rarely occurring rainfall
593 events, sediment redistribution is mostly controlled by the animal burrowing activity; (c) describes the initial
594 burrow surface in the mediterranean climate zone, (d) the process of sediment redistribution during a rainfall
595 event and (e) the subsequent animal burrowing activity. Burrowing is triggered by decreased soil resistance
596 due to the increased soil moisture after rainfall as well as by sediment accumulation within the burrow's
597 entrance. Burrowing activity leads to a new supply of sediment being excavated to the surface. In the
598 mediterranean climate zone, sediment redistribution is controlled by both animal burrowing activity and rainfall.
599 The alternating excavation and erosion process ultimately lead to an increase in redistribution rates.

600
601 Our results indicate an up to 338% increase in the sediment volume redistributed during rainfall events
602 measured within burrows when compared to burrow embedding areas. In contrast to our result, the maximum
603 increase estimated in previous studies was 208% (Table A6, (Imeson and Kwaad, 1976). The two climate
604 zones also show different patterns: In the mediterranean climate, the contribution of animals' (vertebrates')
605 burrowing activity appear larger than previously observed by using field methods such as erosion pins or
606 splash traps (from -3% until - 208%, Table A6, (Black and Montgomery, 1991; Hazelhoff et al., 1981; Imeson
607 and Kwaad, 1976). In contrast, in arid PdA, our study found a much smaller increase (40%, Table A6) in the
608 sediment volume redistributed during rainfall events measured within burrows when compared to burrow
609 embedding areas. This is lower than previously estimated (125%, Table A6, (Black and Montgomery, 1991).
610 However, solely one rainfall event above 0.2 mm day⁻¹ occurred during our monitoring period. Hence, we
611 conclude that the contribution of burrowing activity of animals to hillslope sediment transport is much larger in
612 areas with frequent rainfall events than previously thought, while it has been realistically estimated by previous
613 studies for areas with rare rainfall events (Table A6).

614 Magnitudes of sediment volume redistributed within burrows similar to our results were previously
615 obtained solely in studies applying rainfall simulators. These studies estimated an increase in the volume of
616 sediment redistributed during rainfall events, measured within burrows when compared to burrow embedding
617 areas, to be between 205% and 473% (Table A6, (Chen et al., 2021; Li et al., 2018). However, a rainfall
618 simulator can only provide data on surface processes within a plot of a few m² in size and under ideal laboratory
619 conditions while ignoring the uphill microtopography, vegetation cover and distribution (Iserloh et al., 2013),
620 which were shown to reduce erosion rates. More importantly, the rainfall intensity on hillslopes decreases with
621 (i) the angle of incidence of the rain, (ii) the inclination of the surface and iii) the relative orientation of the
622 sloping surface to the rain vector (Sharon, 1980). When simulating a rainfall event with the same rainfall volume
623 as in the field, the rain is induced directly over the treated surface and has thus a higher velocity which leads
624 to an increased splash erosion than under natural conditions (Iserloh et al., 2013). We thus propose that the
625 rainfall experiments overestimate the erosion rate while the correct erosion rate can be measured solely under
626 field conditions.

627 Cumulative sediment redistribution within burrow roof, mound and entrance was, on average, 28%
628 lower than cumulative sediment redistribution only within the mound and the burrow roof (Figure A7). These
629 results suggest that 28% of the eroded sediment from animal mounds and burrow roofs is re-accumulated
630 within the burrow entrance during rainfall-runoff events, and the remaining 62% is incorporated into overall
631 hillslope sediment flux. Our numbers contrast with previous studies, which quantified that about 58% of the

632 sediment excavated by animals will accumulate back in the burrow entrance and only 42% is incorporated to
 633 downhill sediment flux (Andersen, 1987; Reichman and Seabloom, 2002). Hence, our results indicate not only
 634 higher redistribution rates within burrows by burrowing animals but also point to much higher supply of
 635 sediment to the downhill sediment flux than previously thought.

636 Our cost-effective ToF device provides data on surface changes in a high spatio-temporal resolution.
 637 The high temporal resolution was able to unravel ongoing low magnitude but frequent animal excavation and
 638 erosion processes. The high spatial resolution enabled us to estimate the exact volume of sediment fluxes
 639 from the burrows downhill. The here presented results indicate that the contribution of burrowing animals on
 640 the burrow as well as on the hillslope scale was much higher than previously assumed. Our results can be
 641 integrated into long-term soil erosion models that rely on soil processes and improve their accuracy by
 642 including animal-induced surface processes on microtopographical scales in their algorithms.

658 **Appendices**

659 **Table A1.** List of abbreviations

α [°]	Tilt angle of the camera
b [°]	Surface inclination
Ω	Threshold value for the scan scattering error
B	Burrow
Area_{burrow}	mean in the field measured size of the burrows which are monitored
Area	total surface area monitored by the camera
BD	Bulk density
c [m/s]	Speed of light
D	Distance from the camera to the object
Dens_{burrow}	Burrow density
DSM	Digital surface model
DSM_{after}	DSM calculated from the scan taken after the extraction
DSM_{before}	DSM calculated from the scan taken before the extraction

EM	Burrow embedding area
Entrance	entrance to the animal burrow
g [-]	ratio [-] of the reflected photons to all photons
LC	National Park LC
LC-NL	Camera in LC on the lower north-facing hillslope
LC-NU	Camera in LC on the upper north-facing hillslope
LC-SL	Camera in LC on the lower south-facing hillslope
LC-SU	Camera in LC on the upper south-facing hillslope
MAE	Mean absolute error
MAP [°]	Mean annual precipitation
m.a.s.l.	Meters above sea level
MAT	Mean annual temperature
mClay [%]	Mean content of clay
mean_{z-coordinate}	Mean value of the z-coordinates
Mound	the sediment excavated by the animal while digging the burrow
mSand [%]	Mean content of sand
mSilt [%]	Mean content of silt
n	Number of scans
PdA	National Park Pan de Azúcar
PdA-NL	Camera in PdA on the lower north-facing hillslope
PdA-NU	Camera in PdA on the upper north-facing hillslope
PdA-SL	Camera in PdA on the lower south-facing hillslope
PdA-SU	Camera in PdA on the upper south-facing hillslope
Res	Resolution
Roof	sediment pushed aside and uphill the entrance during burrow creation
S_a	scan after the rainfall event
S_b	scan before the rainfall event
SBC	Single board computer
sd_{z-coordinate}	standard deviation of the z-coordinates
SSH	Secure shell
t [s]	Overall time of camera illumination
TOC [%]	Total organic carbon
ToF	Time-of-Flight
Vol_{burrow}	volume of redistributed sediment within burrow
Vol_{detected}	volume of the extracted sediment as detected by the camera
Vol_{add}	difference in redistributed sediment volume between burrows and burrow embedding areas
Vol_{exc}	Volume of the sediment excavated by the animal
Vol_{hillslope-wide}	Hillslope-wide volume of redistributed sediment
Vol_{measured}	volume of the extracted sediment measured by the measuring cup

Vol_{per burrow}	Volume of redistributed sediment per burrow
Vol_{per pixel}	Volume of redistributed sediment per pixel
Vol_{redistributed}	volume of the calculated redistributed sediment
Vol_{embedding}	volume of redistributed sediment within burrow embedding area
y_i	distance of the point to the point of origin at the camera nadir
Z_{cor}	Corrected z-coordinate
Z_{uncor}	Uncorrected z-coordinate

660

661 **Table A2.** Number of usable scans for each camera

Camera	Latitude	Longitude	Number of scans	Percentage of usable scans taken at 1am / 5am / 8am / 10pm	Time period
PdA-NU	-25.98131	-70.61666	238	29 / 27 / 20 / 24	18.3.-18.9.
