9
10 **Abstract.** Granite residual soil landslides are widely distributed in the southeast of Guangxi, China.
11 They are posing threats to local communities, economic development, and ecological restoration. To
12 understand the failure mode of the landslide can provide a scientific basis for early warning and
13 prevention. In this study, it conducted artificial flume model tests to investigate the failure mode of
14 granite residual soil landslide. The macroscopic phenomena of landslides were observed and
15 summarized. The response and variations of soil moisture content and pore water pressure were
16 analyzed. And the discrepancies in landslide initiation were explored. The results had three aspects.
17 (1) The response of volume moisture content was not synchronized with that of pore water pressure.
18 Their variations were influenced by initial dry density, slope angle, and rainfall intensity. The
19 fluctuation of pore water pressure depended on soil mechanical behavior and its diffusion. (2) The
20 differences in the formation process of granite residual soil landslides included the initiation time and
21 mode. The starting time of landslide was delayed with increasing initial dry density and slope angle,
22 but shortened with increasing rainfall intensity. The failure mode could be changed from a sudden
23 type to a progressive type due to the increase of initial dry density. (3) There are five stages in the
24 landslide mobilization as follows: rain infiltration and crack generation, soil slide at the slope toe,
25 occurrence of surface runoff and soil erosion, formation of steep-free surface, and soil slide at the
26 upper slope. Above research provides valuable reference for the prevention and early warning of
27 granite residual soil landslide in the southeast of Guangxi.

30 Southeastern Guangxi
31

33 1 Introduction

34 Rainfall-induced landslides are the most common geohazards in the tropical and subtropical areas
35 covered by granite residual soil, such as Brazil (Lacerda, 2007; Coutinho et al., 2019), Singapore
36 (Rezaur et al., 2003; Rahardjo et al., 2008; Rahardjo et al., 2012; Zhai et al., 2016; Zhang et al.,
37 2019), Malaysia (Rahman et al., 2018), Korea (Kim et al., 2004; Pham et al., 2019), the southern
38 (Jiao et al., 2005; Luo et al., 2021; Liu et al., 2021; Liu et al., 2020a; Liu et al., 2020b) and
39 southeastern China (Xia et al., 2019; Yao et al., 2021; Shu et al., 2021; Zhao et al., 2021). Guangxi is
40 located in southeastern China, where granite is concentrated in the southeast, and landslides occur
41 frequently (Liao et al., 2019). Hot and rainy climatic conditions have caused strong weathering of the
42 surface granite, giving birth to tens of thousands of residual soil. This provides a superior
43 environment for the formation of landslides. Therefore, the southeastern Guangxi has been
44 threatened by granite residual soil landslides for a long time. Granite residual soil is a regional
45 special soil (Ministry of Construction of the People's Republic of China, 2002). One reason is that it
46 has the dual mechanical properties of cohesive soil and sandy soil. The other is that it exhibits an
47 abnormal combination of poor physical properties (such as high liquid limit and large void ratio) and
48 high-strength properties in a natural state (Chen et al., 2011). However, granite residual soil is
49 extremely sensitive to rainfall, and is easy to disintegrate and soften, which will induce large-scale
50 landslides (Dahal et al., 2008; Liu et al., 2020a; Zhang and Tang, 2013). Although shallow landslides
51 are the main type (Rahardjo et al., 2008; Kim et al., 2004), they still have the characteristics of high
52 frequency (Kim et al., 2015), suddenness and mass occurrence.

53 The failure mode of residual soil landslide is an important basis for disaster prevention and
54 mitigation and early warning and prediction of landslide (Rezaur et al., 2003). In this regard, many
55 scholars have conducted in-depth studies on granite residual soil landslide and other residual soil
56 landslide through statistical analysis, model tests and numerical simulations. They classified the type
57 of granite residual soil (Wu, 2006b) and studied on the physical mechanical properties (Zhu and
58 Anderson, 1998; Chen et al., 2011; Zhang and Tang, 2013; Chen and Gong, 2014; Xia et al., 2019),
59 engineering characteristic (Wu, 2006a; Xu et al., 2017) and microstructure (Li et al., 2017; Wang et
60 al., 2018). The formation condition (Zhan et al., 2012; Zuo et al., 2015) and instability mode (Zhao
61 and Hu, 2005; Dahal et al., 2008; Hu et al., 2009; Xu and Jian, 2017) of granite residual soil
62 landslides were revealed. They found and confirmed that the failure mode of residual soil slope is
63 different from that of homogeneous soil and rock slope, it includes arc slip, plane slip and front shear
64 slip, but plane slip is dominant (Zhan et al., 2010; Fu et al., 2018). Its failure surface is parallel to the
65 original slope (Kim et al., 2004). They also pointed out rainfall is the most important external
66 triggering factor due to two aspects (Coutinho et al., 2019). One is the deepening of the wetting peak
67 induced by rainfall infiltration (Kim et al., 2004). Second, the increase in soil water content and pore
68 water pressure can lead to a decrease in slope stability (Gasmo et al., 2000; Rezaur et al., 2003;
69 Rahardjo et al., 2005; Lacerda, 2007; Rahardjo et al., 2008). Thus, in the process of landslide
70 formation, the variation of physical property parameters such as moisture, matric suction or pore
71 pressure play an important role in the residual soil landslide (Kassim et al., 2012; Igwe and Fukuoka,
72 2014; Pham et al., 2019; Zhai et al., 2016). Rainfall triggered mechanisms focus on completely
73 weathered granite fill slope in Hong Kong, China. They are static liquefaction (Chen et al., 2004) and

74 the transition from slide to flow due to localized transient pore water pressure (Take et al., 2004).
75 However, static liquefaction is impossible due to unsaturated condition. Instead, local transient pore
76 water pressure can induce the initially slip, which further triggers the high-speed slide (Take et al.,
77 2004). Another finding is that the initial dry density (Mukhlisin et al., 2008) and slope angle (Liu et
78 al., 2020a; Liu et al., 2020b) can affect the water permeability and control the formation of landslides
79 (Xu et al., 2018). Many scholars have carried out related studies on the relationship between dry
80 density of other types of soil (such as sandy soil, volcanic residual soil, and gravel soil) and the
81 initiation of landslides. They found through model tests that the initial density can determine the
82 stress-strain characteristics of the soil, and it corresponds to the initiation mechanism of dilation and
83 contraction (Dai et al., 1999a; Dai et al., 1999b; Mckenna et al., 2011). The macroscopic phenomena
84 corresponding to these two mechanisms are: saturated loose slopes will suddenly liquefy and flow
85 quickly, while saturated dense slopes will creep slowly (Iverson et al., 2000). It can be seen that there
86 is a significant difference in the sliding motion rate of sand landslides (Iverson, 2005). Especially
87 when the dry density is optimal, the moving speed and sliding distance of the landslide are both
88 maximums (Wang and Sassa, 2001). This is mainly because the initial dry density affects the soil-
89 water interaction and soil permeability (Ng and Pang, 2000; Lin et al., 2009; Jiang et al., 2017). For
90 example, high-density steep slopes are much more resistant to rainwater penetration than low-density
91 gentle slopes (Xu et al., 2018). A gentle slope can lead to better accumulation of rainwater, a faster
92 increase in water content, but a slower rate of soil collapse (Liu et al., 2020a; Liu et al., 2020b).
93 Other scholars have further confirmed the above results through numerical simulations. That is, the
94 initial dry density has a decisive influence on the movement accumulation and evolution process of
95 the landslide, and there are also significant differences in the slip rate (Liang et al., 2017).

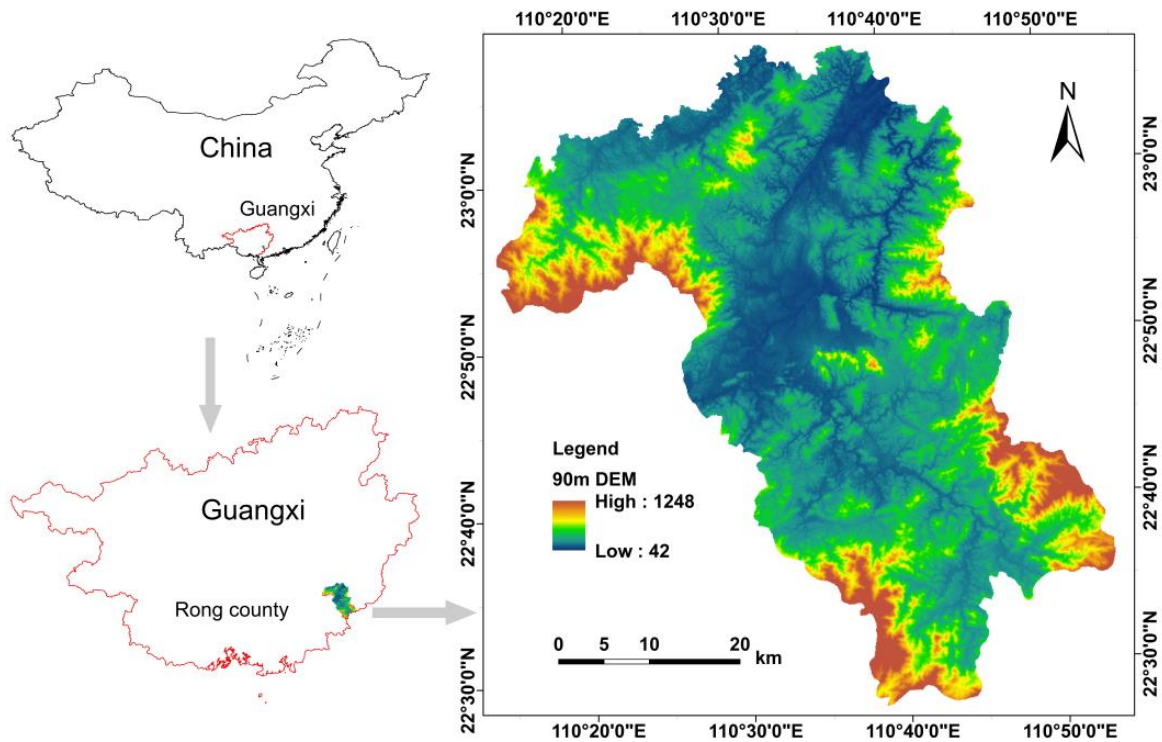

96 The above researches have pointed out the direction for the follow-up work. However, most of the
97 conclusions related to failure process focus on gravel soil (Chen et al., 2017; Liao et al., 2018), sandy
98 soil (Moriwaki et al., 2004; Huang et al., 2008; Huang and Yuin, 2010), fill slope (Chen et al., 2004;
99 Take et al., 2004), clay soil (Elkamhawy et al., 2018) and loess slope (Tu et al., 2009). Moreover, the
100 degree of development of granite weathering crust is closely related to the climate, topography and
101 environment (Qu et al., 2000), its residual soil has significant heterogeneity characteristics in terms
102 of thickness, physical and mechanical property (Rahardjo et al., 2002; Rahardjo et al., 2012). These
103 special characteristics lead to the complex initiation modes of landslides (Calcaterra and Parise, 2005;
104 Mukhlisin and Taha, 2012; Liu et al., 2020a; Xia et al., 2019). At present, the failure mode of granite
105 residual soil slope in the southeast of Guangxi has not been studied, which has brought challenges to
106 the prevention and early warning of landslides. Therefore, some scientific issues need to be solved.
107 For example, what are the similarities and differences of the failure process of granite residual soil
108 slope? How do the physical parameters of residual soil change? In this paper, it conducted artificial
109 flume model tests to resolve the above issues. Firstly, the macroscopic phenomena of landslide is
110 observed and summarized. Subsequently, the variation characteristics of soil moisture content and
111 pore water pressure are analyzed. Finally, the differences in the initiation of rainfall-induced
112 landslide are discussed.

113

114 **2 Field site and method**

115 **2.1 Field site**

116 Rong County is a typical high-prone area of rainfall-induced landslide of granite residual soil in
117 southeast Guangxi (Liao et al., 2019). It is located between longitude 110°15'00"-110°53'00" E and
118 latitude 22°27'00"-23°07'00" N (Fig. 1). The county covers an area of 2257 km², with an average
119 annual rainfall 1737.4 mm a⁻¹. The rainy period is from April to September, and the rainfall in this
120 period accounts for 78.6 % of the average annual rainfall. The area of magmatic rocks is 1260.09
121 km², accounting for 55.83 % of the total area of the county. The lithology is mainly granite with an
122 area 1219.06 km².

123
124 Figure 1. Study area.
125

126 **2.2 Method**

127 Longtou Village in Liuwang Town is a landslide high-prone area in Rong County. Therefore, test soil
128 comes from Longtou village. Specific gravity of the soil is 2.71, and the minimum and maximum of
129 dry density are 1.18 g cm⁻³ and 1.72 g cm⁻³. Particle data is the average of three sets of screen tests
130 on granite residual soil (Fig. 2). The red grid points in Figure 2 represent the cumulative content of
131 gravel (diameter < 2 mm) and silt and clay (diameter ≤ 0.075 mm). They are 87.52 % and 25.62 %.
132 The angles of natural slope in the study area are 30 ° - 45 ° and mainly 40 ° - 45 °. The dry density of
133 superficial soil is 1.20 - 1.40 g cm⁻³; and the average mass moisture content is 6 %-10 % (Wen, 2015).
134 Only two initial dry densities of 1.20 g cm⁻³ and 1.40 g cm⁻³ are set to highlight the discrepancies
135 between tests (Table 1). Two slope angles of 40 ° and 45 ° are established, and initial mass moisture
136 content is controlled in the range of 6 % to 10 %. Heavy rainfall is the main factor in the formation
137 of landslides (Wei et al., 2017). Hence, rainfall intensity and duration are set based on rainfall data

138 from multiple landslide events in the study area in 2010 (Wen, 2015). There are 1-3 periods of
 139 rainfall, and each period lasts for 8 hours with an interval of 15 hours. Rainfall intensities are 60 mm
 140 h⁻¹ and 90 mm h⁻¹ respectively. Furthermore, the groundwater level in the study area is relatively deep,
 141 the landslide initiation of granite residual soil does not depend on the fluctuation of groundwater
 142 level. Therefore, the factor of groundwater level is not considered in the tests.

143
 144 Figure 2. Particle gradation of granite residual soil.

145
 146 Table 1. Scheme of artificial flume model tests.

Test number	Slope angle (°)	Initial dry density (g cm ⁻³)	Rainfall intensity (mm h ⁻¹)	Rainfall duration (h)
1	45	1.20	60	8, 8, 8
2		1.40	60	8, 8, 8
3		1.20	90	8, 8
4		1.40	90	8, 8
5	40	1.20	60	8, 8, 8
6		1.20	90	8

147
 148 Test equipments are composed of rainfall control system, data testing system, and flume model.
 149 Rainfall control system contains central control system, suction pump, water tank, hose, brace, and
 150 nozzle. The size of water output can be set in the rainfall control system. The distance from the
 151 nozzle to slope crest is 2.3 m. The effective rainfall area of the tests is 6 m², and the rainfall is
 152 calibrated before the formal test. Data testing system consists of sensors and data collectors (Fig. 3).
 153 The minimum unit of time for data collection is 1 min, and storage space of data collector is limited.
 154 Hence, the frequency of data collection for volume moisture content and pore water pressure is set to
 155 1 min and 3 min respectively.

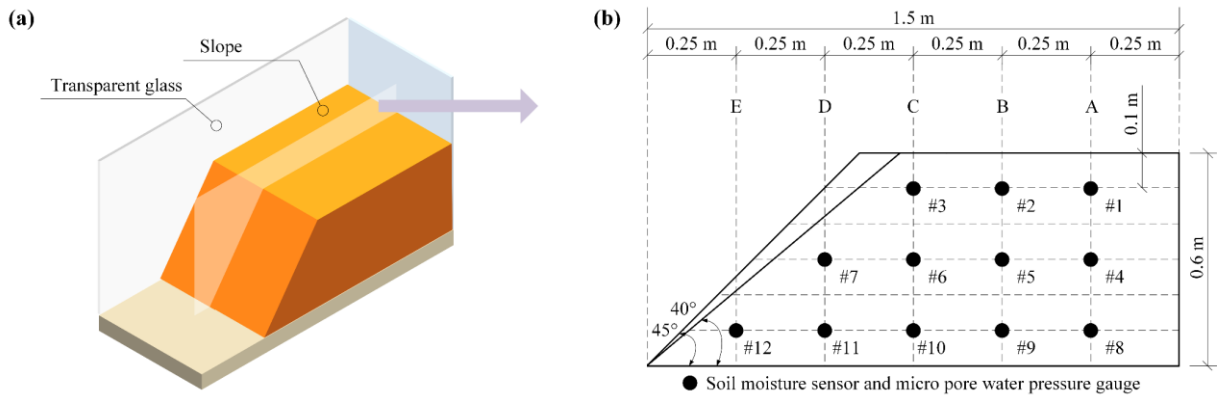

156

157
 158 Figure 3. Testing instrument. (a) MP-406B sensor of soil moisture. (b) M-16 collector of soil moisture. (c) HC-25 micro
 159 gauge of pore water pressure. (d) MCU collector of pore water pressure.

160
 161 The length, width and height of test slope are 1.5 m, 0.8 m, and 0.6 m respectively. The slope is
 162 divided into six layers, and the thickness of each layer is 0.1 m (Fig. 4). Firstly, a sufficient amount
 163 of air-dried soils are screened. Secondly, the required water is calculated based on the current and
 164 designed moisture content. Subsequently, this water is sprayed evenly into the soil. When the water
 165 and soil are fully mixed, they are placed in a container and kept for 24 hours. Finally, when moisture
 166 content of the mixture meets the requirement of designed moisture content, the slope model begins to
 167 be made. The accuracy of initial dry density must be guaranteed, so the soil of each layer is
 168 compacted with the wooden hammer. In addition, twelve monitoring points are set up inside the
 169 model. They belong to five positions. Each monitoring point consists of a soil moisture sensor and a
 170 micro gauge of pore water pressure (Fig. 4b).

171

173 **3 Results**
 174 **3.1 Macroscopic phenomena of tests**

175 (1) Test 1

176 During the first rainfall, when the rainfall lasts for 50 min, two small ditches are found on the
 177 slope surface. At this time, the soil at the slope toe slips, and triggers the soil on the trailing edge to
 178 slide. The instability area is fan-shaped and located at the left side of the slope toe. Its length is three-

179 quarters of the total length of the slope. When the rainfall lasts 421 minutes, a new ditch developing
180 on the slope shoulder is connected with the original instability area. In the second rainfall, the ditches
181 are continuously eroded. At the same time, many fine particles are moved to the slope toe by rain.
182 When the rainfall lasts for 559 min, the soil of the left slope shoulder begins to slide, causing the
183 formation of tensile crack at the slope crest. Then the soil around the crack slips and accumulates to
184 the slope toe. During the third rainfall, the continuous soil slide leads to the occurrence of a steep
185 free surface. When the rainfall lasts for 1324 min, the soil of the steep surface starts to slide. The soil
186 sliding does not stop until the slope gradient becomes gentle.

187 (2) Test 2

188 When the first rainfall lasts for 67 min, the soil on the left side of the slope toe begins to slip. The
189 area of sliding range gradually extends. When the rainfall lasts 431 minutes, the instability range has
190 been extended to the slope shoulder, and the seventh sensor is exposed. Subsequently, the soil on the
191 right side of the slope toe slips, causing the soil slide in the middle of slope. During the second
192 rainfall, tiny cracks are found on the right side of slope. When the rainfall lasts for 524 minutes, the
193 soil around the crack slips, and the sliding surface is arc-shaped. Owing to continuous rainfall, the
194 process of soil slide occurs repeatedly, and the gullies forms. The slope surface is eroded by third
195 rainfall. The ditch on the right side of slope extends and the slope eventually stabilizes.

196 (3) Test 3

197 In the first rainfall process, when the rainfall lasts for 32 minutes, tensile cracks appear
198 successively on the slope toe, and the soil around the cracks slips (Fig. 5a). Subsequently, a steep free
199 surface is formed. When the rainfall lasts for 39 minutes, the soil in the middle slope begins to slide
200 (Fig. 5b). When the rainfall lasts for 215 minutes, the soil on the slope shoulder starts to slip due to
201 unbalance internal forces (Fig. 5c). It causes the sensor #3 to deviate from the embedded position.
202 When the second rainfall lasts for 811 min, blocky soil slides suddenly on the right slope toe (Fig.
203 5d). When the rainfall lasts for 923 min, massive soil on the right slope shoulder begins to slides
204 owing to the unloading effect of the slope toe (Fig. 5e). Subsequently, the slope is stable (Fig. 5f).
205 This sliding process is accompanied by the sinking of the slope.

206 (4) Test 4

207 When the first rainfall lasts for 45 min, the soil on the left slope toe starts to slip. Muddy water
208 flows from the area of sliding soil. When the rainfall lasts for 78 min, the area of instability soil
209 extends to the slope shoulder. However, only a small amount of soil on the right slope toe slips.
210 During the second rainfall, the right slope is scoured away by rain, which results in a deep gully.
211 When the rainfall lasts for 496 min, the soil on the right side of slope slips, but the slide scale is small.
212 The slope is not completely destroyed.

213 (5) Test 5

214 When the first rain lasts for 26 minutes, the soil on the right foot begins to slide. The failure range
215 extends to the middle of slope as the rainfall continues. At the same time, rainfall gravity leads to the
216 formation of low-lying areas. When the rainfall duration is 208 min, the sunken area becomes larger,
217 and the soil at the slope toe has basically slipped. When the second rainfall lasts for 766 minutes, the
218 low-lying areas are connected, and a steep free surface is formed. Subsequently, the soil at the slope
219 toe continues to slide. In the third rainfall, a small amount of soil slips. However, there is no
220 significant change in the slope eventually.

221 (6) Test 6

222 When the rainfall lasts for 5 min, tensile cracks occur at the slope toe, resulting in the soil failure.
223 When the rainfall lasts for 27 min, the failure range extends to the shoulder of slope. Subsequently,
224 massive soil on the free surface slides from time to time. When the rainfall lasts for 96 min, the soil
225 in the middle of slope begins to slip, causing the exposure of sensor #7. When the rainfall lasts for
226 133 min, the soil on the left slope shoulder begins to slide. The slope begins to be sinking. When the
227 rainfall lasts for 220 min, the soil on the right slope toe continues to slide. The failure area extends to
228 the middle of slope as the rainfall continues. At the end of the rainfall, the soil on the right slope
229 shoulder remains stable.

Figure 5. Typical phenomena of test 3. (a) The soil at the slope toe begins to slip after tensile cracks appear. (b) The soil in the middle slope slides. (c) The soil on the slope shoulder slips owing to unbalance internal forces. (d) Blocky soil slides suddenly on the right slope toe. (e) Massive soil on the right slope shoulder slides due to the unloading effect of the slope toe. (f) The slope is stable at the end of the rainfall.

237 3.2 Volume moisture content

238 A-E inside the flume model represents the crest, shoulder, middle, and foot of the slope respectively.
239 The variation characteristics of the volume moisture content (VMC) at A, B, and C are relatively
240 similar. Therefore, the VMC of C is selected in the paper to indicate a general trend. In addition, the
241 three positions (C, D, and E) are close to the sliding surface. Thus, the data of these three positions

242 are analyzed in this section and shown in Figure 6-Figure 11. The general variation of VMC mainly
 243 consists of three stages: initial constant, significant increase, and stability. When the monitoring
 244 depth of the same position increases from 0.1 m to 0.5 m, the response time of VMC is delayed, but
 245 the stable value of VMC increases. It is attributed to the rainwater infiltration process and its
 246 accumulation. In addition, VMC is reduced due to water evaporation during the interval between two
 247 rainfall periods. This phenomenon is particularly obvious for soils with a depth of 0.1-0.3 m. VMC
 248 can be restored to the previous level or even higher value in subsequent rain.

249 Figure 6 and Figure 7 shows the differences of VMC between test 1 and test 2 as follows. (1)
 250 When the monitoring depth of the position C is 0.1 m and 0.3 m, the stable value of VMC of test 1 is
 251 smaller than that of test 2. The main reason is that the capacity of soil to store water can be enhanced
 252 as initial dry density (IDD) increases (Lu et al., 2018). (2) VMC of three depths in the position C of
 253 test 2 is similar. However, the VMC between three depths of test 1 has great difference. It is
 254 especially noticeable in the first rain. (3) When the depth is 0.5 m, the VMC of the slope foot in test 1
 255 is significantly smaller than that of the slope middle, but the VMC at these two locations is similar in
 256 test 2.

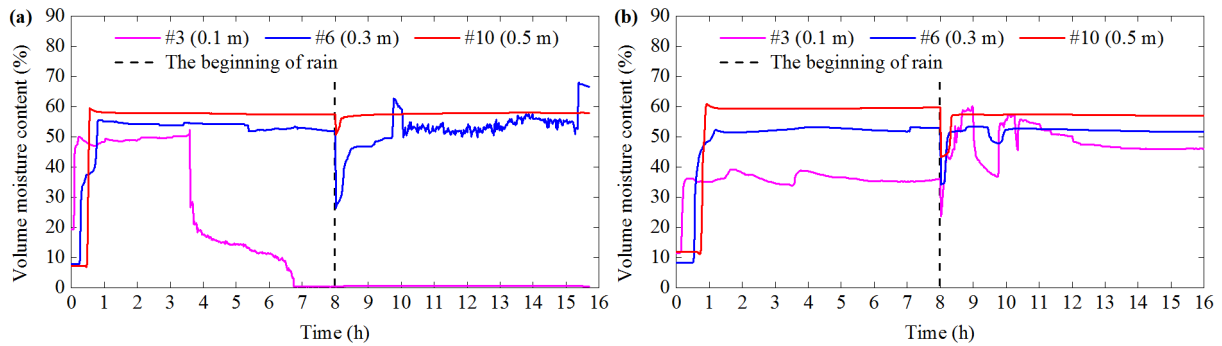

257
 258 Figure 6. Volume moisture content in position C of (a) test 1 and (b) test 2.

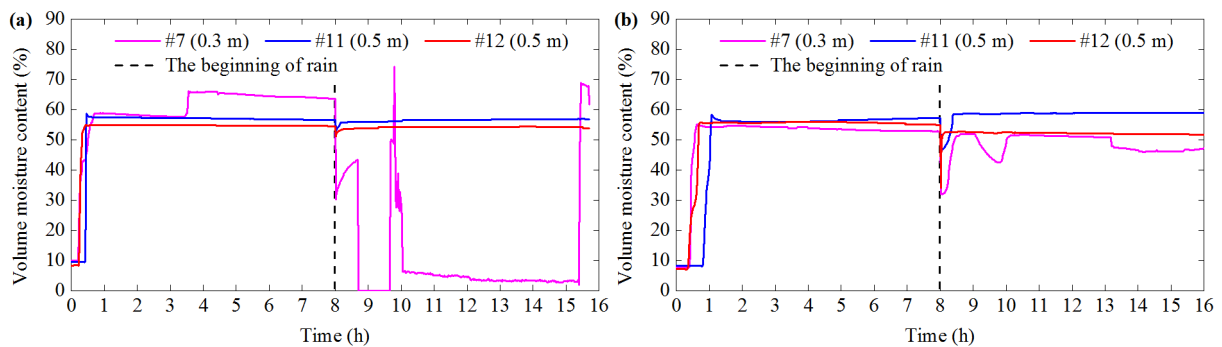

259
 260 Figure 7. Volume moisture content in positions D and E of (a) test 1 and (b) test 2.

261
 262 The VMC of test 3 and test 4 is shown in Figure 8 and Figure 9. The response time of VMC of test
 263 3 is shorter than that of test 4 at the same location. The reason is that the increase of IDD of the soil
 264 results in the weakening of rain infiltration (Lee et al., 2005). The VMC at a depth of 10 cm in test 3
 265 decreases sharply and eventually becomes zero in the first rain (Fig. 8a). This is due to the soil
 266 sliding causing the third sensor to deviate from its original position. In addition, the VMC at the
 267 depth of 0.3 m in positions C and D of test 3 fluctuates significantly (Figs. 8a and 9a). The
 268 macroscopic phenomena in section 3.1 indicate the time of the soil failure is basically corresponding
 269 to the fluctuation time. Thus, the fluctuation is attributed to the soil failure. The maintenance of water

270 pipe causes a short water stop. Hence, VMC fluctuates at the beginning of the second rainfall in test
271 4 (Figs. 8b and 9b).

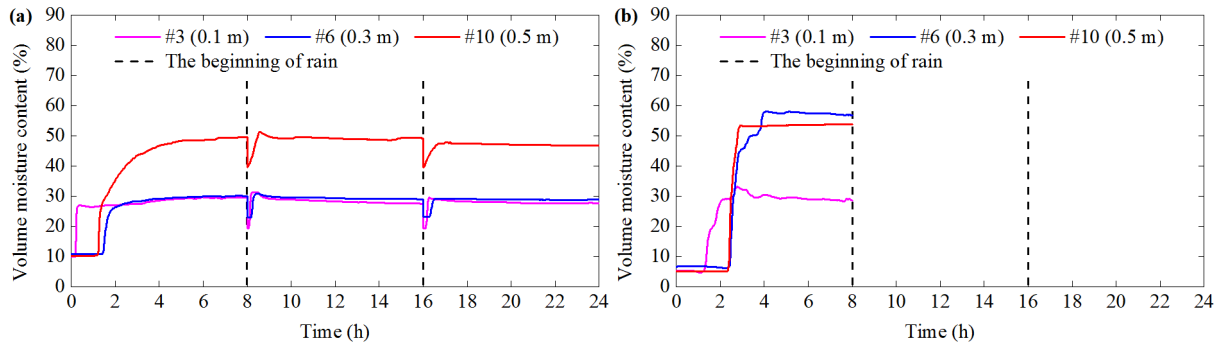

272
273 Figure 8. Volume moisture content in position C of (a) test 3 and (b) test 4.

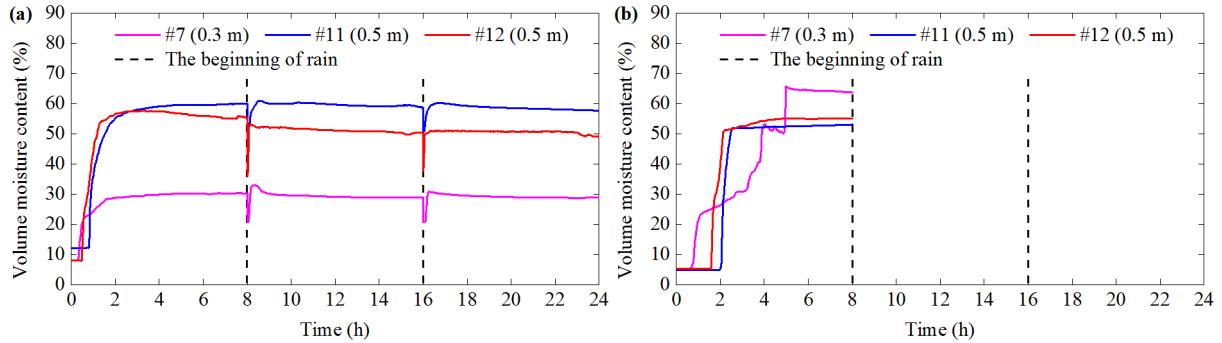

274
275 Figure 9. Volume moisture content in positions D and E of (a) test 3 and (b) test 4.

276
277 The VMC of test 5 and test 6 is shown in Figure 10-Figure 11. When the rainfall intensity
278 increases from 60 mm h^{-1} to 90 mm h^{-1} , the stable value of VMC of test 5 is less than that of test 6.
279 However, the VMC in test 6 has a longer response time than that in test 5. It is obvious in the slope
280 crest, such as the position C. The worth noting in section 3.1 is that the sliding time of test 6 is earlier
281 than that in test 5. The main reasons of the above abnormal phenomena are including three aspects.
282 One is that when the rainfall intensity is relative larger, more rainwater can penetrate the soil quickly.
283 Shallow layer can be saturated. This process can cause silt and clay to migrate vertically and
284 accumulate at a certain depth (Fang et al., 2012). Subsequently, the microstructure of soil is changed
285 (Chen et al., 2018), and the infiltration path is blocked by the fine particles. Furthermore, rainwater
286 cannot infiltrate the soil smoothly, and causes the long response time of VMC at the slope crest. The
287 other is that rainfall infiltration can cause a difference in water pressure between the slope crest and
288 the slope foot; this effect of seepage force will cause the slope foot to slide first (Zhou et al., 2014).
289 In test 5 and test 6, the soil failures are both found in the slope foot at the beginning of rainfall. It
290 is consistent with the research made by Zhou et al. (2014). This local deformation of the slope can
291 cause internal force unbalance and soil microstructure change. The rainfall infiltration will be
292 affected later (Chang et al., 2021). On the other hand, the tensile crack of the slope toe can provide a
293 preferential path of rainwater. It is the main reason for the relative early sliding time in test 6.
294 However, the sensor #12 cannot observe this data because it is not located under the crack.

295
296

Figure 10. Volume moisture content in position C of (a) test 5 and (b) test 6.

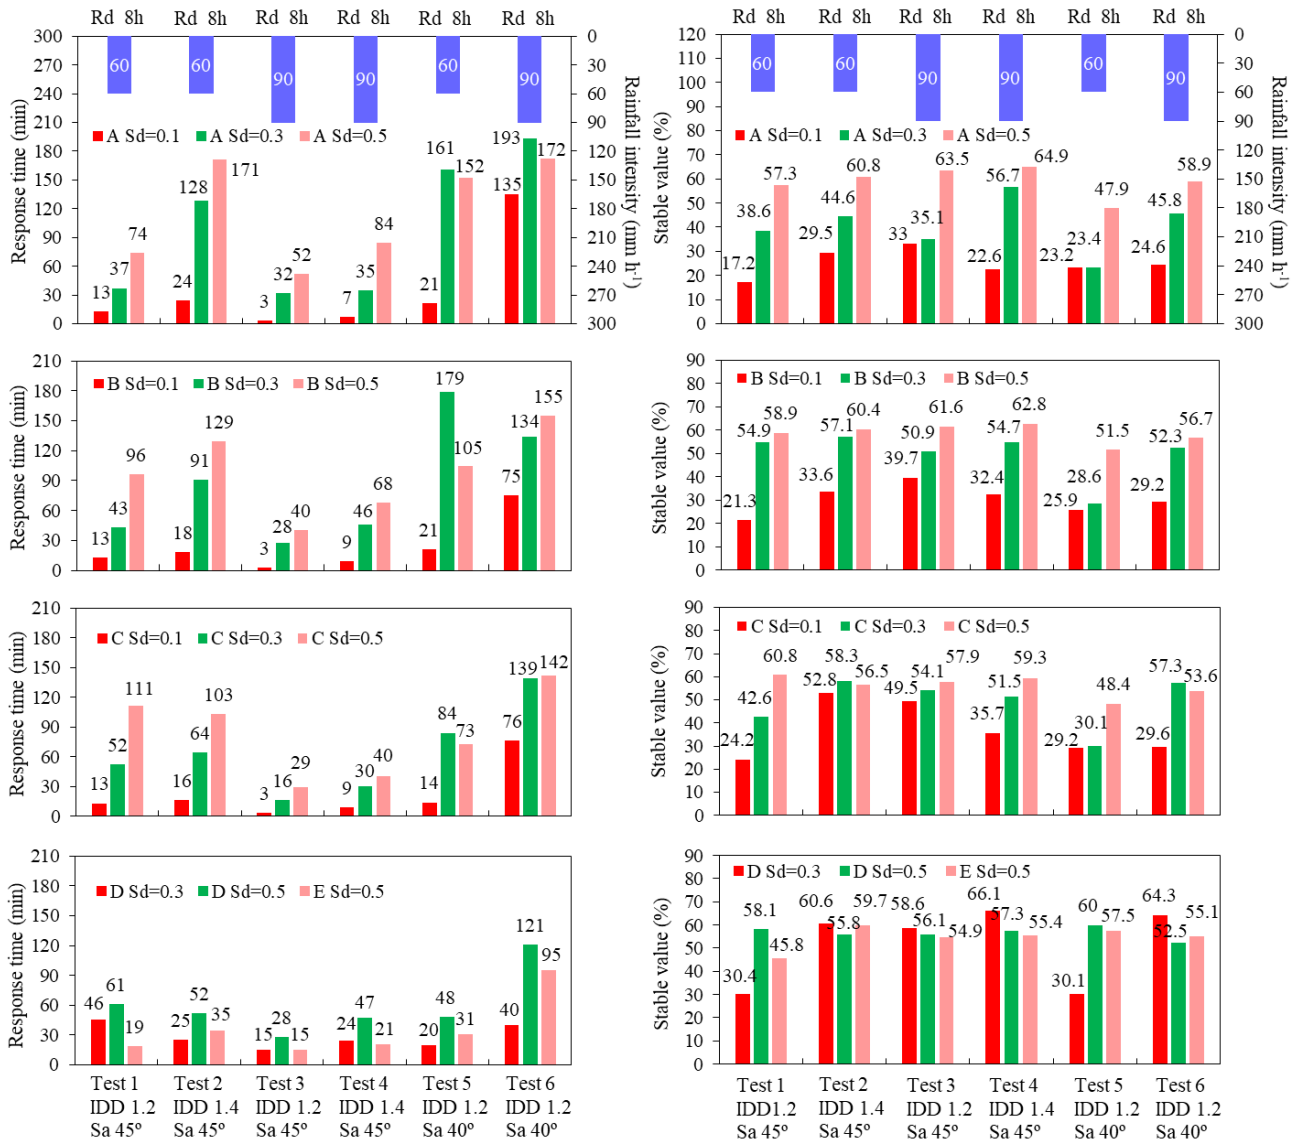

297
298
299

Figure 11. Volume moisture content in positions D and E of (a) test 5 and (b) test 6.

300 Figure 12 shows the response time and stable value of VMC at five positions during the first
301 rainfall. Test 1 and Test 2, Test 3 and Test 4 in Figure 12 are respectively compared. The similar result
302 is that when an IDD increases from 1.20 g cm^{-3} to 1.40 g cm^{-3} , the response time of VMC at the same
303 location is delayed. However, this similarity does not apply to the position D. The reason is that the
304 local soil sliding is found in the shallow layer in the position D of test 2. It can lead to the decrease in
305 the part of the soil thickness. Thus, the position D of test 2 affected by the rainfall is earlier than that
306 of test 1.

307 The stable value of VMC with an IDD of 1.20 g cm^{-3} is smaller than that of 1.40 g cm^{-3} . It is
308 suitable for most of the depths of test 1 to test 4. The abnormal points include as follows: the depth of
309 0.5 m at C and D of test 1 and test 2, the depth of 0.1 m at A, B and C and the depth of 0.3 m at C of
310 test 3 and test 4. This is due to the difference in soil – water action during rainfall. When rainfall
311 intensity is 60 mm h^{-1} , all the rainwater can percolate through the soil with an IDD of 1.20 g cm^{-3} and
312 1.40 g cm^{-3} . However, when rainfall intensity is 90 mm h^{-1} and an IDD is 1.40 g cm^{-3} , the rainwater
313 seepage capacity is less than 90 mm h^{-1} . Subsequently, rainwater cannot completely penetrate the soil
314 and surface runoff is formed. The slope is eroded by surface runoff; it can be found in the
315 macroscopic phenomena of test 4. Therefore, even if the rainfall intensity is 90 mm h^{-1} , the stable
316 value of VMC is relative small. In addition, test 5 and test 6 have the same initial dry density, but the
317 response time cannot decrease when the rainfall intensity is from 60 mm h^{-1} to 90 mm h^{-1} . The
318 reasons are mentioned in the previous paragraph.

319

320 Figure 12. Response time and stable value of volume moisture content in six tests during the first rainfall.

321 **3.3 Pore water pressure**

322 Pore water pressure (PWP) at three positions (C, D, E) is shown in Figure 13-Figure 18. The sensor
 323 #3 of PWP in test 2 and test 4 breaks down, and it deviates from its original position in test 3. Thus,
 324 the PMP of the sensor #3 are not analyzed in this section. The variation of PWP mainly consists of
 325 similar three parts: stability, significant increase, dynamic fluctuation. Some differences between
 326 these tests can be clarified. In test 1, the PWP at a depth of 0.3 m at C fluctuates drastically during
 327 the first rain. However, the PWP of test 2 does not fluctuate, and its variation is smaller than that in
 328 test 1 (Fig. 13). In addition, the PWP with a depth of 0.3 m at D varies gently in test 1, but it
 329 increases significantly during the second and third rain in test 2. The fluctuation occurs at a depth of
 330 0.5 m at D in test 1 (Fig. 14). The changes of PWP and VMC are not synchronized, which manifests
 331 in two aspects. One is the response time of PWP is later than that of VMC; the other is that VMC is
 332 in a stable stage when PWP fluctuates.

333
334 Figure 13. Pore water pressure in position C of (a) test 1 and (b) test 2.

335
336 Figure 14. Pore water pressure in positions D and E of (a) test 1 and (b) test 2.

337 In the first rainfall, the PWP response time of test 3 is shorter than that of test 4 at the same
338 location (Figs. 15 and 16). The difference in PWP response time is consistent with that in VMC. It
339 directly reflects the soil seepage capacity when an IDD is 1.20 g cm^{-3} and 1.40 g cm^{-3} respectively.
340 Besides, the frequent fluctuation of PWP mostly appears in test 3. In particular, PWP in test 3 is
341 decreasing after increasing at the most locations except for the depth of 0.5 m of D. This downward
342 trend exists at position C of test 4, but is not significant at D and E.

343
344 Figure 15. Pore water pressure in position C of (a) test 3 and (b) test 4.

345
346 Figure 16. Pore water pressure in positions D and E of (a) test 3 and (b) test 4.

347 Figure 17-Figure 18 shows the differences between test 5 and test 6 during the first rainfall. One is
 348 that the PWP curve at C in test 5 is flat. However, all the PWP in test 6 experiences the flat, increase
 349 and decrease stages. The other is that PWP at E in test 5 has an obvious volatility characteristic. It
 350 fluctuates to the peak at the end of the first rain. Whereas, PWP at E in test 6 has a downward trend
 351 after it reaches the peak. This opposite trend is related to the differences between the soil failures of
 352 these two tests. Soil sliding can cause stress to relax, which further results in an increase in soil
 353 porosity. It will induce pore water pressure to decrease. When rainwater is enough, pore water
 354 pressure can be restored.

355
 356 Figure 17. Pore water pressure in position C of (a) test 5 and (b) test 6.

357
 358 Figure 18. Pore water pressure in positions D and E of (a) test 5 and (b) test 6.

359 Figure 19 shows the response time and variation of PWP at five positions during the first rainfall.
 360 Test 1 and Test 2, Test 3 and Test 4 in Figure 19 are respectively compared. The main commonality is
 361 that when the location and rainfall duration is same, the response time of PWP with an IDD of 1.20 g cm^{-3}
 362 is shorter than that of 1.40 g cm^{-3} . Nonetheless, most of the variation in PWP has a contrary
 363 pattern. The reason is that even if the rainfall intensity is the same, the slope with different density
 364 has diverse hydrological characteristics (Lan et al., 2003). For example, the permeability of a slope
 365 with a large density is relatively small, thus, the variation in PWP is restricted. A significant
 366 difference is that although PWP change of the surface soil layer at each position is the smallest
 367 except for test 3, the PWP changes of other two depths do not increase with the increase of depth.
 368 The reasons are analyzed as follows. When the rainwater accumulates at a depth of 0.3 m, the PWP
 369 variation is relative large. At this moment, the PWP with a depth of 0.3 m can be larger than that of
 370 0.5 m. The continuous seepage can cause soil gravity to increase. It can produce the compressive
 371 stress on the soil layer at a depth of 0.5 m. The further decrease in soil porosity can cause PWP to
 372 increase. At the same time, if the soil with a depth of 0.3 m begins to slide, PWP will be released.
 373 Therefore, in these conditions, the PWP with a depth of 0.5 m may be larger than that of 0.3 m. It
 374 suggests that changes in PWP depend on soil deformation and its diffusion. This validates the study

375 by Iverson et al. (1997).

376

377

378 4 Discussion

379 Six model tests have commonness in the patterns of slope failure based on the macroscopic
 380 phenomena. Based on these tests, the landslide formation can be classified into five stages and shown
 381 in Table 2. They are basically consistent with the results of the field survey in Southeast Guangxi
 382 (Wei et al., 2017). Therefore, the initiation processes of granite residual soil landslides can be
 383 reproduced by flume model tests.

384 (i) Rain infiltration and crack generation. At the beginning of rainfall, all rainwater can seep into
 385 the slope. There is no surface runoff on the slope. Volume moisture content begins to increase.
 386 However, matrix suction decreases, which results in the reduction of shear strength. In addition, the
 387 gravity load of the slope increases and favors the downward creep. The differential distribution of
 388 soil strength can cause cracks to generate at the slope toe, which provide a preferential path for
 389 rainwater.

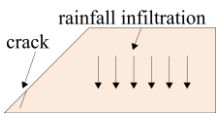

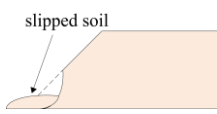

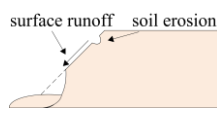

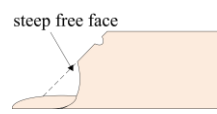

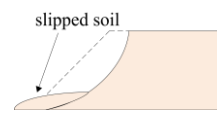

390 (ii) Soil slide at the slope toe. As rainfall continues, rainwater penetrates the soil through the crack.
 391 The accumulated rainwater in the crack can produce the pressure acting on the slope. It facilitates the
 392 propagation of the crack. Hence, the soil strength around the crack decreases. Meanwhile, the
 393 underground runoff converges at the toe of the slope. The VMC at the slope toe is relative large. The
 394 water pressure's difference between the top and toe of the slope increases. This difference in pressure
 395 and changes in the soil microstructure can lead to a reduction in the shear strength of the slope.
 396 Therefore, the soil at the foot of the slope softens and slides first. Subsequently, muddy water
 397 gradually flows out from the slope toe. This indicates that fine particles migrate through subsurface
 398 runoff, causing changes in the microstructure of some soils along the flow network.

399 (iii) Occurrence of surface runoff and soil erosion. The water content of shallow soil layer
 400 increases to a saturation value with the continuing rain. A saturation zone appears. This process
 401 allows fine particles to migrate vertically to a certain depth. Subsequently, the infiltration path will be
 402 blocked, and rainwater cannot permeate the soil smoothly. The surface runoff gradually forms. On
 403 the other hand, the gravel of the soil remains on the slope surface, which is conducive to seepage
 404 along the slope. Therefore, subsurface runoff can lead to the loss of the surface layer soil. Multiple
 405 low-lying areas and ditches are generated by the erosion of surface runoff and splash erosion of
 406 rainfall. The erosion destruction is most serious in the slope toe and the slope middle.

407 (iv) Formation of steep-free surface. As the soil at the foot of the slope continues to slide, the
 408 geometry and stress of the slope have changed due to the removal of downward support. Even the
 409 internal force balance of the slope is destroyed. The unstable range expands to the surroundings. A
 410 steep free surface begins to form subsequently. However, the soil on the top of the slope has not
 411 slipped.

412 (v) Soil slide at the upper slope. The presence of macro-pores between the gravel can promote the
 413 rainwater penetration through the soil. This process facilitates the rainwater transmission to a deep
 414 layer. The sliding force of the slope can be further improved. Meanwhile, the unbalance internal
 415 forces gradually increase due to the repeat slide of the slope toe. Besides, the increase of PWP leads
 416 to a reduction in the effective stress and shearing strength. Finally, when the sliding force is greater
 417 than the soil resistance, the soil at the slope top begins to slide. Obvious shear deformation is formed.

419
 420 One difference between six tests is the time of landslide initiation (Table 3). Six initiation times
 421 are 50 min, 67 min, 32 min, 45 min, 26min and 5 min respectively. When the slope angle and rainfall

422 intensity are the same, the initiation time of a landslide with a density of 1.20 g cm^{-3} is shorter than
 423 that of a landslide with a density of 1.40 g cm^{-3} . The difference is 17 min and 13 min. The reason is
 424 that when the IDD increases, the slope permeability decreases (Lan et al., 2003), and the infiltration
 425 process is relative slow. Therefore, the slope needs more penetration time. This corresponds to the
 426 difference of the response time of VMC in section 3.2. In section 3.2, when an IDD increases from
 427 1.20 g cm^{-3} to 1.40 g cm^{-3} , the response time of VMC and PWP is delayed. The decrease rate of the
 428 shearing strength is correspondingly slow. This is beneficial to the stability of the slope. When the
 429 slope angle and density are the same, the initiation time of a landslide with the rainfall intensity of 90
 430 mm h^{-1} is 18 min-22 min shorter than that of a landslide with the rainfall intensity of 60 mm h^{-1} . The
 431 reason is that when the rainfall intensity is relative larger, more rainwater can penetrate the soil
 432 quickly. This leads to a rapid increase in VMC and PWP in shallow soil layers. The shearing strength
 433 decreases. At this time, the difference of water pressure between the slope toe and the slope crest is
 434 obvious, which result in the first soil sliding at the slope toe. Meanwhile, when the IDD is 1.20 g cm^{-3} ,
 435 the rainfall intensity is 60 mm h^{-1} and 90 mm h^{-1} , if a slope angle increases from 40° to 45° , the
 436 starting time can be delayed by 24 min and 27 min. This is because steep slopes are not conducive to
 437 infiltration of rainwater (Xu et al., 2018). Hence, the VMC and PWP respond to rainfall slowly,
 438 which is favorable to slope stability. In a word, the initiation time of landslide is closely related to
 439 density, slope angle, and rainfall intensity. It is mainly controlled by the hydrological response of the
 440 slope.

441 Table 3. Initiation time of landslide for six tests.

Test number	1	2	3	4	5	6
Initiation time (min)	50	67	32	45	26	5

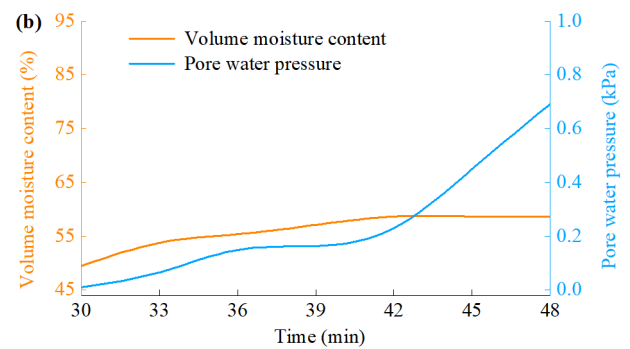

442
 443 The other difference in six tests is the failure mode and process of landslide. In test 1, all the
 444 surface soil slips, and the frequent sliding soil is in the shape of a block. In test 2, the sliding area
 445 slowly spreads to the surroundings, and the partial right shoulder fails to slide eventually. In test 3,
 446 the soil around the crack slides quickly, and all the soil on the slope surface is destroyed. In test 4, the
 447 scouring action of rain results in the formation of a deep gully, but the slope has stabilized finally. In
 448 test 5, the low-lying areas are enlarged with the continuous rainfall, and all the soil at the slope toe
 449 slips suddenly. In test 6, the soil surrounding crack slide rapidly, and the soil failure are repetitive.
 450 The above mentioned macroscopic phenomenon contains two main characteristics. When the IDD is
 451 1.20 g cm^{-3} , tensile crack is an important triggering factor for soil failure, and the formation process
 452 of landslide is relatively sudden and large in scale. When the IDD is 1.40 g cm^{-3} , soil failure of the
 453 slope foot can trigger the trailing edge slip. Therefore, the sliding process is gradual and small-scale,
 454 often accompanied by the appearance of low-lying areas and ditches. The main reason is required
 455 energy for the destruction of large density is significantly greater than that of small density (Xu et al.,
 456 2018). Hence, the formation process of landslide is different due to the initial state of the slope.

457 Section 3.3 shows that the pore water pressure fluctuates significantly during the soil failure.
 458 However, the variation of pore water pressure at the same position and depth is not synchronized
 459 with the water content. The typical periods of test 2 and the test 3 are selected in this section to
 460 understand the relationship between them. In test 2 with an IDD of 1.40 g cm^{-3} , when the rainfall
 461 lasts for 195-225 minutes, the soil in the slope middle slides. It promotes the development of cracks

462 and causes massive soil on the slope to slide (Fig. 20a). The seventh sensor is the closest to unstable
 463 soil, thus, the data of this sensor is selected for detailed analysis. Figure 20b shows that the water
 464 content is stable at about 61.6 % during this period, and the soil is in an over-saturated state; however,
 465 pore water pressure gradually increases to a peak of 0.361 kPa when the rainfall duration is 195-201
 466 minutes. Subsequently, pore water pressure decreases rapidly, and maintains a certain degree of
 467 volatility. When the rainfall duration is 210 minutes, pore water pressure begins to increase again. In
 468 test 3 with an IDD of 1.20 g cm^{-3} , when the rainfall lasts for 30-48 minutes, the shallow soil is
 469 softened and slides many times (Fig. 21a). Figure 21b shows that when the rainfall duration is 30-36
 470 minutes, VMC and PWP both increases; when the rainfall lasts for 36 minutes, the increasing trend
 471 of them is relatively gentle; when the rainfall lasts for 42 minutes, although PWP increases rapidly
 472 again, but VMC remains stable at 58.7 %. In a word, the differences in the variation of PWP and
 473 VMC comprise two aspects. One is that when VMC begins to increase, PWP is invariant. The
 474 response time of PWP is behind that of VMC. The other is that when VMC is constant or is in a
 475 significant rise, PWP has almost no change or only dramatic fluctuations. These may be related to
 476 mechanical behavior of granite residual soil.

477
 478 Figure 20. Typical phenomenon and result with an initial dry density of 1.40 g cm^{-3} . (a) Slope failure. (b) Results for
 479 sensor #7 closest to sliding surface.

480
 481 Figure 21. Typical phenomenon and result with an initial dry density of 1.20 g cm^{-3} . (a) Slope failure. (b) Results of
 482 sensor #7 closest to sliding surface .

483
 484 The above results may be explained by the research made by Iverson (Iverson, 2005; Iverson et al.,
 485 2000). He found that landslide mobilization is affected by mechanical properties of the shear zone
 486 related to the initial density. When dry density is low and rainfall intensity is high, the "hammering"
 487 effect of rain can squeeze the shallow soil. In addition, pore water pressure can increase due to the
 488 decrease in void ratio and leads to a reduction in shear strength. When the initial local shear
 489 deformation occurs, the shear zone is mainly contractive. At the same time, excessive pore water

490 pressure is generated. However, excess pore water pressure is difficult to dissipate completely in a
491 short time, which can promote the continuous increase of pore water pressure and the connection of
492 potential sliding surfaces. Therefore, the type of landslide failure is a sudden sliding type in the
493 macroscopic phenomenon (Dai et al., 1999a; Dai et al., 1999b; Mckenna et al., 2011). When the dry
494 density is larger, the infiltration rate of rainwater is smaller. At the same time, the response time of
495 water content and pore water pressure is delayed, and the fluctuation of pore water pressure is limited.
496 As a result, the ability of the slope to resist seepage damage is improved effectively. When dilative
497 shear deformation appears, it can cause pore water pressure to dissipate, and even leads to the
498 occurrence of negative pore water pressure (Chen et al., 2018). It can results in the delay of the VMC
499 and the recovery of the shear strength. After that, long-term rainfall can restore the loss of pore
500 pressure due to soil dilation, and shear deformation will reappear. At this time, the macroscopic
501 phenomenon of landslide start is progressive (Dai et al., 1999a; Dai et al., 1999b; Mckenna et al.,
502 2011). The landslide mobilization mode in this paper is consistent with the above mentioned.

503 **5 Conclusion**

504 The present study is executed to analyze the failure mode and process of granite residual soil
505 landslides in Guangxi province, China. The following conclusions can be summarized.

506 (1) Volume moisture content and pore water pressure exhibits a non-synchronous response to the
507 rain. Initial dry density and rainfall intensity has a significant effect on the hydrological response.
508 Large density can restrain the rainwater infiltration rate and limit the fluctuation of pore water
509 pressure. In addition, high rainfall intensity is corresponding to the short response time of volume
510 moisture content. However, this is unsuitable for the soil with a small density, because the change of
511 soil microstructure alters the seepage path. The fluctuation of pore water pressure depends on soil
512 mechanical behavior and its diffusion.

513 (2) The differences in the formation process of granite residual soil landslides include the initiation
514 time and mode. The starting time of landslide is closely related to initial dry density, slope angle, and
515 rainfall intensity. It is mainly controlled by the hydrological response of the slope. The initiation time
516 of 1.20 g cm^{-3} is 13-17 min earlier than that of 1.40 g cm^{-3} . The initiation time of 90 mm h^{-1} is 18
517 min-22 min shorter than that of 60 mm h^{-1} . Mechanical properties of the shear zone play the
518 important role in the failure modes of landslides, which are closely related to the initial dry density.
519 Two failure modes can be observed. One is a sudden sliding in a large scale with a density of 1.2 g
520 cm^{-3} ; the other is a progressive sliding in a small scale with a density of 1.40 g cm^{-3} .

521 (3) Landslide mobilization can be classified into five stages as follows: rain infiltration and crack
522 generation, soil slide at the slope toe, occurrence of surface runoff and soil erosion, formation of
523 steep-free surface, and soil slide at the upper slope. It is accompanied by the migration of fine
524 particles, and the formation of crack and macro-pores. Cracks and macro-pores can facilitate the
525 hydrological response in the deep layer.

526 Future research includes four aspects. Firstly, more tests involving multiple factors will be
527 conducted through the orthogonal experimental design. Secondly, triaxial instrument will be used to
528 perform the stress path tests. Thirdly, the influence of variation along the vertical direction of initial
529 dry density on slope failure will be analyzed. Fourthly, the quantitative relationship between volume
530 moisture content and pore water pressure during landslide initiation will be explored.
