**Abstract.** Chemical weathering driven by physical erosion is ~~one a of the manifestations of~~ natural processes that strongly affects chemical and solid matter budgets at the Earth’s surface. However, the influence of extreme climatic erosion on chemical weathering dynamics is poorly understood. Badland landscapes formed in highly erodible, homogeneous substrates have the potential to respond to individual events on scales that are rapid enough for direct observation. Here, we assess the geochemical and grain-size composition of suspended sediment and riverine chemistry measurements collected from two catchments during the 2017 Nesat and Haitang typhoons in southwestern Taiwan. During the typhoons, the ~~sodium adsorption ratio~~ Na<sup>+</sup> concentration covaried with suspended sediment concentration, which we attributed to sodium-induced deflocculation. Evaporite weathering at peak rainfall is succeeded by peak silicate weathering at maximum discharge, which dominates the weathering signal of the event. Overall, our observations suggest that initial weathering of near-surface evaporite enhances the physical erosion of silicate rock during extreme rainfall events.

## 22 1. Introduction

23 Chemical weathering induced by physical erosion controls nutrient supply to ecosystems (Milligan  
24 and Morel, 2002), reflects dynamic surface processes (e.g., Calmels et al., 2011; Clift et al., 2014;  
25 Emberson et al., 2016; Meyer et al., 2017), and regulates the global carbon cycle and the evolution  
26 of Earth's long-term climate (Berner et al., 1983; Ram et al., 1992; Gaillardet et al., 1999). In most  
27 landscapes, physical erosion and chemical weathering operate on geological timescales that may be  
28 difficult to observe on human timescales (e.g., Maher et al., 2014). However, in many landscapes  
29 ~~studies show that most~~ erosion dominantly occurs during stochastic events, such as storms (e.g.,  
30 Hartshorn et al., 2002; Lee et al., 2020; Wang et al., 2021). In particular, typhoons are able to transport  
31 large volumes of water and dissolved solids within hours to days, allowing us to observe the  
32 interactions between physical erosion and chemical weathering in landscapes impacted by them.  
33 Nevertheless, observations of the interaction between extreme physical erosion and chemical  
34 weathering dynamics are limited (Meyer et al., 2017). Furthermore, the ~~lack~~ lack of high-frequency  
35 stream water sampling leads to a fundamental difficulty in constraining the dynamic behavior between  
36 physical erosion and chemical weathering during a high discharge period (e.g., a typhoon), which could  
37 have key implications for our ability to quantify topographic responses to these events,~~the~~  
38 ~~quantification of topographic responses~~.

39

40 Badlands are landscapes characterized by highly erodible and weathered substrates, ~~which~~ that are  
41 largely devoid of vegetation. The high erodibility of these landscapes provides a unique opportunity  
42 to investigate and quantify denudation processes that operate at short timescales (Cheng et al., 2019;  
43 Yang et al, 2019, 2021a; 2021b). Badlands is typically dominated by mudstones and clays, and ~~Soils~~  
44 soils that contain clays saturated in sodium ions are particularly vulnerable to erosion by water. Sodium  
45 ions alter the layer charge of double-layered clay minerals (i.e. smectite) and cause the clays to  
46 deflocculate, which refers to the process of breaking up the clay (and ultimately the soil) into finer  
47 particles that are more easily washed away by water (e.g., Faulkner et al., 2004; Mitchell et al., 1993;

48 Rengasamy and Olsson, 1991; Rengasamy et al., 1984; Sherard et al., 1976; Kašanin-Grubin et. al.,  
49 2018). Additionally, mineral assemblage affects the stability of soil aggregates; for example, small  
50 amounts of smectite in kaolinitic materials cause it to be more dispersive and unstable (Levy et al.,  
51 1993).

52

53 Previous studies in the badlands of southwestern (SW)SW Taiwan have revealed that ~~dissolving~~ halite  
54 and gypsum dissolve at depth and migrate to the hillslope surface and deposit in desiccation cracks  
55 during the dry season (Higuchi et al., 2013, 2015; Nakata and Chigira, 2009). Others have observed  
56 that~~This produces~~ pore waters found in the near-surface mudstone have ~~with a concentration of~~ Na<sup>+</sup>  
57 concentrations of 1–3 million μmol/L at 1–2 cm depth (Nakata and Chigira, 2009). Mud cracks lead  
58 to the properties of the mudstone, e.g., rock density, water permeability, and ion concentration between  
59 the surface (a few centimeters to 10 cm depth) and bedrock are different (Fig. S1). For example, the  
60 bedrock hardly participates in physical erosion during a rainfall event due to low permeability. We  
61 hypothesize that the ~~dissolved~~~~dissolving~~ halite and gypsum re-crystallizes in the near-surface and ~~is~~  
62 are deposited in the mudstone cracks through capillary action during the dry season. Subsequent  
63 ~~extreme~~ precipitation dissolves the evaporite, and the dissolved Na<sup>+</sup> ~~which~~ enhances erosion by clay  
64 dispersity and ~~further~~ exposes more weatherable materials, forming a positive feedback cycle.  
65 Assuming a mudstone substrate that is primarily comprised of silicate minerals, we expect that ~~the~~  
66 concentration of ~~the~~ evaporite ions should be consistent with ~~the~~ changes in the sediment concentration  
67 and the concentration of silicate ions.

68

69 To investigate this potential feedback~~the relationship~~ between evaporite dissolution and erosion, we  
70 use suspended sediment concentrations (SSC) and stream chemistry data from two catchments in the  
71 badlands of SW Taiwan (Fig. 1), collected at ~~collected with~~ a temporal resolution of 3 hours over 3  
72 days. We interpret our observations in the badlands to reflect how the excess sodium that re-precipitates  
73 at surface in dry season enhances physical erosion and chemical weathering in the following ~~during a~~

74 typhoon event, ~~and the importance of this process for exposing fresh bedrock available for weathering~~  
75 ~~in the following dry season.~~

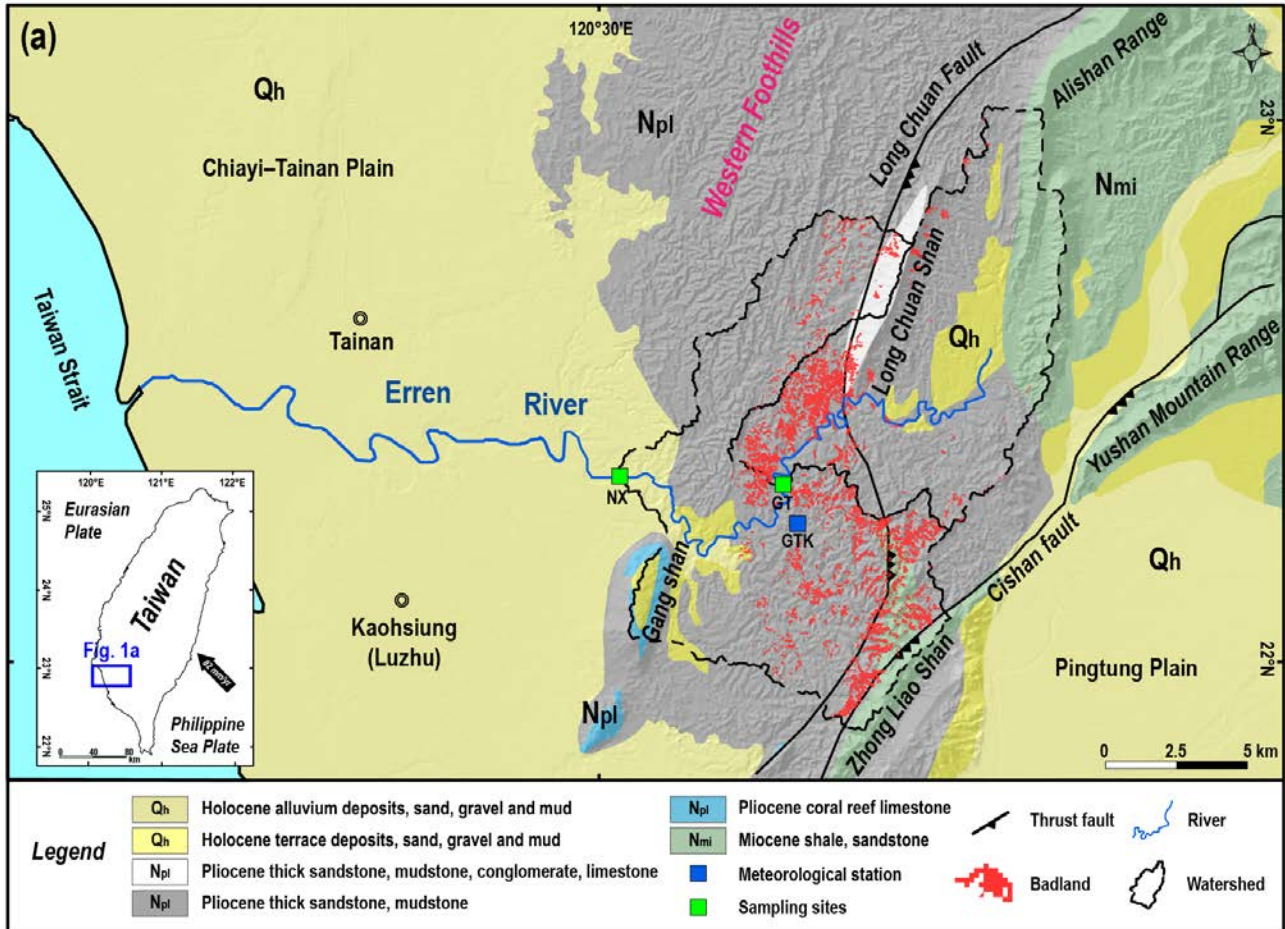

76

## 77 **2. Geological and Meteorological Setting**

78 In Taiwan's badlands, the annual precipitation ~~exceeds~~ is about 2 m, and 90% of the rainfall is  
79 concentrated in the rainy season. The rainy season lasts from May to October and reaches its peak in  
80 August, with over 400 mm of precipitation within a single month. In contrast, less than 40 mm of  
81 average monthly rainfall is measured from November to April. We collected river water samples from  
82 two sites downstream of the studied badland areas. The first site, Nanxiong Bridge (NX), is located at  
83 the midstream of the Erren River and has a drainage area of 175 km<sup>2</sup>. This area includes badlands  
84 covering an area of 4.37 km<sup>2</sup>, which accounts for 2.49% of the total catchment area (Fig.1). The Erren  
85 River catchment is predominantly underlain by Plio-Pleistocene mudstones, which are several  
86 kilometers thick, and mainly feature illite (30.54%) and chlorite (28.70%) minerals (Tsai, 1984a).  
87 During the dry seasons, the pore water chemistry in the near-surface mudstones is mainly composed  
88 of Na<sup>+</sup>, Cl<sup>-</sup>, Ca<sup>2+</sup> and SO<sub>4</sub><sup>2-</sup> (Nakata and Chigira, 2009).

89

90 The gauging station at Nanxiong Bridge (NX) provides hourly discharge data for calculating sediment  
91 and solute fluxes. The annual average discharge of Nanxiong Bridge station is 10.2 m<sup>3</sup>/s, and the  
92 typhoon season accounts for 84% of the total discharge. The meteorological station at Gutingkeng  
93 (GTK) is located 5.5 km from Nanxiong Bridge and provides hourly precipitation data. Our second  
94 sampling site is Guting (GT) Bridge, with an upstream drainage area of 79 km<sup>2</sup> and a badlands area of  
95 1.87 km<sup>2</sup>, corresponding to 2.37% of the total area. Guting Bridge is located adjacent to a badlands  
96 conservation area, so the riverine water chemistry reflects the weathering products derived from the  
97 adjacent hillslopes. Due to a lack of stream discharge observations at Guting Bridge, we use hourly  
98 precipitation data at GTK, which is less than 1 km from the sampling site, to quantify the impact of  
99 the typhoon events.

101

102 **Figure 1.** Location of sampling sites and geology of the study area. (a) The geological map of the  
 103 study area (Source: Central Geological Survey, 2013). The green squares are sampling sites; hourly  
 104 stream discharge data were obtained from the Nanxiong Bridge (NX) hydrometric station (Water  
 105 Resources Agency). The blue square is the meteorological station, which provides hourly precipitation  
 106 data (Central Weather Bureau, <https://dbar.pccu.edu.tw/>).

107

### 108 3. Methods and Materials

#### 109 3.1 Water Sampling

110 We collected 42 stream samples from the two sampling sites for the typhoon period of July 2017.  
 111 During sample collection, two 1000 ml PE bottles were dropped 1 to 2 meters below the water surface  
 112 of the river simultaneously. Suspended sediment concentration (SSC) was subsequently calculated  
 113 from the water collected in one of the PE bottles, and riverine chemistry was determined from water  
 114 collected in the other bottle. Samples were filtered *in situ*, and the filtrate was preserved in the  
 115 refrigerator for laboratory analysis. Additionally, 31 samples were collected from September 2014 to

116 December 2016 in the second half of every month at Nanxiong Bridge for non-typhoon periods, using  
117 the same sampling procedure.

118

### 119 3.2 Dissolved load and sediment chemistry analysis

120 For the riverine dissolved load, we measured major dissolved anions ( $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ ,  $\text{F}^-$ ) on an  
121 Ion chromatography (IC, Metrohm Basic-883 plus), and we measured major dissolved cations ( $\text{Na}^+$ ,  
122  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Si}^{4+}$ ) on an ICP-OES (PerkinElmer, Optima 2100DV). We measured bulk  
123 sediment chemistry from two samples of suspended sediment collected from Guting Bridge at low  
124 flow before the typhoon event ( $2.26 \text{ m}^3/\text{s}$ ) and at the peak of runoff ( $724.32 \text{ m}^3/\text{s}$ ). About 0.7 g of dried  
125 sediment sample was combusted in the muffle furnace at  $650^\circ\text{C}$  for 2 hours and then weighed to obtain  
126 the loss on ignition (LOI). Afterwards, an aliquot of  $\sim 100 \text{ mg}$  from the residue was digested with a  
127 mixture of concentrated HF and aqua regia. After digestion and drying, the sample was dissolved in  
128 0.3 N  $\text{HNO}_3$  for elemental determination. Major elemental concentrations of sediment samples were  
129 obtained by ICP-OES (Varian 720-ES) at the GFZ German Research Centre for Geosciences.

130

### 131 3.3 Grain size of suspended load

132 Before measuring grain size, we removed the non-clastic deposition, i.e., sea salt, organic matter, and  
133 carbonate. To remove sea salt,  $\sim 1 \text{ g}$  of dried sediment sample was added to 15 ml of distilled water,  
134 placed in a shaker, and shaken at a speed of 4000 rpm for 5 minutes. The centrifuged supernatant was  
135 then poured out and these steps were repeated 3 times. To remove organic matter, 10 ml of a 15%  
136  $\text{H}_2\text{O}_2$  solution was added to the sediment and placed in an ultrasonic oscillator for 24 hours. After  
137 adding a second 10 ml of  $\text{H}_2\text{O}_2$  (15%) to confirm the completion of the reaction, the mixture was  
138 centrifuged and the supernatant containing the organic matter was removed. The sediment was then  
139 washed by adding 30 ml of distilled water, and the supernatant was again removed after centrifugation.  
140 This washing step was repeated 3 times to remove residual  $\text{H}_2\text{O}_2$  in the centrifuge tube. To remove the

141 carbonates, we added 10 ml of 10% HCl solution to the centrifuge tube and allowed the acid to react  
142 with the sediments for 24 hours. An additional 10 ml of HCl was then added to confirm the  
143 completeness of the reaction. The sample was then centrifuged, and the supernatant was decanted to  
144 remove the carbonates. The sample was then rinsed with 30 ml of distilled water, centrifuged, and  
145 decanted. This step was performed 3 times to remove any residual HCl.

146

147 To disperse sediment agglomeration, we added 10 ml of 1%  $\text{Na}(\text{PO}_3)_6$  solution to the sediment and let  
148 the sample react for more than half a day. The grain size of the sediment samples was obtained by  
149 Laser Diffraction Particle Size Analyzer LA950 at the GFZ German Research Centre for Geosciences.  
150 By using LA950, we measured grains in the size range of between 100 nm to about 3 cm.

151

#### 152 3.4 Calculation of the enriched ratio and sodium adsorption ratio (SAR)

153 In order to classify the supply of different ion sources during the typhoon event, we used the enriched  
154 ratio of concentration as a reference. The enriched ratio is the ion concentration at a certain time  
155 divided by the ion concentration at the first observation. A value greater than 1 represents a point in  
156 time when the sample is more concentrated relative to the first observation, whereas a value smaller  
157 than 1 represents a point in time when the sample is more diluted relative to the first observation. [The  
158 first observation was sampled 6 hours before the typhoon which represents the background value of  
159 river water chemistry in this study.](#)

160

161 Dissolved calcium and magnesium can stabilize soil aggregates and therefore ~~facilitate~~[enhance](#) water  
162 permeability (Nadler et al., 1996). By contrast, excess sodium can disperse soil particles through  
163 deflocculation, thereby reducing water permeability (Hanson et al., 1999). The potential for material  
164 dispersion in badlands is generally determined by measuring the presence and behavior of sodium and  
165 is quantified by the sodium absorption ratio (SAR), (1):

$$SAR = \frac{Na^+}{\sqrt{\left(\frac{Ca^{2+}+Mg^{2+}}{2}\right)}} \quad (1)$$

Here, the cation measurements are expressed in milliequivalents per liter (meq/L). For pore water, ~~When~~-when SAR is greater than 13, the excess sodium causes soil particles to repel each other, preventing the formation of soil aggregates (Seelig, 2000; Horneck et al., 2007). Given the influence of soil structure, SAR value for irrigation water smaller than 3 is low, from 3 to 9 is medium and above 9 is high (Ayers and Westcot, 1985).

### 3.5 Calculation of TDS and chemical weathering rate

Riverine TDS is widely used to estimate chemical weathering rates of river catchments (e.g. Gaillardet et al. 1999). In this study, riverine TDS (in units of  $\mu\text{mol/L}$ ) is expressed as:

$$TDS = TDS_{rain} + TDS_{evaporite} + TDS_{sil} + TDS_{carb} \quad (2)$$

where the contributions from precipitation ( $TDS_{rain}$ ), evaporite ( $TDS_{evaporite}$ ), silicate weathering ( $TDS_{sil}$ ) and carbonate weathering ( $TDS_{carb}$ ) are considered. We calculated the proportions of ion contributions from rainwater, evaporite, silicate and carbonate for Ca, Mg, Na, Cl, and  $SO_4$  with the MEANDIR inversion model (Kemeny and Torres, 2021), a MATLAB script for inverting fractional contributions of end-members, and for constraining the chemical compositions of those end-members with Monte Carlo propagation of uncertainty. To exclude the input of precipitation ( $TDS_{rain}$ ) from riverine TDS, we used local rainwater  $Cl^-$  concentrations with an average value of  $68 \mu\text{mol/L}$  (Lu, 2014), and also the ratios of  ~~$Cl^-$  and  $SO_4/Cl^{2-}$ ,  $Na/Cl^+$ ,  $K/Cl^+$ ,  $Mg/Cl^{2+}$ ,  $Ca/Cl^{2+}$~~  in rainfall based on the rainfall chemistry from 2007 to 2013 reported by Lu (2014) (Table 1  $SO_4^{2-}/Cl^- = 0.35$ ,  $Na^+/Cl^- = 0.90$ ,  $K^+/Cl^- = 0.09$ ,  $Mg^{2+}/Cl^- = 0.18$ ,  $Ca^{2+}/Cl^- = 0.35$ ) (Lu, 2014). ~~Thus, we estimated the annual deposition of those cations using equation (3):-~~

$$[X]_{norain} = [X]_{river} - [X]_{rain} \quad (3)$$

$$TDS_{rain} = \sum [X]_{rain} \quad (4)$$

190 Here  $[X]_{norain}$  reflects the remaining concentration of ion X after the removal of atmospheric inputs;  
 191  $[X]_{river}$  is the concentration of ion X in river water, and  $[X]_{rain}$  is the concentration of ion X from  
 192 atmospheric deposition. In the second step, we corrected for evaporite inputs ( $TDS_{evaporite}$ ) using the  
 193 following equation:

$$194 \quad [X]_{NSS} = [X]_{norain} - [X]_{evap} = [X]_{norain} - \left( [Cl]_{norain} \times \left( \frac{X}{Cl} \right)_{evap} \right) \quad (5)$$

$$195 \quad TDS_{evaporite} = \sum [X]_{evap} \quad (6)$$

196 where  $[X]_{NSS}$  is the concentration of ion X after the removal of ions attributed to evaporites,  $[X]_{evap}$ .

197  $[X/Cl]_{evap}$  is the ratio of ion X and Cl by using the end-member molar ratios of evaporite [reported by](#)  
 198 [Burke et al. \(2018\)](#), of which K/Cl is referred to [Chao et al., \(2011\)](#) (Table 1)  ~~$SO_4^{2-}/Cl^- = 0.4$ ,  $Na^+/Cl^-$~~

199  ~~$= 1$ ,  $Mg^{2+}/Cl^- = 0.10$ ,  $Ca^{2+}/Cl^- = 0.5$ , [Burke et al., 2018](#);  $K^+/Cl^- = 0.026$ , [Chao et al., 2013](#)~~). Then, after

200 the correction for evaporite, the chemical weathering budget can be divided into contributions by

201 silicate ( $TDS_{sil}$ ) and carbonate weathering ( $TDS_{carb}$ ), expressed as:

$$202 \quad TDS_{sil} = [Na]_{sil} + [K]_{sil} + [Mg]_{sil} + [Ca]_{sil} + [SiO_2]_{sil} \quad (7)$$

$$203 \quad TDS_{carb} = [Mg]_{carb} + [Ca]_{carb} + [HCO_3]_{carb} \quad (8)$$

$$204 \quad [HCO_3]_{carb} = \frac{1}{2} ([Mg]_{carb} + [Ca]_{carb}) \quad (9)$$

205 where  $[Na]_{sil}$  and  $[K]_{sil}$  are riverine  $[Na]_{NSS}$  and  $[K]_{NSS}$  concentrations, respectively. We used

206 endmember values for silicate- and carbonate-dominated rocks reported by [Gaillardet et al. \(1999\)](#),

207 [\(Table 1\)](#). [We agree that the use of global endmembers leads to a larger range of estimations, but is](#)

208 [still appropriate in discussing trends in weathering rates](#), ~~which gave ratios of  $Ca/Na = 0.35$  and  $Mg/Na$~~

209  ~~$= 0.24$  for silicates, and  $Ca/Na = 50$  and  $Mg/Na = 10$  for carbonates.~~

210 [Considering the hydrological response, we use flow weighted method to calculate the flux of solute](#)

(Huang et al., 2012), expressed as:

$$Flux_{(rain, \text{ evap, sil, carb})} = \frac{(m \times \frac{\sum_{i=1}^n TDS_{(rain, \text{ evap, sil, carb})i}}{\sum_{i=1}^n Q_i} \times Q_t)}{\text{catchment area}} \quad (10)$$

where  $m$  is the conversion factor for a specific unit (ton/km<sup>2</sup>/yr).  $Q_i$  is the hourly discharge corresponding to sampling time.  $Q_t$  is total discharge during the year or during the typhoon.

**Table 1** Input end-members for the mixing model.

End-member	SO <sub>4</sub> /Cl	Na/ Cl	K/ Cl	Mg/Cl	Ca/Cl
Precipitation	0.35	0.90	0.09	0.18	0.35
Evaporites	0.6±0.6	1.0±0	0.026	0.1±0.08	0.5±0.5
	Ca/Na	Mg/Na			
Silicates	0.35±0.25	0.24±0.2			
Carbonates	60±30	30±15			

## 4. Results

### 4.1 Geochemistry of river water and suspended sediment

In 2017, the Nesat and Haitang typhoons brought 579 mm of rainfall over three days, with a maximum intensity of 74 mm/hr. The discharge at Nanxiong Bridge demonstrated that the climatic co-response has two pulses (Fig. 2). Since the time interval between the two typhoons was less than 6 hours, we define the two typhoons as one typhoon event and distinguish between a first and second discharge pulse. We quantify time relative to the onset of the typhoon (0 hr). The first pulse occurred from 8.5 to 32.5 hr, with a mean water discharge of 66.2 m<sup>3</sup>/s. The second pulse that occurred from 32.5 to 62.5 hr had a 5.5 times higher mean discharge of 369.2 m<sup>3</sup>/s. The maximum discharge (753.2 m<sup>3</sup>/s) was observed during the second pulse at 44.5 hr (July 31st, 2017, at 6:00 a.m.) (Fig. 2).

At Nanxiong Bridge, SSC has a statistically significant positive correlation with SAR ( $\rho = 0.51$ ,  $p < 0.05$ ). SSC has two peaks, one during each pulse, but SAR only shows a peak during the first pulse. During the first pulse, SSC ranged from 10 to 33757 mg/L and SAR increased from 8.21.44 and to 17.73.14. During the second pulse, SSC increased from 5445 to 16900 mg/L and SAR

234 is steadily remained about 7.31.44.

235 The median grain size ( $D_{50}$ ) ranged from 3.9 to 8.2  $\mu\text{m}$ , with an average value of 5.6  $\mu\text{m}$  during the

236 second pulse, and exhibited a positive correlation with discharge ( $\rho = 0.40$ ). At Guting Bridge, SSC

237 has a statistically significant positive correlation with SAR ( $\rho = 0.69$ ,  $p < 0.05$ ) during the survey. SSC

238 ranged from 164 to 19538 mg/L before the first pulse and ranged from 2857 to 35920 mg/L during the

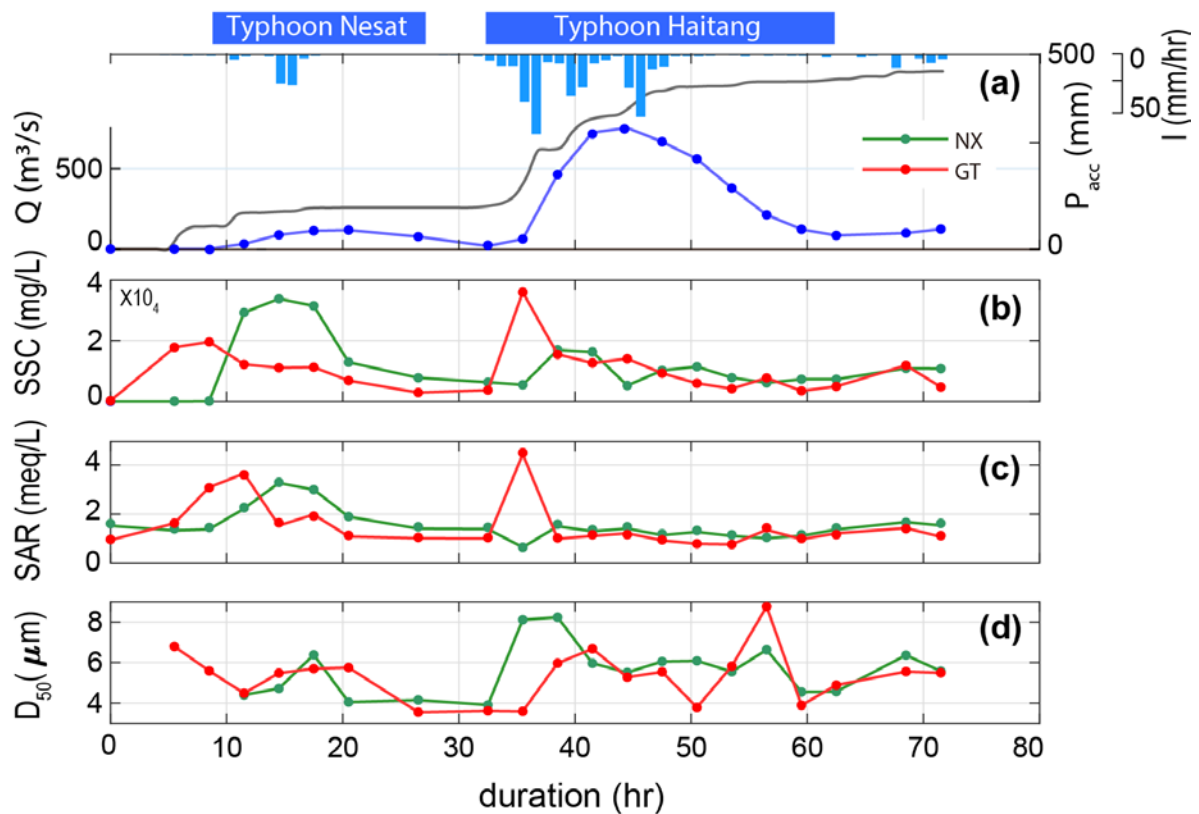

239 second pulse, while SAR showed a mean of 8.21.46 and two peaks with a value over 20.4 during both

240 pulses.  $D_{50}$  ranged from 3.6 to 8.8  $\mu\text{m}$ , with an average value of 5.3  $\mu\text{m}$  during the second pulse, (Fig.

241 2). In terms of sediment chemistry at Guting Bridge, major elements of the two selected sediment

242 samples show that calcium and sodium accounted for about 10% of the mass loss between the typhoon

243 event (5.5 hr of duration) and the peak of discharge (41.5 hr of duration) (Table. S4).

244

245 **Figure 2.** Timeseries SSC, SAR and median grain size of suspended sediment ( $D_{50}$ ) at two sampling

246 sites. The blue line denotes hourly discharge (Q) at Naxiong Bridge, and the blue bar denotes hourly

247 precipitation (I) at Gutingkeng station. The gray line denotes precipitation accumulation ( $P_{acc}$ ), the

248 green line denotes the Naxiong Bridge (NX) dataset, and the red line denotes the Guting Bridge (GT)

249 dataset.

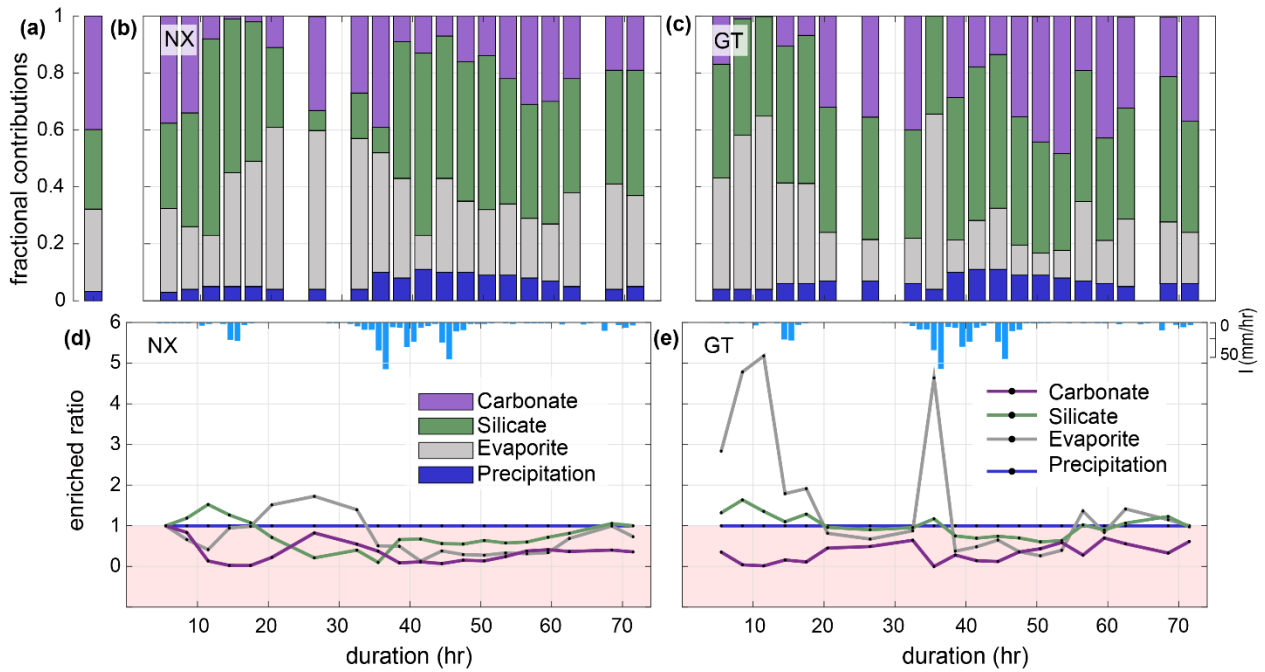

250

251 The fractional proportions of TDS at Nanxiong Bridge during baseflow show that precipitation,  
252 evaporites, silicates, and carbonates contribute  $3.0\pm 1.1\%$  [\(uncertainty gives the standard error of the](#)  
253 [mean\)](#),  $28.7\pm 14.6\%$ ,  $26.9\pm 6.5\%$ , and  $41.4\pm 13.2\%$ , respectively (Fig. 3a). During the typhoon event,  
254 the proportion of TDS at Nanxiong Bridge attributed to  $TDS_{rain}$  is  $6.3\pm 2.4\%$ .  $TDS_{evaporite}$  contributes  
255  $32.4\pm 13.6\%$  and increases from 27.4% to 61.1% at the incipient first pulse.  $TDS_{sil}$  contributes  
256  $39.5\pm 15.2\%$ , which is 12.6% higher than the non-typhoon period.  $TDS_{carb}$  contributes  $21.8\pm 11.5\%$   
257 (Fig. 3b), which is 19.6% lower than the non-typhoon period. The fractional proportions of TDS at the  
258 Guting Bridge show that  $6.5\pm 2.1\%$  of TDS is contributed by  $TDS_{rain}$ .  $TDS_{evaporite}$  contributes  
259  $24.8\pm 16.2\%$  and increases from 13.6% to 61.6% at the incipient second pulse, when the SSC and SAR  
260 peak simultaneously.  $TDS_{sil}$  and  $TDS_{carb}$  contribute  $39.5\pm 15.2\%$  and  $27.5\pm 16.7\%$ , respectively (Fig.  
261 3c).

262

263 Enriched ratios [of](#) less than ~~1~~[one](#) indicate dilution, and values greater than ~~1~~[one](#) indicate concentration.  
264 Since we set the ion concentration of rainfall to be constant during the typhoon event, the enriched  
265 ratio of precipitation is constant throughout the observation period. At Nanxiong Bridge, the evaporites  
266 enriched ratio increases from 0.4 to 1.7 between the two pulses and decreases to 0.1 at the discharge  
267 peak. The silicates enriched ratio increases from 1 to 1.5 before the first pulse and decreases to 0.1 at  
268 the peak of discharge, then returns to 1 before the observation ends. The concentration attributed to  
269 carbonates is always diluted. The evaporites and carbonates enriched ratio ~~have~~[has](#) a statistically  
270 significant negative correlation with discharge (evaporites:  $\rho = -0.67$ , carbonates:  $-0.60$ ,  $p < 0.05$ ) and  
271 the silicate enriched ratio has a negative correlation with discharge ( $\rho = -0.32$ ), indicating dilution by  
272 typhoon rainfall (Fig. 3d). At Guting Bridge, the evaporites enriched ratio has two peaks during the  
273 two pulses with a value of 5.2 at the first peak, a value of 4.7 at the second peak. After the event, the  
274 value returns to about 1.2. Notably, the evaporites enriched ratios during ~~the~~ both pulses are similar,  
275 but the peak discharge of the second pulse is 5.5 times higher than that of the first pulse. The silicate

276 enriched ratio has an analogous pattern with the evaporites enriched ratio, but the enriched ratio is  
277 smaller. Similar to Nanxiong Bridge, the carbonates enriched ratio is always diluted at Guting Bridge  
278 (Fig. 3e). The evaporite and silicate enriched ratio shows a statistically significant positive correlation  
279 ( $\rho = 0.96$ ,  $p < 0.05$ ), and the evaporite and silicate enriched ratios have a statistically significant positive  
280 correlation with SAR ( $\rho = 0.86$ ,  $\rho = 0.84$ ,  $p < 0.05$ ). We also use the concentration–discharge (cQ)  
281 relationship of each ion at rising and recession limb, as well as baseflow at Nanxiong Bridge to assess  
282 the state of dilution behavior (Fig. S2). Overall, our results show that all ions are in a dilution, and the  
283 dilution in recession limb is stronger than that in rising limb, except for SO<sub>4</sub> during baseflow ( $\theta=0.07$ ).  
284 The concentration of Na, Cl and K during baseflow have a higher variability than the values during  
285 the event. Additionally, Na, Cl, and SO<sub>4</sub> increase the concentration with increasing flow at the certain  
286 period of rising limb.

288

289 **Figure 3.** Timeseries illustrating TDS sources during the typhoon event at the two sampling sites.  
 290 Fig.3a shows the average proportion of TDS for the non-typhoon period from September 2014 to  
 291 December 2016 at Nanxiong Bridge; Fig.3b-c denotes the endmember contributions to TDS at  
 292 Nanxiong Bridge dataset and Guting Bridge dataset from the typhoon period; the purple bar denotes  
 293  $TDS_{carb}$  (Eq. 8); green denotes  $TDS_{sil}$  (Eq. 7); the gray bar denotes  $TDS_{evaporite}$  (Eq. 6); the blue bar  
 294 denotes  $TDS_{rain}$  (Eq. 4). Fig.3d-e denotes the enriched ratio of ion concentrations by TDS sources from  
 295 the Nanxiong Bridge dataset and Guting Bridge dataset during the typhoon period. The purple line  
 296 denotes  $TDS_{carb}$ , the green line denotes  $TDS_{sil}$ , the gray line denotes  $TDS_{evaporite}$ , the blue line denotes  
 297 the  $TDS_{rain}$ , and blue bar denotes hourly precipitation (I) at GTK station.

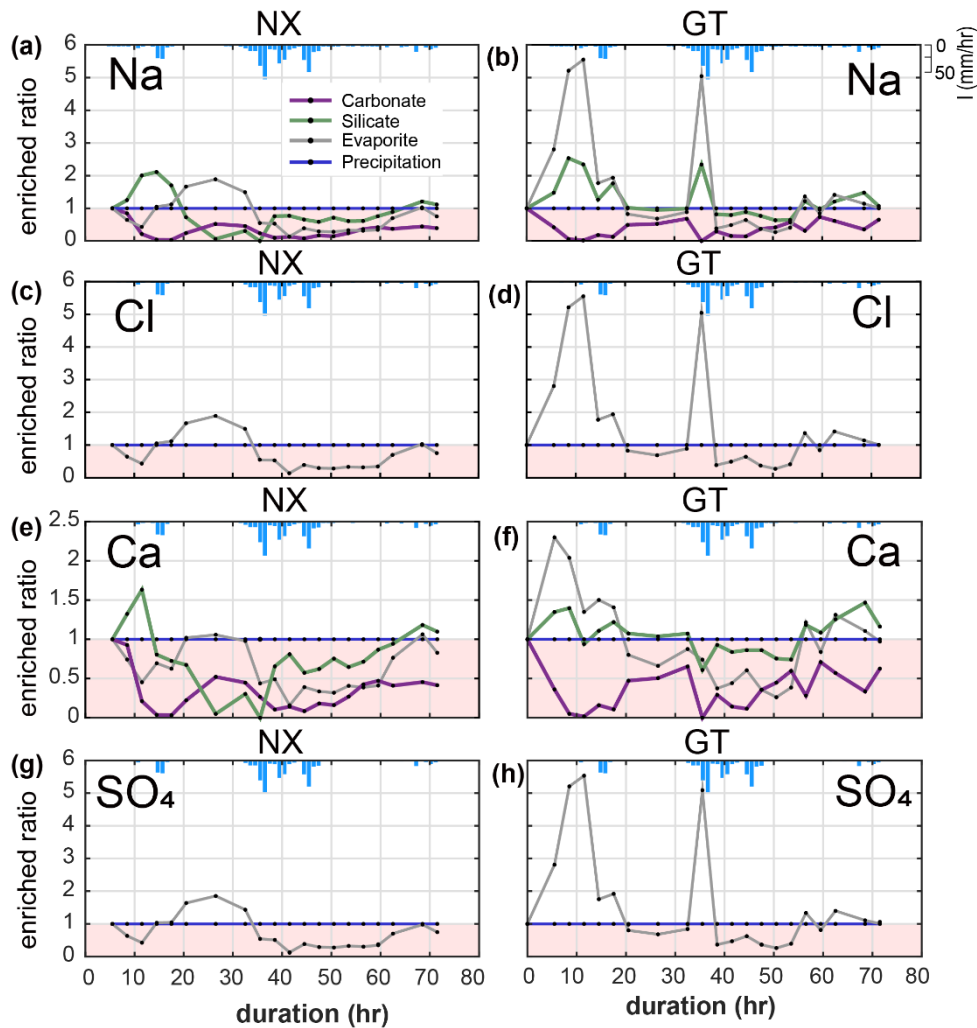

## 298 4.2 Evaporite, silicate and carbonate dissolution over time

299 We calculated the enriched ratios of ions (i.e.,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$ ) that are sourced from evaporites  
300 (i.e., halite ( $\text{NaCl}$ ) and gypsum ( $\text{CaSO}_4$ )). The variability in the concentrations of each of these ions  
301 reflects the overall trends in TDS (Fig. 3d-e & Fig. 4).

302

303 At Nanxiong Bridge, all evaporite and carbonate ions have a statistically significant negative  
304 correlation with discharge. The enriched ratios in evaporite  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  have the same trend (Fig.  
305 4), which show an initial decrease during the first pulse, followed by an increase to 2 between the two  
306 pulses, and a final decrease during the second pulse. Evaporite  $\text{Ca}^{2+}$  shows a similar trend with  
307 evaporite  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$ , but the values are below 1. The enriched ratios of silicate  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ; and  
308  ~~$\text{SO}_4^{2-}$~~  show an increase during the first pulse and a decrease to less than 1 before the rainfall peak,  
309 followed by an increase from about 0.06 to 1.11 at the end of observation. At Guting Bridge, all  
310 evaporite ions have a statistically significant positive correlation with the corresponding silicate ions  
311 ( $\text{Na}^+$ ,  $r=0.98$ ;  $\text{Ca}^{2+}$ ,  $r=0.81$ ;  ~~$\text{SO}_4^{2-}$ ,  $r=0.98$~~ ,  $p<0.05$ ). Evaporite  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{SO}_4^{2-}$  each have two peaks  
312 that occur prior to the maximum rainfall and reflect a factor of 5 increase in the enriched ratio.  
313 Compared with Nanxiong Bridge (downstream), the enriched ratio in evaporite  $\text{Ca}^{2+}$  at Guting Bridge  
314 concentrates at the onset of the first pulse and after peak discharge. Additionally, the enriched ratios of  
315 carbonate at Guting Bridge are similar to Nanxiong Bridge, and are always below 1.

316

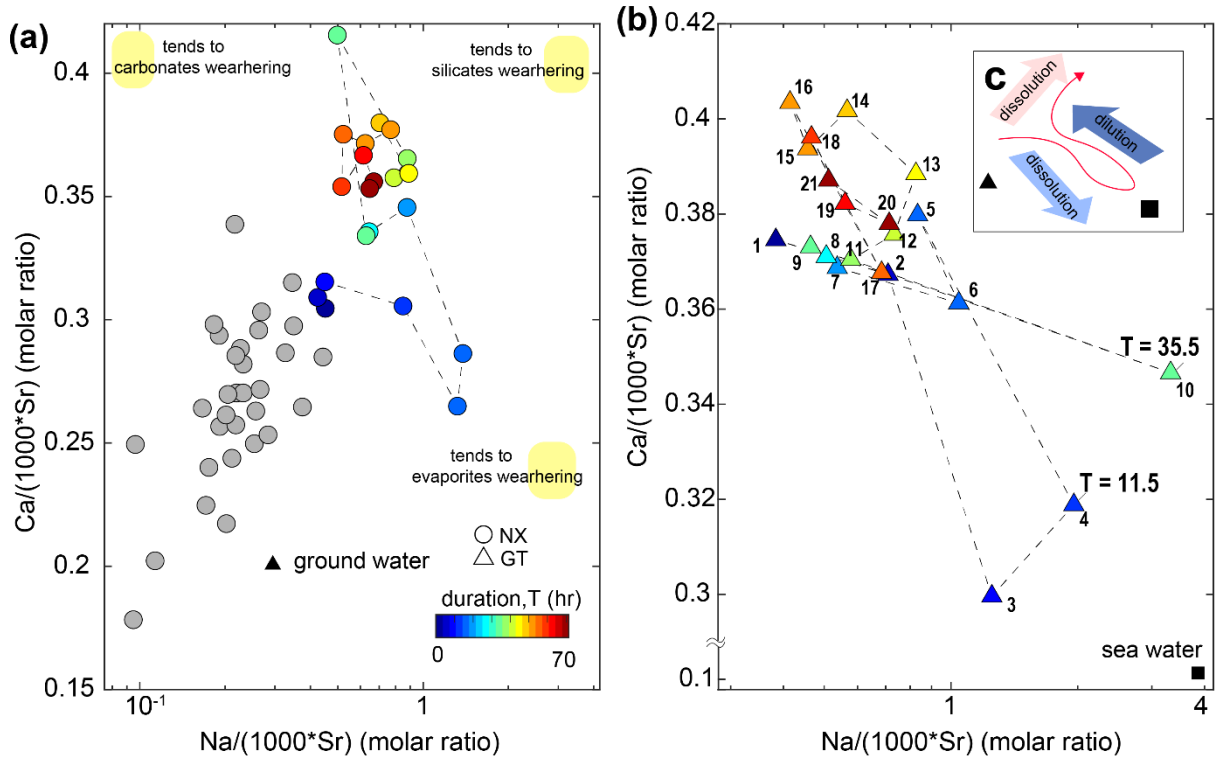

317 **Figure 4.** Time-series patterns in enriched ratio at two sampling sites. NX denotes the Nanxiong Bridge  
 318 dataset and GT denotes Guting Bridge dataset. The pink area indicates enriched values below 1. Blue  
 319 bar denotes hourly precipitation ( $I$ ) at Gutingkeng station.

320

321 Gaillardet et al. (1999) documented that dissolved ions ratios of Ca/Sr and Na/Sr are distinct for  
 322 carbonates (low Na/Sr, high Ca/Na) versus silicates or evaporites (high Na/Sr, low Ca/Na). We use  
 323 these ratios to elucidate potential mixing between carbonates, ~~and~~ silicates, and evaporite  
 324 endmembers (Fig. 5). At Nanxiong Bridge, non-typhoon ratios of Na/(1000\*Sr) and Ca/(1000\*Sr) are  
 325 0.23–0.68 and 0.19–0.35, respectively (Table S4). These values increase markedly during the typhoon  
 326 events, with enriched ratios of Na<sup>+</sup> exceeding 5 at T = 11.5 and 35.5 hr. The high concentration of  
 327 Na<sup>+</sup>, Cl<sup>-</sup> and SO<sub>4</sub><sup>2-</sup> (as illustrated in the enriched ratio) indicate that there is enhanced dissolution of  
 328 evaporites at the onset of the typhoon event, especially at Guting Bridge. Subsequently, the

329 concentration of  $\text{Na}^+$  decreased with sustained rainfall. Then, the ratios approach the  
 330 silicates/carbonates weathering (high  $\text{Na}/\text{Sr}$ , high  $\text{Ca}/\text{Sr}$  ratios ) after the peak discharge.

331

332

333 **Figure 5.** Molar ratio mixing diagrams of Erren River waters for (a-b)  $\text{Na}/(1000 \cdot \text{Sr})$  versus  
 334  $\text{Ca}/(1000 \cdot \text{Sr})$ , circles denote dataset at Nanxiong Bridge, and triangles denote dataset at Guting Bridge.  
 335 Colorbar denotes survey duration. Gray circles denote the dataset at Nanxiong Bridge during baseflow  
 336 conditions from 2014 to 2016. The black triangle illustrates the groundwater endmember (Chao et al.,  
 337 2011); the black square illustrates the seawater endmember. Numbers in the triangle represent the time  
 338 sequence, 1 represents the start point, and 21 represents the end point. Yellow areas indicate trends in  
 339 weathering types rather than the locations of endmember. (c) Illustration of dynamic weathering. The  
 340 red line indicates the direction of change with time. The light blue arrow denotes dissolution of  
 341 evaporite, the dark blue arrow denotes dilution from rainfall, and the red arrow denotes dissolution of  
 342 suspended sediment.

343

## 344 5. Discussion

### 345 5.1 Relationships between dissolved evaporite and river water chemistry

346 Before the survey, the monthly rainfall of the study area was 72.5 mm, which is only 18% of the

347 average monthly rainfall, implying that it provides a relatively dry environment for accumulating  
348 evaporites on the slope surface. Under maximum rainfall intensity,  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2+}$  at Guting Bridge  
349 show markedly increased concentrations at the onset of the typhoon, peaks in enriched ratios that  
350 exceed 5 (Fig. 4), and the greatest contribution of dissolved ions from evaporites (Fig. 3). ~~In addition,~~  
351 Calculated with pore water chemistry during the dry season from the same study site, the sodium  
352 absorptions ratio (SAR) is 240.8 and exceeds the threshold value of 13. During the typhoon event, the  
353 river water SAR has a maximum value of 4.41 at Guting Bridge (3.14 at Nanxiong Bridge), suggesting  
354 soil deflocculation within river is weaker than on the hillslopes. However, the ~~sodium absorptions ratio~~  
355 ~~(SAR)~~ has a statistically significant positive correlation with  $\text{TDS}_{\text{evaporite}}$  ( $\rho = 0.86$ ,  $p < 0.05$ ) at Guteng  
356 Bridge (upstream). ~~During the typhoon event, the SAR increases from 4.8 to 24.9 and exceeds the~~  
357 ~~threshold value of 13 at the incipient first pulse and at the incipient second pulse.~~ This pattern indicates  
358 that excess sodium is effective at inducing material dispersion at hillslopes and thus, contributing to a  
359 higher suspended sediment load. The trend of river water SAR is able to reflect the extent of dissolved  
360  $\text{Na}^+$  from hillslope. (Fig. 2).

361  
362 These observations and results suggest that rainwater in the typhoon event rapidly dissolves the  
363 evaporites on the slope surface, which produces high measured concentrations of  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{SO}_4^{2+}$   
364 during the time of peak precipitation (30-40 hr of duration). Furthermore, the dissolution of the near-  
365 surface evaporite deposits should be most heavily influenced by runoff from the hillslopes, so we  
366 expect that excess sodium and enhanced erosion will be most significant on the hillslopes.

367  
368 At Nanxiong Bridge, we observe a 10-hour delay in the peak enriched ratio relative to the SAR (Fig.  
369 3d) and overall lower enriched ratios relative to Guteng Bridge (Fig. 3d-e). We suggest that dilution  
370 and the transport distance from the badlands ~~is~~ are responsible for this. The two catchments have a  
371 similar areal extent of badlands within the total catchment area, which is about 2.49% at Nanxiong  
372 Bridge catchment and 2.37 % in Guting Bridge catchment. Badlands contribute considerable evaporite

373 solutes (Chou, 2008), but the higher downstream drainage area will result in dilution of the solutes  
374 without additional inputs. Additionally, Nakata and Chigira (2009) have observed that salt dissolution  
375 induces an increase in electrical conductivity during intermittent rainfall events and decreases  
376 gradually after rainfall events when evaporation and salt precipitate. Therefore, re-crystallization during  
377 the transportation is to be expected.

378

## 379 5.2 From evaporite dissolution to silicate weathering

380 Our observations show that silicate weathering during the typhoon event contributes 16.8  
381 ton/km<sup>2</sup>/yr~~the water chemistry of the typhoon event is dominated by silicate weathering at 16.8~~  
382 ~~ton/km<sup>2</sup>/day~~, corresponding to~~contributing~~ 16.6% ~~to~~of the annual silicate weathering flux (Table S3).

383 Additionally, we observed a change in dominant chemical weathering mechanism during the typhoon  
384 event. We rule out significant contributions from groundwater and deep seawater after peak discharge,  
385 since ratios shift to higher Na/Sr, and Ca/Sr ratios relative to the non-typhoon ratio (Fig. 5a–b), and  
386 the Ca/Sr ratio of mud volcanoes in the study site is one order of magnitude less than river water (Chao  
387 et al., 2011). Carbonate weathering is the primary contributor of Ca<sup>2+</sup> for most of the world's large  
388 rivers (Gaillardet et al. 1999), but the increased Na<sup>+</sup> and consistently enriched ratio of carbonate Ca<sup>2+</sup>  
389 does not make this a likely main contributor to the Erren River during the typhoon. We thus suggest  
390 that the primary contributor to weathering is ~~from~~ enhanced silicate dissolution. This interpretation is  
391 supported by the temporal evolution of the enriched ratio of silicate Ca<sup>2+</sup>, which gradually increases  
392 after the discharge peak, to approach a value of about 1 at the end of survey (Fig. 4e&f). As such, in  
393 the waning of the event, excess Ca<sup>2+</sup> originates from a silicate source. Therefore, we suggest that the  
394 ratios shift to higher Na/Sr, Ca/Sr ratios ~~is~~ due to enhanced silicate weathering during the typhoon. We  
395 also observe that the masses of Na and Ca are reduced by 10.6% and 9.9%, respectively, in the  
396 suspended sediment during the course of the typhoon event (Table S6).—

397

398 Given that the sediment transported in the channel is supplied by physical erosion, we suggest that  
399 physical erosion in our study site enhances silicate chemical weathering, which is consistent with  
400 previous studies (Chung, 2002; Chou, 2008). ~~Thus~~ Moreover, we associate the change in weathering  
401 regime during the course of the typhoon with abrasive erosion of silicate sediments in the channel.  
402 Mechano-chemical dissolution of weakly bound ions, e.g., F<sup>-</sup> from the fresh muscovite surfaces is  
403 driven by abrasion under high energy sediment transport with reorganization of the river bed  
404 (Andermann et al., 2022). Mudstones ~~is~~ are mainly composed of silicate minerals (e.g., illite and  
405 chlorite minerals) (Tsai, 1984a), and a few swelling clay minerals (e.g., montmorillonite), which  
406 provide an abundant silicate pool. We suggest that high suspended sediment concentrations, combined  
407 with high energy flow during the typhoon, caused increased silicate input from the weathered silicates  
408 in the suspended sediment. This trend can explain about 10% of the reduced mass and it has also been  
409 observed ~~on~~ in typhoon-driven silicate chemical weathering from silicate minerals at surface (Meyer  
410 et. al., 2017). Importantly, the global annual silicate weathering flux of rivers is 15.7 ton/km<sup>2</sup>/yr  
411 (Gaillardet et al. 1999), relative to our value of 16.8 ton/km<sup>2</sup>/yr. ~~the silicate weathering flux that we~~  
412 ~~calculate in this study is comparable to the global annual flux of rivers (Gaillardet et al. 1999),~~  
413 suggesting that individual stochastic events may have global relevance.

### 414 415 **5.3 Typhoon-controlled cycles of physical and chemical erosion**

416 Evaporites, including halite (NaCl) and gypsum (CaSO<sub>4</sub>), are found in few sedimentary environments,  
417 and they are often excluded from the estimation of CO<sub>2</sub> consumption ~~global chemical weathering~~  
418 ~~eyeles~~ (Gaillardet et al., 1999). Compared to silicate rocks, the relation between evaporites weathering  
419 and physical erosion has rarely been discussed. Through the interactions among riverine chemistry,  
420 suspended sediment properties, and previous soil water chemistry studies, we suggest a positive  
421 feedback cycle of physical-chemical erosion driven by mobile dissolved evaporite (Fig. 5). The  
422 feedback cycle includes three steps. (1) precipitation and deposition of evaporite during the dry season  
423 in near-surface mudstone desiccation cracks through capillary transport (Higuchi et al., 2013, 2015;

424 Nakata and Chigira, 2009). In the dry season, exposed bedrock with low water content develops  
425 desiccation cracks (Allen, 1982; Goehring et al., 2010; Kindle, 1917; Seghir and Arscott, 2015; Xiaa  
426 and Hutchinson, 2000), providing space for the re-precipitation of evaporite minerals. Using evidence  
427 from core samples in mudstone bedrock at the study site, the depth of the crack of about 20 cm can be  
428 regarded as the thickness of the weathering layer. Higuchi et al. (2013) suggested that the weathering  
429 layer in the top 10 cm of mudstone can easily be eroded by intense rainfall. Erosion exposes fresh  
430 bedrock, which would dry in the following dry season and further produce weatherable material.

431

432 (2) Rainfall dissolves the evaporites, producing sodic water that increases physical erosion during  
433 typhoon events. The resulting dissolved sodium causes higher hillslope erosion by deflocculation,  
434 leading to increased suspended sediment in the channels. In the study site, hillslope erosion rate is  
435 about 9-30 cm/year (Higuchi et al., 2013; Yang et al., 2021a). At Nanxiong Bridge, the denudation rate  
436 approaches about 142,857 ton/km<sup>2</sup>/yr, measured from river suspended load (Dadson et. al., 2003), and  
437 the chemical weathering flux is 124-2357 ton/km<sup>2</sup>/yr (Chou, 2008; this study). The high hillslope  
438 erosion rate ensures a steady supply of freshly exposed bedrock, allowing for high chemical weathering  
439 rates.

440

441 (3) Physical erosion enhances silicate weathering and bedrock exposure on hillslopes. Clay minerals  
442 in mudstone deposits are abraded from the abundantly available sediment and provide material for  
443 silicate weathering in streams. Ultimately, with frequent typhoon events and high temperatures in the  
444 study area, this dynamic cycle could repeat several times a year.

445

446 **Figure 6.** Cycle of feedback between physical erosion rate (PER) and solute flux ~~chemical weathering~~  
 447 ~~rate (CWR)~~ in badlands catchment. Red blocks represent dry season conditions. Blue region represents  
 448 typhoon conditions. Brown region represents the bedrock and indicates the type and proportion of  
 449 minerals of mudstone (Tsai, 1984b).

450

451 6. Conclusion

452 We presented major element compositions of stream water from two sites in the Erren River catchment  
 453 at three-hour intervals during a three-day typhoon event in 2017. At ~~the~~ Guteng Station (upstream),  
 454  $TDS_{\text{evaporite}}$  is covariant with  $TDS_{\text{sil}}$ , the sodium adsorption ratio, and the suspended sediment  
 455 concentration, which can be assigned to dissolved evaporite (e.g., halite and gypsum). The excess  
 456 sodium in the evaporite deposits causes material dispersion through deflocculation, which enhances  
 457 the suspended sediment flux. Our observations show that the water chemistry of the typhoon event is  
 458 ~~dominated~~ mainly contributed by silicate weathering at  $16.8 \text{ ton/km}^2/\text{yday}$  and evaporite weathering

459 [at 10.9 ton/km<sup>2</sup>/yr](#), in contrast with baseflow (non-typhoon) conditions that are [mainly](#)  
460 [contributed](#)~~dominated~~ by carbonate weathering. Moreover, during the course of the typhoon, we  
461 observed a shift from predominantly evaporite weathering during peak precipitation to silicate  
462 weathering at peak discharge.

463

464 Combining the observation of riverine chemistry, suspended sediment properties, and previous soil  
465 water chemistry studies, we propose a feedback cycle between physical erosion and chemical  
466 weathering in badlands topography, illustrating that precipitation of evaporites during the dry season  
467 produces sodic water during typhoon events and preferentially triggers higher local erosion. The  
468 enhanced hillslope erosion and abrasive effects of clay in a high discharge stream enhance bedrock  
469 exposure on hillslopes and silicate weathering, respectively. Newly exposed bedrock then produces  
470 more weathered material. Although measurements of bedrock mineral chemistry and Sr isotope are  
471 still needed for confirming sources of excess sodium and calcium (Fig. 5), we suggest that the  
472 conceptual model could provide an insight into landscape change of badlands. The results from our  
473 study suggest that high erosion rates in mudstone badlands of the Erren River catchment ~~is~~[are](#) due to  
474 both weakened lithology and ~~to~~ the interaction between evaporites and hillslope erosion.
