Abstract. The width of valleys and channels affects the hydrology, ecology, and geomorphic functionality of drainage networks. Valley and channel widths are often estimated through a power-law scaling between width (W) and drainage area (A), and where lithologic variability or differential uplift rates dominate, width was suggested to scale with both slope (S) and drainage area, through the relation $W = k_b A^b S^c$. However, in fluvial systems that experience drainage reorganization, abrupt changes in drainage area distribution can result in widths that are disproportional to their drainage areas. Consequently, in such cases, the width-area-slope scaling is expected to deviate relative to drainages that did not experience reorganization.

15

To explore the effect of reorganization on width-area-slope scaling, we studied 12 valley sections in the Negev desert, Israel, categorized into undisturbed, beheaded, and reversed valleys. We found that the drainage area exponent, b , differs between valley categories, and that reversed valleys are characterized by a negative b exponent, indicating valley narrowing with increasing drainage area. A detailed study of a reversed valley reveals that unlike the negative b exponent that links drainage area to valley width, the relation between drainage area and channel width is best fitted with a positive b exponent. This difference indicates that the timescale of channel width adjustment to post-reorganization drainage area distribution is faster than that of the valley width adjustment. We find that the difference in channel width across the divide causes a step change in unit stream power between the adjusted reserved channel and the unadjusted, beheaded channel. Gradients in width and unit stream power across the divide, lead to a width-feedback that promotes ongoing divide migration and reorganization.

25

The identified distinct width-area-slope scaling of reorganized valleys could assist in recognizing and constraining the dynamics of landscapes influenced by drainage reorganization and likely has critical implications for the distribution of erosion rates in reorganized landscapes.

30

1 Introduction

The width of channels and their hosting valleys control river's dynamics and functionality with far-reaching
35 implications across a wide range of disciplines, from flood and seismic hazards (e.g., Lóczy et al., 2009; Mashael Al,
2010; Morell et al., 2020; Sampson et al., 2015), to river ecosystems and habitats (e.g., Beeson et al., 2018; Brussock
et al., 1985; May et al., 2013; Sweeney et al., 2004), and to hydrological modeling (e.g., Looper et al., 2012). Valley
and channel width further play a central role in landscape evolution, as they respond to changes in the forcing that act
on the landscape (Amos and Burbank, 2007; Fisher et al., 2013; Hancock and Anderson, 2002). The ratio between
40 valley width, which integrates the channels, terraces, and floodplains, on the one hand, and morphometric valley
properties such as depth or fill thickness, on the other hand, are used to elucidate drainage evolution over geological
timescales (Gibling, 2006; Schumm and Ethridge, 1994) and for inferring climate changes (Dury, 1964; Hancock and
Anderson, 2002; Marcotte et al., 2021) and tectonic variations (Giaconia et al., 2012). The channel width is a key
component in landscape evolution for its control on the shear stress, sediment transport capacity, and erosion rate
45 (Whittaker et al., 2007b; Yanites et al., 2010). Particularly, many landscape evolution and hydrologic models
approximate the local erosion rate as a function of the channel stream power per channel width (i.e., unit stream power,
Harbor, 1998; Lague, 2014; Magilligan et al., 2015; Turowski, 2018; Yanites, 2018).

The wide use of valley and channel width across various disciplines highlights the value of high-resolution
width measurements, which could vary by several orders of magnitude within a single basin and across basins and
50 landscapes (Schumm and Ethridge, 1994). However, producing high-resolution field-based width measurement is
challenging and time-consuming. In recent years, a growing body of work focused on developing tools for automatic
width extraction based on remotely-sensed data (e.g., Fisher et al., 2013; Gilbert et al., 2016; Hilley et al., 2020;
Monegaglia et al., 2018; Roux et al., 2014; Rowland et al., 2016). Although these tools enabled a significant
advancement in river research and management, they commonly focus on specific types of river morphology, and
55 require parameter calibrations, as well as human supervision (Fryirs et al., 2019; Golly and Turowski, 2017). Due to
these limitations, width of natural channels and valleys is more commonly estimated based on the widely recognized
scaling relationships between valley and channel widths and fundamental basin properties such as discharge (or its
proxy, drainage area), which could be relatively easily measured (e.g., Lavé and Avouac, 2001; Wobus et al., 2006).
Furthermore, these scaling relationships are used frequently in landscape evolution models, where the width is
60 parametrized based on the drainage area (e.g., Goren et al., 2014; Lague et al., 2014; Shobe et al., 2017; Yanites et al.,

2013). Beyond steady conditions, several studies demonstrated that width can adjust dynamically in response to transient environmental conditions (Snyder and Kammer, 2008; Whipple et al., 2013; Yanites, 2018), and that in such landscapes, a more complex scaling involving width, area, and slope might be more applicable.

65 1.1 Width scaling relations

The common approach for width estimation relies on the seminal work of Leopold and Maddock (1953), who used empirical data to establish a power-law relation between the channel width, W [m] and discharge, Q [m³/sec]. Based on the well-established correlation between discharge and drainage area, A [km], (e.g., Dunne and Leopold, 1978), the scaling between channel width and drainage area is often expressed as

$$70 \quad W = k_c * A^d \quad (1)$$

Leopold and Maddock's relation, (Eq. (1)), was initially established for alluvial rivers, where d was found to be ~0.5. A similar scaling was later reported for bedrock rivers, with an exponent that typically ranges between 0.3–0.6 (Kirby and Ouimet, 2011; Montgomery and Gran, 2001; Snyder et al., 2003; Tomkin et al., 2003; Whitbread et al., 2015; Yanites et al., 2010). The exponent's range was attributed to differences in rock properties, where erodible and/or
75 fractured rocks widen faster than resistant and/or intact rocks (Spotila et al., 2015; Whitbread et al., 2015; Wohl and Achyuthan, 2002; Wohl and David, 2008).

Several studies suggested that the relation between the valley width and drainage area follows a similar power-law scaling (Beeson et al., 2018; Brocard and van der Beek, 2006; Langston and Temme, 2019; Langston and Tucker, 2018; May et al., 2013; Phillips, 2011; Schanz and Montgomery, 2016; Snyder et al., 2003; Tomkin et al.,
80 2003). In these cases, the reported range of the exponent d was significantly wider, between 0.1 (Langston and Temme, 2019) and 1.18 (Beeson et al., 2018). Here too, the range was attributed to differences in the properties of the valley-bounding rocks (Keen-Zebert et al., 2017; Langston and Temme, 2019; Schanz and Montgomery, 2016), or, in some high relief landscapes, to the spatial distribution of deep-seated landslides (Beeson et al., 2018; May et al., 2013).

While the applicability of the simple width-area power law scaling (Eq. (1)) was demonstrated in many
85 settings (Montgomery and Gran, 2001; Whitbread et al., 2015), field observations show that it is not applicable across all landscapes. Particularly, the scaling was demonstrated to fail when channels respond to transient conditions, such

as crossing areas of enhanced uplift rate (e.g., due to local faulting or folding) (Allen et al., 2013; Finnegan et al., 2005; Lavé and Avouac, 2001; Montgomery, 2004; Whittaker et al., 2007a; Yanites et al., 2010), inducing dynamic changes to channels local slope and width (Amos and Burbank, 2007; Kirby and Ouimet, 2011; Whipple et al., 2000; 90 Whittaker et al., 2007a, 2007b; Yanites, 2018). Consequently, substantial research focused on understanding dynamic adjustments of bedrock channel width in response to uplift rate changes (e.g., Turowski, 2018; Wobus et al., 2006; Yanites, 2018).

Finnegan et al. (2005) developed a model for the case of a channel that crosses terrains with variable rock uplift rates. Adopting Manning's equation (Manning et al., 1890) and assuming a constant bankfull width-to-depth 95 ratio along the channel, Finnegan's model predicted that the channel width not only depends on drainage area, as in Eq. (1), but also on the channel slope, S [m/m]:

$$W = k_b * A^b * S^c, \quad (2)$$

Based on theoretical calculations, the exponents b and c in Finnegan's model equal 0.38 and -0.19, respectively. These values were also validated in the field (Finnegan et al., 2005) and were later applied by following studies that examined 100 width-area-slope scaling in field settings with alternating lithologies and variable uplift rates (Kirby and Ouimet, 2011; Spotila et al., 2015). Whittaker et al. (2007a) and Attal et al. (2008) studied settings of transient channels adjusting to changing tectonic forcing and suggested a more negative value of -0.44 for c , reflecting the dominant role of the slope in these settings.

105 1.2 Drainage reorganization and width scaling

Another form of variability and transiency in rivers is associated with drainage reorganization, which is widely recognized as an important process affecting the evolution of fluvial systems (e.g., Bishop 1995, Willett et al. 2014, Fan et al., 2018; Prince et al., 2011). Reorganization occurs when drainage divides shift through time (Bishop, 1995; Davis, 1889), change basin geometry, and consequently induce changes in the discharge and drainage area distribution 110 along the channels (e.g., Menier et al., 2017; Pechlivanidou et al., 2019). The scaling of Eq. (1) and (2) predicts that the addition or reduction of drainage area will result in widening or narrowing, respectively, of the channel and valley. However, when drainage area changes via reorganization, width adjustment may not occur synchronously and can

persist over long time scales (e.g., Jones, 2018; Snyder and Kammer, 2008). Valley width, particularly, is likely to adjust at slower rates than channel width because it represents the channel location integrated over long periods, commonly in the scale of $>1ky$ (Hancock and Anderson, 2002; Langston and Tucker, 2018; Schumm and Ethridge, 1994; Tomkin et al., 2003). Nonetheless, despite the intrinsic links between drainage reorganization and drainage area change, to the best of our knowledge, the effect of drainage reorganization on fluvial width scaling has not yet been evaluated. Recognizing and accounting for these scaling deviations could be highly consequential for predicting the hydrologic and geomorphic functionality of reorganized drainages.

We hypothesize that the scaling between drainage area and width could express the delayed response of width adjustment to changes in drainage area following the reorganization of drainage networks. Accordingly, the coefficient and exponent values that relate drainage area with valley and channel width in reorganized drainages could meaningfully deviate from drainages that did not experience reorganization.

To test this hypothesis and to evaluate the effect of reorganization on the width-area-slope scaling, we analyzed and compared the geometry of reorganized and undisturbed drainages in the southern Negev desert, Israel, where drainage reorganization is well established by field observations (Avni et al., 2000; Ginat et al., 2000, 2002; Harel et al., 2019). In the current analysis, we aim to (1) explore if and how the scaling between valley width, drainage area, and slope varies between reorganized and non-reorganized drainages and between drainages that experienced different modes of reorganization; (2) compare the adjustment of channel width relative to valley width following reorganization; and (3) examine implications of the width-area-slope scaling for reorganized drainages on landscape evolution.

2. Study area

2.1 Geologic and Geomorphic setting

We explore the scaling between the valley and channel width, drainage area, and slope along ephemeral valleys that incise into the southeastern Negev Highlands, Israel. The eastern boundary of the study area is the ~400-600m cliff of the Arava Valley (Fig. 1). The Arava Valley is a rift-like structure stretching between the Dead Sea and the Gulf of

Aqaba and is the southern segment of the transtensional Dead Sea plate boundary, between the Arabia plate and Sinai sub-plate (Garfunkel, 1981; Garfunkel et al., 2014, Fig 1A).

140 The main drainage divide in the study area mostly separates east-flowing basins that drain across the cliff toward the Arava Valley, from west-flowing, low relief channels that flow on the Negev highlands (Fig. 1b-c). The lithology exposed along the highland valleys consists primarily of Cretaceous limestone and dolomite strata (Ginat, 1991). The climate is hyper-arid with an average annual precipitation of \sim <50 mm (Bitan and Rubin, 1991), typically generating one to few flashflood events per year. These climatic conditions had generally persisted through most of
145 the Pleistocene (Amit et al., 2006, 2011), except for relatively short episodes of transition to wetter conditions (Ginat et al., 2018; Vaks et al., 2013).

 The eastern Negev desert has been experiencing ongoing fluvial reorganization since the late Miocene (Avni et al., 2000, 2012). Before the development of the Arava Valley, rivers that originated in the Jordanian highlands, east of the Arava Valley, flowed westward, crossing the plate boundary along the Negev highlands towards the
150 Mediterranean (Garfunkel and Horowitz, 1966; Zilberman and Calvo, 2013). Since the Miocene, tectonic activity along the Dead Sea plate boundary formed the Arava Valley that gradually became a prominent base level. Consequently, during the Plio-Pleistocene, several large-scale capture events had redirected major drainage systems in the Negev toward the central Arava valley (Avni et al., 2000; Ginat et al., 2000, 2002; Guralnik et al., 2010). Field observations and a regional χ analysis (a morphometric parameter used to approximate the stability of drainage divides,
155 (Willett et al., 2014)) suggest that the regional divide between the Arava Valley and the Negev highlands is still actively migrating westward (Harel et al., 2019).

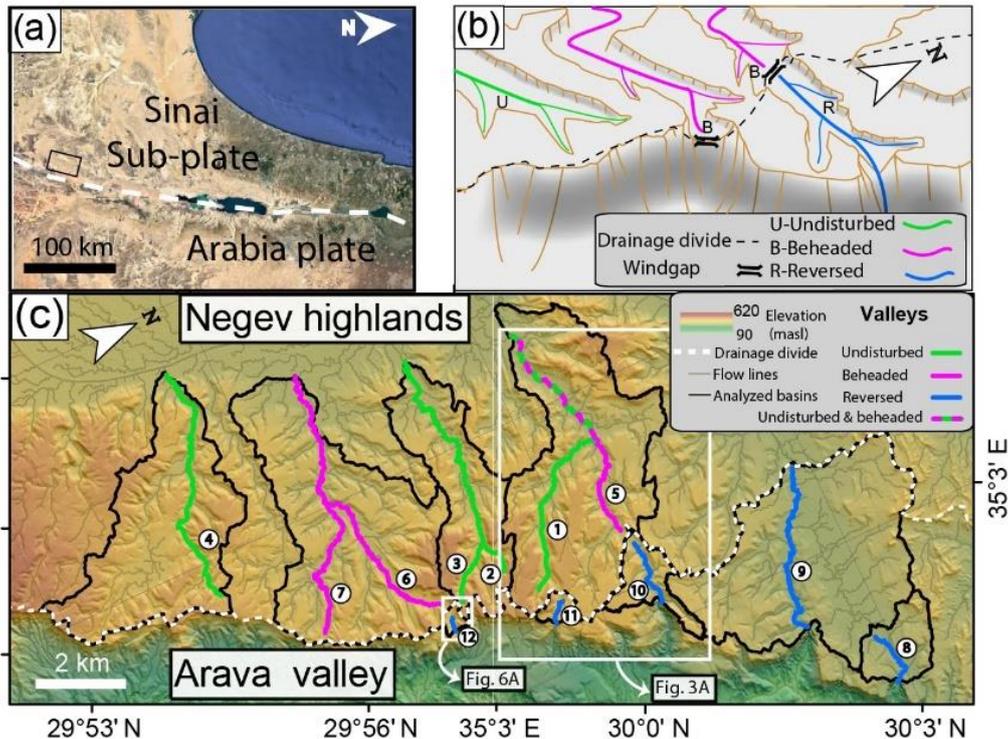

Figure 1 (a) Regional map of the study area (black rectangle) near the Sinai-Arabia plate boundary (dashed white line), based on © Google earth aerial photo (2020). (b) A simplified sketch of valley categorization in the study area: Undisturbed valleys (Green, 'U' tag) are valleys that do not intersect with the cliff and are not affected by drainage reorganization. Beheaded valleys are valleys that were beheaded due to cliff retreat or drainage reversal (pink, 'B' tag), and Reversed valleys (blue, 'R' tag), that presently flow toward the cliff, are commonly recognized by their barbed tributaries which join the main channel at a >90 degrees angle. (c) Shaded elevation map of the study area, based on TanDEM-X 0.4 arcsec DEM (Wessel, 2016), illustrating the drainage divide (white dashed line) between the Negev highlands and the Arava Valley. The basin boundaries (black lines) are defined by the valley section's outlet. Encircled numbers refer to the valley serial number in Table 1.

2.2 Categories and characteristics of valleys in the study area

To explore the effects of drainage reorganization on the scaling relations between width, drainage area, and slope, we analyzed 12 valley sections associated with different drainage reorganization categories. All sections are located adjacent to the Negev-Arava drainage divide, resulting in relatively small drainage areas of 0.2-14.2 km². The valleys are incised into bedrock, generating a relief of several tens of meters between the valley bottoms and the highlands'

flat interfluves. The valleys were classified into three categories, based on the association of the valley to the Arava cliff (Fig. 1b-c), the morphology of the valley section (Fig. 2), and additional supporting field observations:

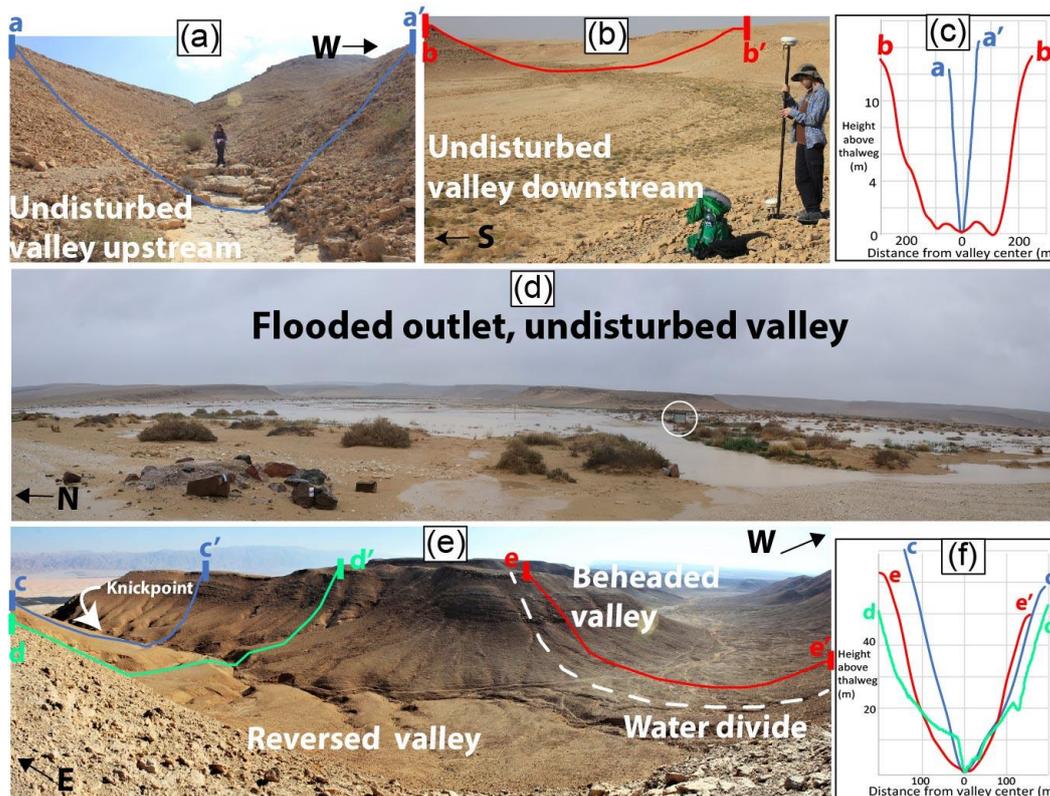

175 1. **Undisturbed valleys (n=4)** are westward flowing sections that do not show evidence of local drainage reorganization, suggesting that they were not directly affected by the formation of the Arava base level. In these valleys, the low-order (*sensu* Strahler) segments are characterized by a V-shaped morphology (Figs. 2A and 2C) and relatively rapid downstream widening. Higher-order valleys widen downstream slower and typically have a trapezoid cross-section with a sediment-filled flat valley bed, whose relief is tens of cm (Figs. 2b-d). Here, the definition of
180 valley and channel could be ambiguous because the low local relief results in braided and dynamic flow pathways, and because the entire valley is flooded during large rainstorm events (Fig. 2d).

 2. **Beheaded valleys (n=3)** are west-flowing sections whose headwaters were beheaded. Beheading is recognized by a windgap, i.e., a valley confined drainage divide that occurs along the cliff, or that is shared with a reversed valley (described below), indicating a paleo-valley that was formed by a channel that used to drain a larger
185 area. Close to the windgap, the beheaded valleys are characterized by a U-shaped cross-section (e.g., Figs 1b, 2e-f, 3a, and 6a), likely controlled by the colluvial aprons concave profile. West and downstream from the windgap, these valleys become indistinguishable from the undisturbed valleys with the trapezoid-shaped cross-section. Valley's beheading is associated with either the receding cliff and its coinciding divide, or with localized divide migration within the valley as part of a reversal process on the opposing side of the windgap (e.g., Figs. 2e and 3a, Bishop, 1995;
190 Harel et al., 2019, Shelef and Goren, 2021).

 3. **Reversed valleys (n=5)** host east-flowing channels that had reversed their drainage direction (Bishop, 1995) from west to east. These valleys are bounded between a windgap and a knickpoint generated where the channel flows across the cliff (e.g., Figs 2e, 3a and 6a). Harel et al. (2019) identified these sections as reversed drainages based on the presence of barbed tributaries and west grading terraces that record the antecedent valley gradient, opposite to
195 the present-day channel's drainage direction. The reversed valley sections share windgaps with beheaded valleys, indicating that they were part of the antecedent west-flowing drainage (e.g., Fan et al., 2018). In the reversed valleys, the valley morphology near the windgap is typically U-shaped, and downstream the channel incises into the alluvial-colluvial valley fill, creating cut terraces and forming a V or box-shaped channel cross-section within the broader

valley. In most cases, as the valley approaches the knickpoint over the cliff, the channel incises into bedrock and the
200 valley cross-section changes to a V-shaped morphology (Figs. 2e-f).

205 Figure 2: Field photos and valley transects of valley sections in the study area. (a,b) Upstream and downstream segments
 of undisturbed valleys ((a) and (b) respectively). The drainage area in panel (a) is 0.08 km² and in panel (b) is 1.85 km².
 Blue and red lines (a-a' and b-b', respectively) mark the cross-section profiles shown in panel (c). (c) Transects of a-a'
 and b-b'. Note the V-shaped transect of the valley head relative to the trapezoid morphology of the downstream section. (d)
 210 Flooded valley bottom at the outlet of valleys 6 and 7, after an intense rain event in February 2020. An ~1.5 meter wide sign
 is encircled for scale. (e) Panorama of reversed and beheaded valleys (valley 12 and 6 in Table 1 and Fig. 1c), and the
 confined, flat windgap between them. The c-c' transect (blue) was measured near the knickpoint at the edge of the reversed
 section, d-d' (green) follows the terraces representing the paleo-valley and the channel that incises into them, and e-e' (red)
 was measured close to the drainage divide on the beheaded side. (f) Cross-sections of transects c-c', d-d', and e-e'
 emphasizing the difference between the U-shape transect near the windgap (e-e'), the V-shaped channel profile incised into
 the U-shaped valley terraces (d-d'), and the V-shaped transect above the knickpoint (c-c').

215 **3. Methods**

We study the effect of reorganization on valley width scaling by exploring the relations between valley width, drainage area, and slope following Eq. (2). While Eq. (2) was originally developed to estimate channel width, we adopt it here for valley width due to its generality. In Sect. 5.2, we devote a detailed discussion to the slope effect on valley width, which distinguishes the predictions of Eqs. (1) and (2).

220 To compute the coefficient k_b , and exponents b and c (Eq. (2)) that best fit the valley sections' geometry in
the study area, we applied a multivariate regression over the valley width, drainage area, and slope along the studied
sections. The topography data were derived from TanDEM-X DEM (Wessel, 2016) with 0.4 arcsec resolution (~11.6m
in the field area).

Unlike the upstream drainage area and channel slope, which are derived by simple morphometric analysis
225 over the DEM, defining and extracting the valley width based on DEM is not straightforward and requires a tailored
procedure (Clubb et al., 2017; Golly and Turowski, 2017; Hilley et al., 2020; Roux et al., 2014; Rowland et al., 2016;
Sechu et al., 2021). Particularly, the location and orientation of valley width measurements require caution because
the width is not necessarily well-defined in proximity to side tributaries and valley bends (e.g., Beeson et al., 2018).
To overcome these challenges, we developed a semi-automatic approach for optimal measurements of valley width.

230

3.1 Valley width measurements

Valley width was measured by applying two main operations. First, a polygon representing the valley bottom of
drainage basins is extracted, and second, valley width is measured over the valley bottom polygon at optimal points
(Fig. 3a). The first step is achieved by applying the ArcGIS plugin VBET- 'Valley bottom extractor tool' (Gilbert et
235 al., 2016). In VBET, valley boundaries are identified based on user-defined slope thresholds, representing the
transition from the valley bottom to the hillslope. VBET parameters used for the current analysis are described in
Table S1 in the Supplement. Importantly, these parameters were fitted to each basin separately by an iterative process
of visually comparing the valley bottom polygons against 0.5m/pixel aerial orthophotos and fine-tuning the parameters
to achieve the best visual fit. In six basins, this procedure was not sufficient to achieve a satisfying fit between the
240 VBET polygon and the orthophoto, mainly due to local DEM inaccuracies. In these cases, the polygons were manually
edited to correct mismatches. Manual editing was based on the orthophotos, available topographic data, and field
observations. Except in one case where the area difference between the original and edited polygons was 10%, the
differences in the other five basins were <5% (Table S1 in the Supplement).

Width measurements over the VBET polygons were achieved by applying an ArcGIS-based algorithm that
245 identifies optimal locations for measuring valley width. The algorithm identifies points along the valley talweg that
are sufficiently far from bends and confluences, such that they don't affect the valley width. The algorithm operates

iteratively, where each iteration identifies optimal width measurement points in valleys of a different order. The final output of the algorithm is a set of pixels located along the intersections between the valley transects, whose length represent the valley width, and the valley talweg (flowlines) (e.g., Fig 3a). The algorithm is described in detail in
250 Section S1 and Figs. S1-S5 in the Supplement.

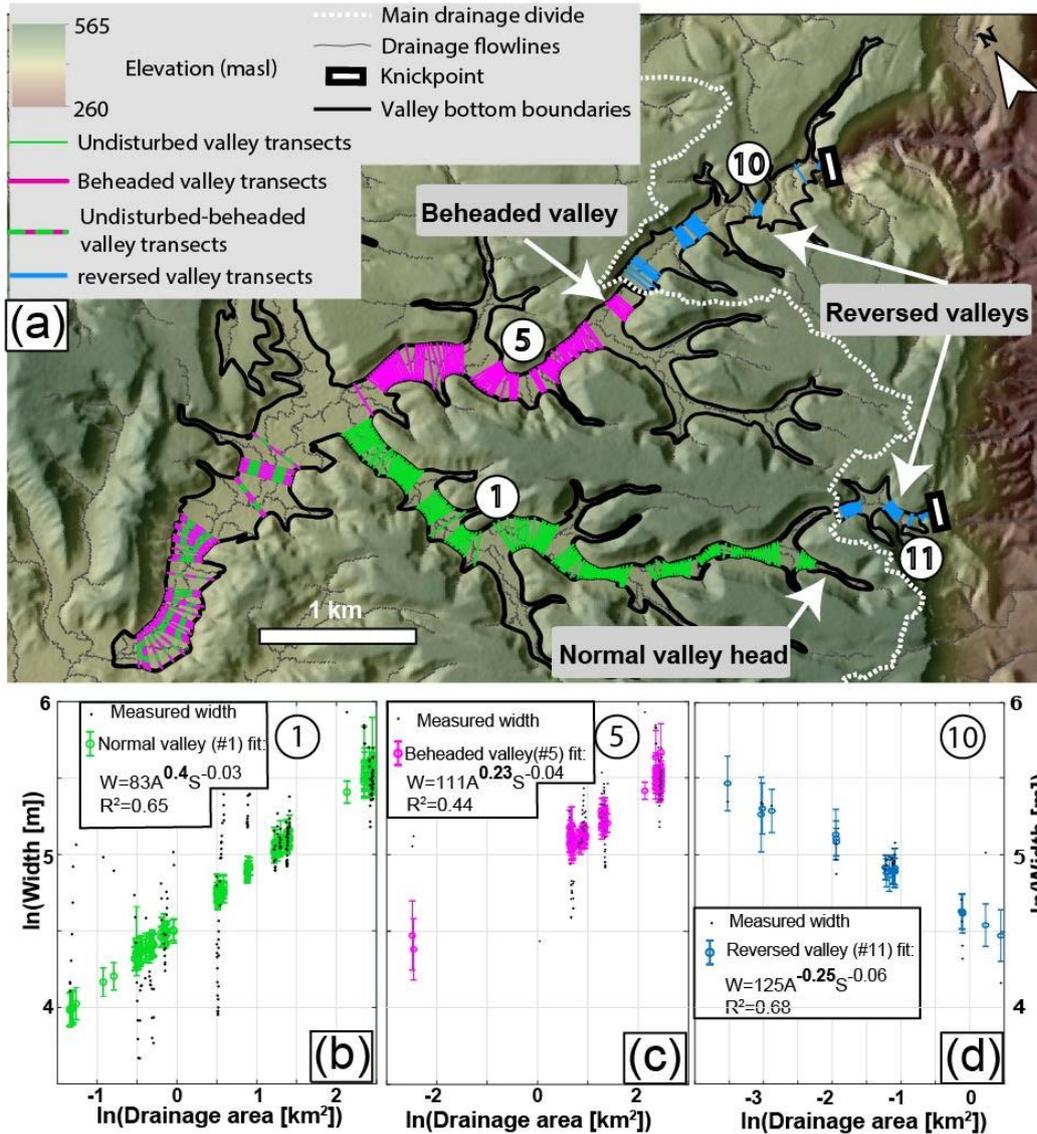

3.2 Drainage area and slope extraction, and multivariate regression

Along the intersection pixels between width transects and the valley talweg, drainage area and slope were extracted based on the DEM. The drainage area was extracted from a flow accumulation raster, computed using a D8 flow
255 routing algorithm (O'Callaghan and Mark, 1984). The slope was calculated using a 5-pixel running window along the channel profile, where the slope that was calculated between the terminal pixels of the window was assigned to the central pixel.

Importantly, the extracted slope is that of the channel. In the undisturbed and the beheaded valley sections, field observations indicate that the channel and the valley slope are indistinguishable (e.g., Fig. 2b,2d and 2e). This is
260 not the case for reversed valley sections, where the channels are decoupled from the valleys. The reversed channels are incised into the bottom of paleo-valleys, whose grading may be opposite to that of the active channel (Harel et al., 2019).

Direct measurements of the reversed valley's slope are unlikely to produce reliable results because the preservation of the antecedent valley bed is, in most cases, poor and patchy. In Sect. 3.3 and 5.2, we present an
265 independent analysis dedicated to the reversed valleys and discuss the implications of using the channels' slope in the valley analysis.

After extracting the valley width, drainage area, and slope at the intersection pixels, the best-fit values of k_b , b , and c in Eq. (2) were obtained. The best-fit values were calculated by using a multivariate least-squares linear regression over W [m], A [km], and S [m/m] (following Attal et al., 2008; Spotila et al., 2015) that were log-
270 transformed, (Fig. 3b-d). The data points were not binned.

275 Figure 3: Valley width measurements and a regression-based model for valleys 1, 5, and 10 from Fig. 1c and Table 1. (a) A
 valley bottom polygon (black) overlays a shaded elevation map based on TanDEM-X 0.4 arcsec DEM (Wessel, 2016). Green,
 pink, and blue lines represent transects of undisturbed, beheaded, and reversed valley sections, respectively. Dashed lines
 represent measurements at valley sections, downstream of confluences between undisturbed and beheaded valleys. The
 280 reversed valleys extend between the main drainage divide (dashed white curve) and knickpoints (white boxes located at the
 cliff-flowlines intersections). (b-d): Multivariate regression and the associated k_b coefficients and b and c exponents for the
 undisturbed, beheaded, and reversed valleys 1, 5, and 10, respectively. 95% confidence interval is represented by error
 bars.

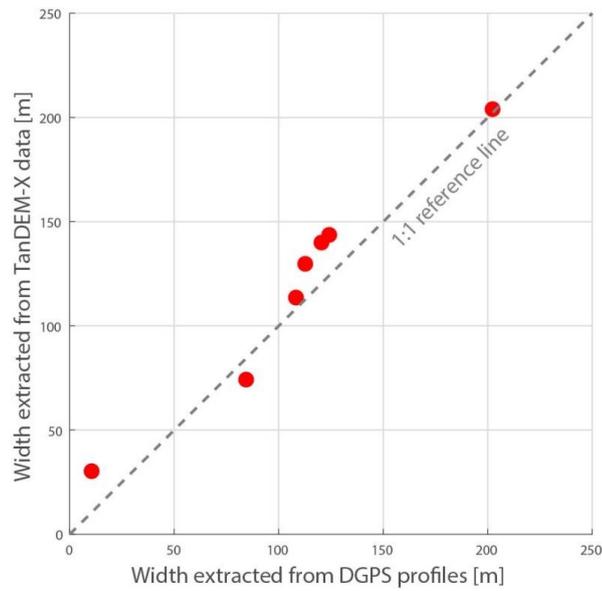

3.3 Detailed analysis of channel and valley width

For the reversed category, where the valley and the channel are decoupled, we examined how fitting the valley width compared to the channel width affects the predictors k_b , b , and c in Eq. (2). Valley 12 (Fig. 1c and Table 1) is a
285 thoroughly surveyed site investigated in a previous study (Harel et al., 2019) that was chosen for this analysis. The channel analysis is based on a 15 cm/pixel DEM and a 3 cm/pixel orthophoto generated using a structure from motion (SfM) algorithm over drone-acquired aerial photos (80% overlap). Here, the channel bottom polygon was delineated manually based on the high-resolution DEM and orthophoto. Then, the width measurement algorithm described in Sect. 3.1 was applied over the channel polygon. The multivariate regressions for the channel and the valley used the
290 slope and drainage area based on the high-resolution DEM, following the procedure described in Sect. 3.2.

3.4 Validations and errors in the measurements and model

The main potential sources of width measurement errors originate from the DEM horizontal resolution, R (~11.6 m²/pixel), and the relative vertical accuracy (~2m, Wessel, 2016). To incorporate the uncertainty stemming from the
295 horizontal resolution of the DEM, we assigned each width measurement with a constant error, evaluated as $\sqrt{2} * R$.

To independently explore the effect of the vertical accuracy on the final width measurements, valley transects of seven selected sites were measured with a differential GPS (DGPS). The valley bottom was extracted from the transects by applying the same slope criteria as the VBET tool for that basin. The correspondence between the DEM and the DGPS-based width measurements is shown in Fig. 4: The differences between the DEM-based width
300 measurements relative to the DGPS-based measurements range between 1.7-19.8 m, and are scale-independent. Overall, the RMSE is 13.08 m, smaller than the error of $\sqrt{2} * R$ evaluated from the horizontal DEM resolution. The width measurements are available in Table S2 in the Supplement.

305 **Figure 4: Validation of the width measurements extracted from TanDEM-X against width measurements based on differential GPS valley transects. The maximal difference between the measurements is less than 20 m.**

4. Results

4.1 Width, drainage area, and slope scaling along valley sections

310 The best-fit coefficients and exponents of individual valley sections, their 95% confidence intervals, and the adjusted R^2 for the regression are presented in Table 1 and Fig. 5. P-values of the predictors and of the multivariate regressions are provided in Table S3 in the Supplement.

315 Table 1: Best-fit regressions for individual valley sections.

^a Predictor P-value >0.05.

320 The multivariate regression results reveal a unique range of the drainage area exponents values, b , for each predefined valley category (Fig. 5b). The undisturbed valleys are characterized by the highest exponents, ranging from 0.25 to 0.55, whereas the b exponents of the beheaded valleys are lower, 0.17- 0.23. Uniquely, the reversed valleys have negative b exponents, ranging from -0.24 to -0.71, indicating that the valley narrows with increasing drainage area in this category.

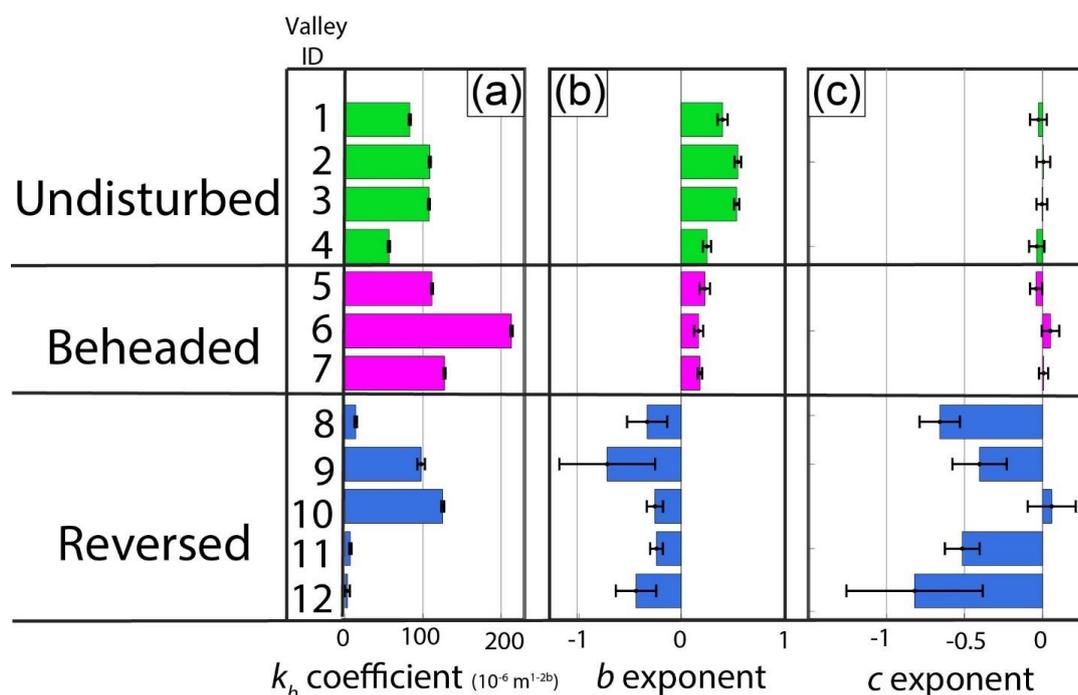

325 Unlike the b exponent values, the k_b coefficient values and the slope exponent values, c , are non-unique for the categories (Fig 5a and 5c). The values of the k_b coefficient, which represents the valley width at $A=1 [km^2]$, ranges

from 56.26 to 108.73 ($10^{-6} m^{1-2b}$) in the undisturbed valleys, which overlaps with the range of the beheaded valleys, 127.74 - 213.51 ($10^{-6} m^{1-2b}$) (Fig 5a). The k_b coefficient values along the reversed valleys cluster into two groups, three valleys with low values of 3.04-13.72 ($10^{-6} m^{1-2b}$), and two with higher values of 97.63 and 125.32, showing a similar range to the undisturbed and beheaded valleys.

330 In the undisturbed and beheaded valleys, the values of the slope exponent c are smaller by an order of magnitude relative to the values of the area exponent, b , and are statistically insignificant (with one exception in valley 5), at the 5 % significance level (Table 1). On the other hand, in all the reversed valleys except for valley 10, the values of the c exponent are negative, have the same order of magnitude as the area exponent values, and are statistically significant (P-value <0.05).

335 The model performance was evaluated through the adjusted R^2 , which was higher than 0.6 in most valleys, and overall >0.38 (Table 1, Fig. 5). The model P-value for all valleys was <0.05 (Table S3 in the Supplement).

340 **Figure 5: Bar plots of the k_b , b , and c values (panels (a), (b) and (c), respectively) produced by least-square multivariate regression for valley sections of the categories defined in Fig. 1b. The error bars represent the 95% confidence interval. k_b values are generally higher in beheaded valleys, but no clear trend is observed. The most prominent trend emerges in the values of the b exponent (b), which are characterized by an exclusive range for each valley category. The values of the slope exponent, c , are approximately zero in the undisturbed and beheaded categories and mostly negative in the reversed valleys.**

345

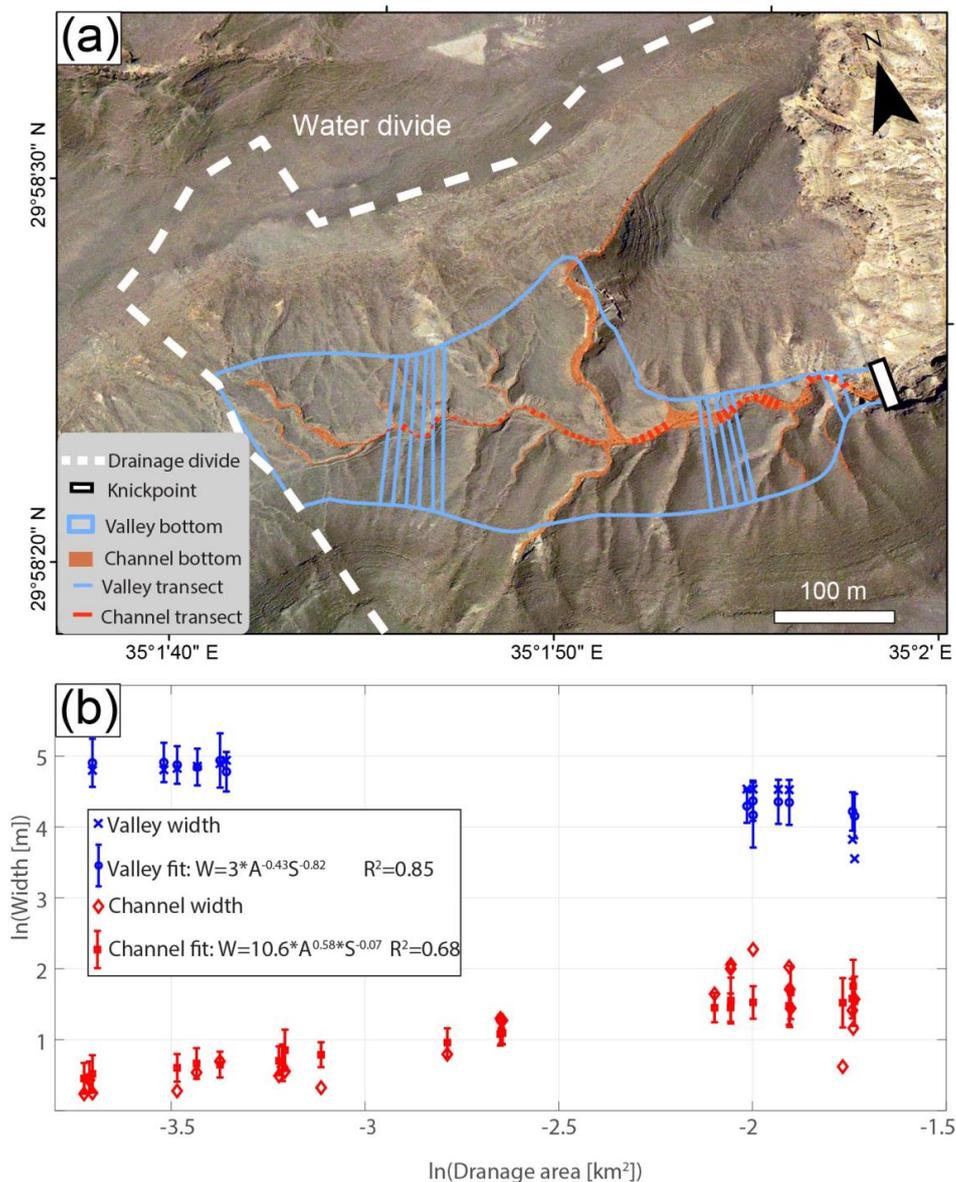

4.2 Comparing valley width and channel width in a reversed drainage

We explored the effect of drainage area and slope on the width of the channel vs. the width of the valley using a drone-derived high-resolution DEM of reversed valley 12 (Table 1, Fig. 6). Unlike the undisturbed and beheaded valley categories, the channels in the reversed settings are incised into the valley fill (Harel et al., 2019). The channel in valley 12 initiates east of the windgap and incises into the erodible valley fill, where it merges with short side tributaries that drain the valley bottom. Further downstream, it merges with a barbed tributary that joins the valley from the north (Fig. 6a), and after ~160 m, bedrock is exposed at the base and the north bank of the channel. At this point, the reversed channel is incised ~20 m below the surfaces of the antecedent valley bottom. The channel then

continues for additional ~40 m until it traverses the escarpment across a steep knickpoint that marks the edge of the
355 reversed section.

Field observations show that while the reversed valley narrows downstream (i.e., eastward), the channel
width increases in the downstream direction (Fig. 6a). A multivariate regression over the channel data reveals a
drastically different dependency between the channel's width, drainage area, and slope compared to the valley (Fig
6b). For the channel, the least-square multivariate regression ($R^2=0.68$) yields a k_b coefficient of $10.64 \pm 2.57 (10^{-6} m^4$
360 $^{-2b})$, a positive and high b exponent of 0.58 ± 0.17 , and a relatively small, negative, statistically insignificant c exponent
of -0.07 ± 0.18 . In contrast, the computed values for the valley are $3.04 \pm 3.29 (10^{-6} m^4)^{-2b}$ for k_b , a negative b exponent of
 -0.43 ± 0.19 , and a statistically significant c , -0.82 ± 0.44 .

365

Fig 6: Variations in valley and channel widths along a reversed section (valley 12 in Table 1 and Fig. 1c). (a) Valley (blue) and channel (orange) polygons and width transects sketched over a 0.5 m resolution orthophoto. (b) Width-area-slope scaling of valley width (blue), which narrows with drainage area, contrasting with the width of the reversed channel (red) that increases downstream. This difference is expressed by the drainage area exponent, b , which is positive for the channel and negative for the valley.

370

5. Discussion

5.1. Drainage reorganization affects width-area scaling

The multivariate regression results reveal that undisturbed, beheaded, and reversed valleys could be characterized by a distinct range of the drainage area exponent, b , in the width-area-slope scaling. Therefore, reorganization could
375 meaningfully affect the width-area scaling of valleys. In our study area, the b exponent values of the undisturbed valleys range between 0.25 and 0.55, consistent with previously published exponent values derived based on width-area or width-area-slope scaling of channels and valleys (Kirby and Ouimet, 2016; Spotila et al., 2015; Whittaker et al., 2007a, Beeson et al., 2018; Brocard and van der Beek, 2006; Langston and Temme, 2019; May et al., 2013; Schanz and Montgomery, 2016; Snyder et al., 2003; Tomkin et al., 2003). The beheaded valleys in the study area are
380 characterized by b exponent values of 0.17-0.23. While this range partly overlaps with previously published valley width-area scaling (Beeson et al., 2018; Langston and Temme, 2019; Schanz and Montgomery, 2016), it does not overlap with the b exponents values of the undisturbed valleys in our study area. The lower value of the b exponent of the beheaded valleys, reflecting a smaller change of width ($\log(W [m])$) per unit change in drainage area ($\log(A [km^2])$), is consistent with the process of beheading. During beheading, a valley loses its narrowest headwater sections,
385 and consequently, the beheaded valley is wider at smaller drainage areas compared to undisturbed valleys (e.g., Fig. 3c). Additionally, the drainage loss reduces the sediment transport capacity near the divide and may lead to aggradation that widens the valley. Thus, the $\log(W [m])$ vs. $\log(A [km^2])$ relations for beheaded valleys are characterized by a decreased slope compared to undisturbed valleys (e.g., Fig. 3b-c).

The process described above is expected to also affect the k_b coefficient values of the beheaded valleys.
390 Whereas the median k_b value is indeed somewhat higher for beheaded valleys compared to undisturbed ones (Fig. 5 and Table 1), the difference in k_b is small. This is because the value of the k_b coefficient reflects the valley width at a drainage area of $1 km^2$ (given that the c exponent is approximately zero). In the study area, a $1 km^2$ drainage area is reached only after the beheaded section is joined by several undisturbed tributaries, which likely obscure the beheading influence, making the k_b coefficient of the undisturbed and beheaded valleys overall similar.

395 The negative value of the b exponent of the reversed valleys (between -0.24 and -0.71) represents downstream valley narrowing, supporting the inferred reversal of these valley sections (Harel et al., 2019). Furthermore, the similar

400

magnitude of the b exponent values (i.e., regardless of sign) for the reversed and undisturbed valley sections is consistent with the view that (1) the geometry of the undisturbed valleys is similar to the antecedent valleys whose flow direction was later reversed (e.g., Figs 2e, 3d and 6); and (2) valley width did not drastically change following the reversal process.

405

The ranges of the b exponents differ between the undisturbed and reorganized valleys, in agreement with our hypothesis that drainage reorganization modifies the scaling between valley width and drainage area. Based on these results, we suggest that scaling differences between adjacent drainages could serve as supportive evidence for drainage reorganization. Furthermore, the value of the b exponent could relate to specific categories of reorganization. The value of the b exponent for beheaded valleys is expected to be lower relative to that of undisturbed valleys. Negative b exponents could indicate reversed drainages, where preserved antecedent valleys narrow with increased drainage area. Importantly, however, the width-area scaling could vary across climates (Hancock and Anderson, 2002) and lithologies (Brocard and van der Beek, 2006; Langston and Temme, 2019; Schanz and Montgomery, 2016), and is affected by structures (Keen-Zebert et al., 2017) and landslides (Beeson et al., 2018; May et al., 2013). Thus, invoking b exponents to support reorganization requires comparing the suspected reorganized valley sections to undisturbed sections with similar environmental and structural conditions. Additionally, accurately identifying the extent of the reorganized valley section is crucial because sections that include more than a single category might show a noisy signal, if at all.

410

5.2. Slope-valley width relation in the study area

415

In steady-state drainage networks with uniform lithology, climate, and uplift rates, the slope, S , and the drainage area, A , scale through the power-law $S \propto A^{-\theta}$ (Flint, 1974). In such cases, slope can be substituted for area or vice versa, such that the width in Eq. (2) becomes a function of drainage area only (i.e., Eq. (2) reduces to the form of Eq. (1)) or of slope only. In contrast, when A and S do not covary, each of them can independently influence the width scaling (Finnegan et al., 2005; Whittaker et al., 2007b). In those cases, the width predicted by Eq. (2) is expected to be more accurate than that predicted by Eq. (1).

420

The multivariate regression results reveal three lines of evidence indicating that the valley width is independent of the slope in the undisturbed and beheaded valley sections in the study area: (i) the slope exponent, c , is smaller by an order of magnitude with respect to the b exponent (Figure 5), (ii) the values of the exponent c are

statistically insignificant (with the exception of valley 5), and (iii) Least-square regressions following the slope-
independent Eq. (1) yield similar width predictors and R^2 values as the regression based on Eq. (2) (Fig. S6 in the
425 Supplement). However, a slope-area analysis (Fig. S7a in the Supplement) shows a low covariance between $\log(S$
 $[m])$ and $\log(A [m])$, ($R^2 < 0.24$) in the studied valley sections, indicating that the slope-independent width predictions
do not arise from such covariance. Alternatively, we suggest that the statistical insignificance of the c exponent in the
undisturbed and beheaded valley sections stems from the scatter in the slope data (Fig. S7b in Supplement), which
430 reduces the weight of the slope relative to drainage area in the regression. The scatter is particularly distinct due to the
exceptionally low slope values in these valleys, which could be $< 10^{-4} [m/m]$.

As opposed to the undisturbed and beheaded valleys, in the reversed valley sections (except for valley 10),
the inferred slope exponents, c , are statistically significant, negative, and with the same order of magnitude as the area
exponent b . Furthermore, for these sections, the multivariate regressions based on Eq. (2) produced higher R^2 values
435 than a slope-independent regression based on Eq. (1), indicating that the slope plays a role in predicting the reversed
valley width. The slope significance could be partly explained by the somewhat reduced scatter in the slope data along
the reversed category relative to the other categories, likely due to the overall higher slopes along the reversed sections
(Fig. S7c in the Supplement). However, from a geomorphological perspective, the measured channel slope is expected
to be decoupled from the valley morphology, because in this category, the channel and the antecedent valley grade in
440 opposite directions (Harel et al., 2019). We suggest that the slope significance in these valleys could be explained by
inspecting the width-slope correlation close to the downstream edge of the reversed sections, just above the knickpoint,
where the valley narrows and channel steepens (e.g., valley transects in Fig 2e-f, and Fig. S7c in the Supplement).
Narrowing and steepening could reflect channel and valley response to flow acceleration close to the upper lip of the
knickpoint (Haviv et al., 2010), forming a juvenile narrow valley on the expense of the paleo valley (Fig. 2f). The
445 incision above the knickpoint that contributes to the correlation between channel slope and valley width at the
downstream edge of most reversed sections likely reflects a transient response to reorganization and the onset of valley
width adjustment to the new drainage direction and drainage area distribution.

Valley 10 is an interesting exception in this context. Here, despite a ~80 m high knickpoint at the edge of the
reversed section, slope increase and valley narrowing above the knickpoint are absent. The lack of incision above the

450 knickpoint in valley 10 could imply a recent episode of knickpoint migration to its current location. Accordingly, in this case, the multivariate regression infers a small and statistically insignificant slope exponent (Table 1).

5.3 Differing timescales of the valley and channel width adjustment

Channel width is recognized as a sensitive parameter that adjusts dynamically and relatively rapidly to changes in tectonic (Amos and Burbank, 2007; Attal et al., 2008; Morell et al., 2020; Yanites, 2018) and climatic (DiBiase and Whipple, 2011) conditions. Over longer timescales, the valley width, which depends on the time-integrated location of the channel, is expected to adjust to the same changes in the boundary conditions (Hancock and Anderson, 2002; Langston and Temme, 2019; Tomkin et al., 2003). Drainage reorganization changes the drainage area distribution and, like tectonic and climatic variations, induces dynamic width changes. We suggest that the comparison between the valley and channel width in reversed valley 12 (Fig. 6) demonstrates a temporal snapshot where the channel width is adjusted to the new drainage area distribution inflicted by the drainage reversal, whereas the valley width is not yet adjusted to the same forcing (Fig. 6b), in accordance with the longer timescale expected for valley adjustment.

5.4 Implications to landscape evolution

Delayed valley versus channel adjustment in response to reorganization (Fig. 6) and the diverging response of valleys of different reorganization categories (Fig. 5) can have critical implications for landscape evolution. We explore one such implication by inspecting the influence of width adjustment on a proxy for the unit stream power ($\omega = \rho g Q S / W$ [Watt/m], ρ : density, g : gravitational acceleration, Q : discharge), which is commonly used for evaluating fluvial erosion rate (e.g., Harbor, 1998; Magilligan et al., 2015). Given that ρg can be treated as a constant, and that Q is typically proportional to drainage area, the unit stream power is expected to be proportional to $p_{sp} = AS/W$ [L] (Whittaker et al. (2007a)). We therefore use p_{sp} to compare the unit stream power between a reversed and beheaded valley sections that share the same windgap and flow in opposite directions (Fig. 7a). In the reversed section, p_{sp} is comparably high because of the narrow width and the increased slope of the actively incising channel (Fig. 6a). In contrast, p_{sp} is comparably low in the beheaded section, where anastomosing, low relief channels occupy almost the entire valley bed (Figs. 2a and 2d and 7a), so that the valley width represents the effective channel width. The difference in p_{sp} between the opposing valley sections is expressed as a distinct step-change in the p_{sp} values across

475 the windgap (Fig.7b, black x symbols), where the p_{sp} values in the reversed section are larger by an order of magnitude relative to the beheaded section.

The differences in p_{sp} across the windgap are likely associated with the formation of the reversed section, and feeds back with the reversal process. Harel et al. (2019) proposed that in this study area, channel reversal initiates and extends by gradual windgap migration along an antecedent valley. Linking the windgap migration to the dynamic valley and channel adjustments, we propose that in the extending reversed section, the migrating windgap increases the drainage area above the knickpoint. This, in turn, is expected to increase the erosion rates of the reversed channel, while on the beheaded side, at the other side of the windgap, the valley is losing drainage area, and experiences reduced erosion rate and even deposition, that overall reduce the rate of channel adjustment to reorganization. These differences in stream power across the divide can cause feedback in which divide migration promotes rapid channel width adjustment on the reversed side (whose drainage area is increasing), while on the beheaded side (whose drainage area is decreasing), adjustment is detained. This, in turn, generates a step-change in unit stream power across the windgap that could further push the windgap in the same direction. This process may be perturbed by capture of side tributaries by the reversed section, that cause abrupt changes in drainage area and erosion rate across the windgap (Shelef and Goren, 2021).

490 The step-change in p_{sp} values across the windgap emphasizes the importance of accurate channel width estimates when exploring the evolution of landscapes undergoing drainage reorganization. More specifically, when the width is approximated based on Eq. (2) without accounting for the influence of reorganization on the channel width (i.e., by using the same width scaling across the windgap), the aforementioned step-change in p_{sp} is not recognized (Fig. 7b, blue dots). Consequently, a computed difference in erosion rates across the divide would be lower and the divide will be estimated as being more stable than it actually is (Fig. 7b).

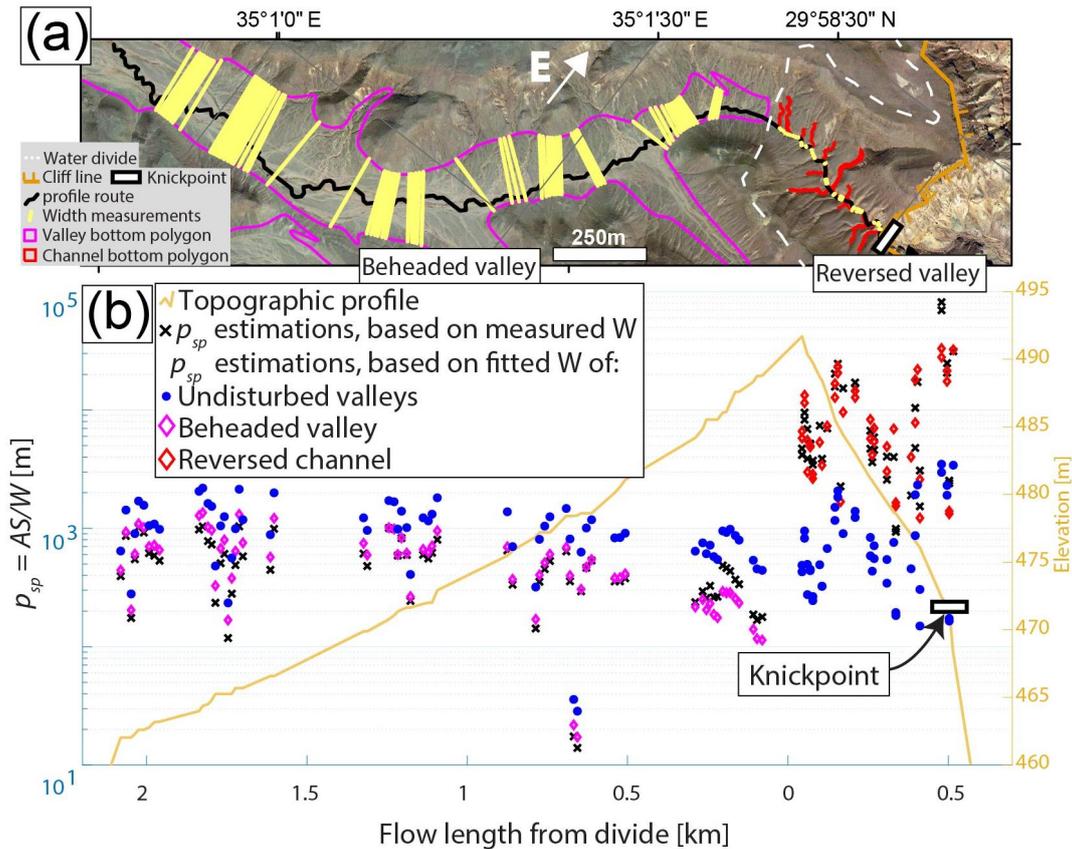

Figure 7: A proxy for unit stream power ($p_{sp}=AS/W$) along a profile from a reversed valley (# 12) to a beheaded valley (# 6) across a windgap. (a) An orthophoto of the reversed and beheaded valley sections that share a common windgap. The black line marks the profile route that follows the main channels and crosses the divide. The dashed white line marks the divide, and yellow lines mark measured width transects. In the reversed valley, east of the windgap, the active drainage is confined to an incised and narrow channel (Fig. 6a), whose width is used for estimating p_{sp} . West of the windgap, in the beheaded side, the channel width aligns with that of the valley, as braided channels occupy most of the valley bed area. (b) p_{sp} estimates, based on different width measurements: i) Algorithm-based, measured from DEMs (black x), ii) Computed based on the median of the fitted predictors for undisturbed valleys in the study area: $W=95*A^{0.47}S^{-0.02}$ (blue dots), iii) Computed based on W - A - S scaling fitted for a beheaded valley (#6 in table 1): $W=214*A^{0.17}S^{0.05}$ (pink rhombuses) and iv) Computed based on W - A - S channel scaling for a reversed valley (Fig. 6b): $W=10.6*A^{0.58}S^{-0.07}$ (blue rhombuses). The contrast between the morphological properties of the channels in the reversed and the beheaded valleys generate a distinct step-change in the p_{sp} values across the windgap, which can promote continuous windgap migration. The trend is not predicted by p_{sp} estimations that do not account for the unique width scaling in reorganizing valleys (blue dots).

510

6. Conclusions

Our analysis of undisturbed and reorganized valley sections in the Negev desert shows that the scaling between valley width, drainage area and slope is modified by reorganization. The analysis further reveals that each reorganization category is associated with a distinct range of b exponent values, relating the valley width to the drainage area. In the undisturbed valleys, the range of b exponent values is consistent with values reported in previous studies (Attal et al., 2008; Kirby and Ouimet, 2011; Whittaker et al., 2007a). The b exponent values of the beheaded valleys are positive and smaller than in undisturbed valleys. In the reversed valleys, the b exponent values are negative, reflecting valley narrowing with increasing drainage area. We suggest that this deviation in scaling could be exploited, with caution, in future studies that aim to identify and categorize drainage reorganization.

Differences in width-area-slope scaling also occur between a channel and its hosting valley. In the reversed valley section that we analyzed in detail, we found that the channel width is best fitted by a positive b exponent, reflecting the faster adjustment of channel width to the post-reorganization drainage area distribution relative to valley width (with a negative b exponent). The contrasting timescales of channel and valley width adjustment are consequential for landscape evolution. This is illustrated in a case study of reversed and beheaded valleys that diverge from a common windgap. The narrow width of the active channel in the reversed section compared to the wide channel (that occupies the entire valley) of the beheaded section, results in a step-change in unit stream power across the windgap. Assuming that erosion rate correlates with unit stream power, this could lead to a divide migration feedback. Erosion rate gradients across the windgap promote windgap migration toward the beheaded valley, which has a smaller unit stream power due to its wider channel. Windgap migration promotes rapid adjustment of the channel width on the extending reversed side, while on the beheaded side, adjustment is delayed, sustaining the gradient in unit stream power. This feedback suggests that the differing response of channel and valley width in different reorganization categories could sustain ongoing divide migration, and may add to the slope and area feedbacks that were previously attributed to the process of divide migration (Shelef and Goren, 2021; Whipple et al., 2016; Willett et al., 2014). This width feedback could be easily overlooked if channel width is parameterized based on standard scaling relations, without accounting for the deviated scaling of reorganized systems.

Insights from this study point at several venues for future research, for example: what are the timescales over which the deviation in scaling persists and how do they vary with climate and lithology? Could the values of the b

exponent quantify the state of adjustment of channels and valleys? And what is the relation between the divide migration dynamics and rates to the valley and channel width adjustment?
