9 **Abstract.** Chemical weathering driven by physical erosion is a natural process that strongly affects  
10 chemical and solid matter budgets at the Earth’s surface. However, the influence of extreme climatic  
11 erosion on chemical weathering dynamics is poorly understood. Badland landscapes formed in highly  
12 erodible, homogeneous substrates have the potential to respond to individual events on scales that are  
13 rapid enough for direct observation. Here, we assess the geochemical and grain-size composition of  
14 suspended sediment and riverine chemistry measurements collected from two catchments during the  
15 2017 Nesat and Haitang typhoons in southwestern Taiwan. During the typhoons, the Na<sup>+</sup> concentration  
16 covaried with suspended sediment concentration, which we attributed to sodium-induced  
17 deflocculation. Evaporite weathering at peak rainfall is succeeded by peak silicate weathering at  
18 maximum discharge, which dominates the weathering signal of the event. Overall, our observations  
19 suggest that initial weathering of near-surface evaporite enhances the physical erosion of silicate rock  
20 during extreme rainfall events.  
21

## 22 **1. Introduction**

23 Chemical weathering induced by physical erosion controls nutrient supply to ecosystems (Milligan  
24 and Morel, 2002), reflects dynamic surface processes (e.g., Calmels et. al., 2011; Clift et. al., 2014;  
25 Emberson et. al., 2016; Meyer et. al., 2017), and regulates the global carbon cycle and the evolution  
26 of Earth's long-term climate (Berner et al., 1983; Ram et al., 1992; Gaillardet et al., 1999). In most  
27 landscapes, physical erosion and chemical weathering operate on geological timescales that may be  
28 difficult to observe on human timescales (e.g., Maher et al., 2014). However, in many landscapes  
29 erosion dominantly occurs during stochastic events, such as storms (e.g., Hartshorn et al., 2002; Lee  
30 et al., 2020; Wang et al., 2021). In particular, typhoons are able to transport large volumes of water and  
31 dissolved solids within hours to days, allowing us to observe the interactions between physical erosion  
32 and chemical weathering in landscapes impacted by them. Nevertheless, observations of the interaction  
33 between extreme physical erosion and chemical weathering dynamics are limited (Meyer et. al., 2017).  
34 Furthermore, the lack of high-frequency stream water sampling leads to a fundamental difficulty in  
35 constraining the dynamic behavior between physical erosion and chemical weathering during a high  
36 discharge period (e.g., a typhoon), which could have key implications for our ability to quantify  
37 topographic responses to these events.

38

39 Badlands are landscapes characterized by highly erodible and weathered substrates, that are largely  
40 devoid of vegetation. The high erodibility of these landscapes provides a unique opportunity to  
41 investigate and quantify denudation processes that operate at short timescales (Cheng et al., 2019;  
42 Yang et al, 2019, 2021a; 2021b). Badlands is typically dominated by mudstones and clays, and soils  
43 that contain clays saturated in sodium ions are particularly vulnerable to erosion by water. Sodium ions  
44 alter the layer charge of double-layered clay minerals (i.e. smectite) and cause the clays to deflocculate,  
45 which refers to the process of breaking up the clay (and ultimately the soil) into finer particles that are  
46 more easily washed away by water (e.g., Faulkner et al., 2004; Mitchell et al., 1993; Rengasamy and  
47 Olsson, 1991; Rengasamy et al., 1984; Sherard et al., 1976; Kašanin-Grubin et. al., 2018). Additionally,

48 mineral assemblage affects the stability of soil aggregates; for example, small amounts of smectite in  
49 kaolinitic materials cause it to be more dispersive and unstable (Levy et al., 1993).

50

51 Previous studies in the badlands of southwestern (SW) Taiwan have revealed that halite and gypsum  
52 dissolve at depth and migrate to the hillslope surface and deposit in desiccation cracks during the dry  
53 season (Higuchi et al., 2013, 2015; Nakata and Chigira, 2009). Others have observed that pore waters  
54 found in the near-surface mudstone have  $\text{Na}^+$  concentrations of 1–3 million  $\mu\text{mol/L}$  at 1–2 cm depth  
55 (Nakata and Chigira, 2009). Mud cracks lead to the properties of the mudstone, e.g., rock density,  
56 water permeability, and ion concentration between the surface (a few centimeters to 10 cm depth) and  
57 bedrock are different (Fig. S1). For example, the bedrock hardly participates in physical erosion during  
58 a rainfall event due to low permeability. We hypothesize that the dissolved halite and gypsum re-  
59 crystallize in the near-surface and are deposited in the mudstone cracks through capillary action during  
60 the dry season. Subsequent precipitation dissolves the evaporite, and the dissolved  $\text{Na}^+$  enhances  
61 erosion by clay dispersity and exposes more weatherable materials, forming a positive feedback cycle.  
62 Assuming a mudstone substrate that is primarily comprised of silicate minerals, we expect that  
63 concentration of evaporite ions should be consistent with changes in the sediment concentration and  
64 the concentration of silicate ions.

65

66 To investigate this potential feedback between evaporite dissolution and erosion, we use suspended  
67 sediment concentrations (SSC) and stream chemistry data from two catchments in the badlands of SW  
68 Taiwan (Fig. 1), collected at a temporal resolution of 3 hours over 3 days. We interpret our observations  
69 in the badlands to reflect how the excess sodium that re-precipitates at surface in dry season enhances  
70 physical erosion and chemical weathering in the following typhoon event.

71

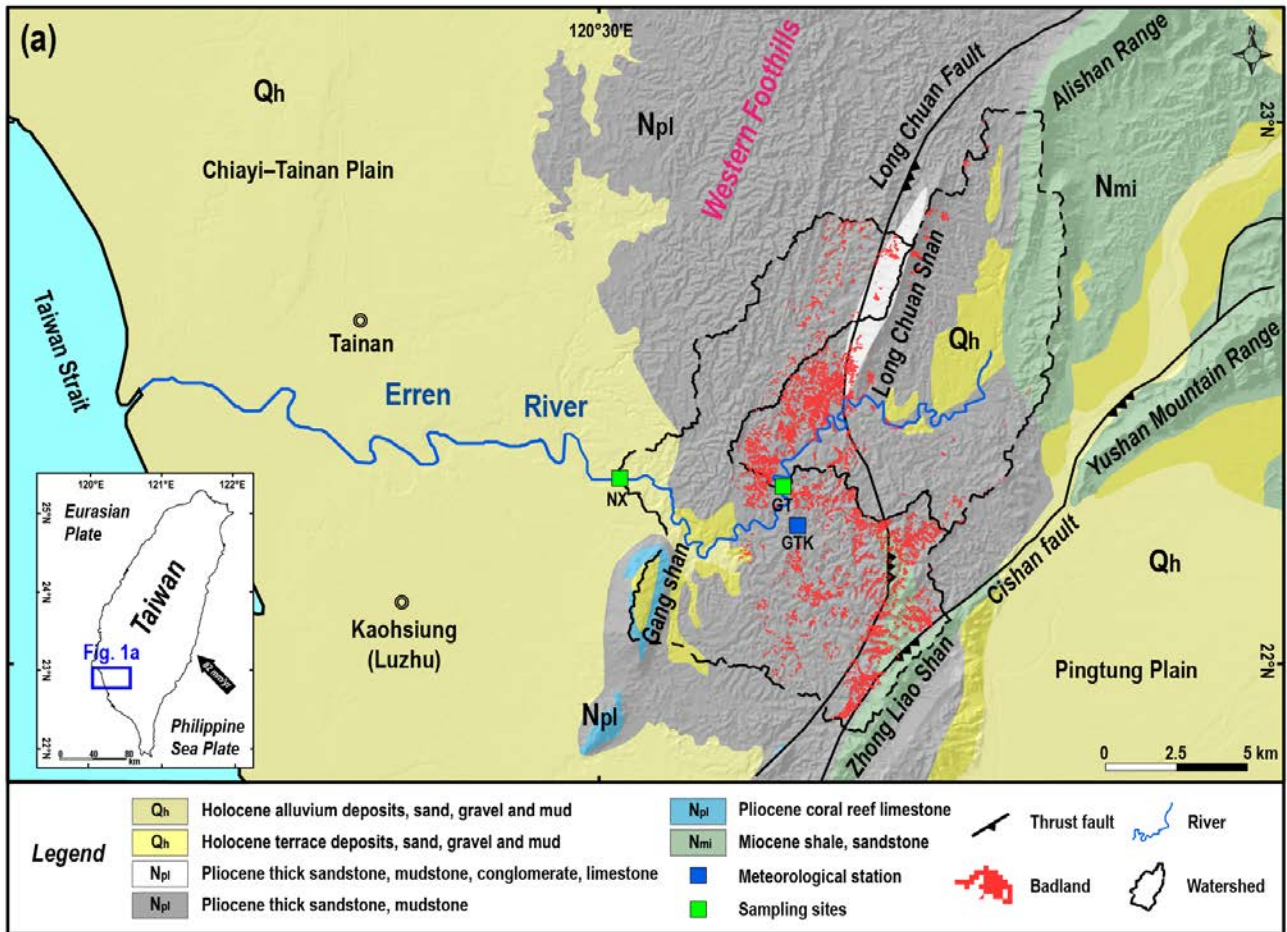

## 72 **2. Geological and Meteorological Setting**

73 In Taiwan's badlands, the annual precipitation is about 2 m, and 90% of the rainfall is concentrated in  
74 the rainy season. The rainy season lasts from May to October and reaches its peak in August, with over  
75 400 mm of precipitation within a single month. In contrast, less than 40 mm of average monthly rainfall  
76 is measured from November to April. We collected river water samples from two sites downstream of  
77 the studied badland areas. The first site, Nanxiong Bridge (NX), is located at the midstream of the  
78 Erren River and has a drainage area of 175 km<sup>2</sup>. This area includes badlands covering an area of 4.37  
79 km<sup>2</sup>, which accounts for 2.49% of the total catchment area (Fig.1). The Erren River catchment is  
80 predominantly underlain by Plio-Pleistocene mudstones, which are several kilometers thick, and  
81 mainly feature illite (30.54%) and chlorite (28.70%) minerals (Tsai, 1984a). During the dry seasons,  
82 the pore water chemistry in the near-surface mudstones is mainly composed of Na<sup>+</sup>, Cl<sup>-</sup>, Ca<sup>2+</sup> and SO<sub>4</sub><sup>2-</sup>  
83 (Nakata and Chigira, 2009).

84

85 The gauging station at Nanxiong Bridge (NX) provides hourly discharge data for calculating sediment  
86 and solute fluxes. The annual average discharge of Nanxiong Bridge station is 10.2 m<sup>3</sup>/s, and the  
87 typhoon season accounts for 84% of the total discharge. The meteorological station at Gutingkeng  
88 (GTK) is located 5.5 km from Nanxiong Bridge and provides hourly precipitation data. Our second  
89 sampling site is Guting (GT) Bridge, with an upstream drainage area of 79 km<sup>2</sup> and a badlands area of  
90 1.87 km<sup>2</sup>, corresponding to 2.37% of the total area. Guting Bridge is located adjacent to a badlands  
91 conservation area, so the riverine water chemistry reflects the weathering products derived from the  
92 adjacent hillslopes. Due to a lack of stream discharge observations at Guting Bridge, we use hourly  
93 precipitation data at GTK, which is less than 1 km from the sampling site, to quantify the impact of  
94 the typhoon events.

95

96  
 97 **Figure 1.** Location of sampling sites and geology of the study area. (a) The geological map of the  
 98 study area (Source: Central Geological Survey, 2013). The green squares are sampling sites; hourly  
 99 stream discharge data were obtained from the Nanxiong Bridge (NX) hydrometric station (Water  
 100 Resources Agency). The blue square is the meteorological station, which provides hourly precipitation  
 101 data (Central Weather Bureau, <https://dbar.pccu.edu.tw/>).  
 102

103 **3. Methods and Materials**

104 **3.1 Water Sampling**

105 We collected 42 stream samples from the two sampling sites for the typhoon period of July 2017.  
 106 During sample collection, two 1000 ml PE bottles were dropped 1 to 2 meters below the water surface  
 107 of the river simultaneously. Suspended sediment concentration (SSC) was subsequently calculated  
 108 from the water collected in one of the PE bottles, and riverine chemistry was determined from water  
 109 collected in the other bottle. Samples were filtered *in situ*, and the filtrate was preserved in the  
 110 refrigerator for laboratory analysis. Additionally, 31 samples were collected from September 2014 to

111 December 2016 in the second half of every month at Nanxiong Bridge for non-typhoon periods, using  
112 the same sampling procedure.

113

### 114 3.2 Dissolved load and sediment chemistry analysis

115 For the riverine dissolved load, we measured major dissolved anions ( $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_2^-$ ,  $\text{NO}_3^-$ ,  $\text{F}^-$ ) on an  
116 Ion chromatography (IC, Metrohm Basic-883 plus), and we measured major dissolved cations ( $\text{Na}^+$ ,  
117  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Sr}^{2+}$ ,  $\text{Ba}^{2+}$ ,  $\text{Si}^{4+}$ ) on an ICP-OES (PerkinElmer, Optima 2100DV). We measured bulk  
118 sediment chemistry from two samples of suspended sediment collected from Guting Bridge at low  
119 flow before the typhoon event ( $2.26 \text{ m}^3/\text{s}$ ) and at the peak of runoff ( $724.32 \text{ m}^3/\text{s}$ ). About 0.7 g of dried  
120 sediment sample was combusted in the muffle furnace at  $650^\circ\text{C}$  for 2 hours and then weighed to obtain  
121 the loss on ignition (LOI). Afterward, an aliquot of  $\sim 100 \text{ mg}$  from the residue was digested with a  
122 mixture of concentrated HF and aqua regia. After digestion and drying, the sample was dissolved in  
123 0.3 N  $\text{HNO}_3$  for elemental determination. Major elemental concentrations of sediment samples were  
124 obtained by ICP-OES (Varian 720-ES) at the GFZ German Research Centre for Geosciences.

125

### 126 3.3 Grain size of suspended load

127 Before measuring grain size, we removed the non-clastic deposition, i.e., sea salt, organic matter, and  
128 carbonate. To remove sea salt,  $\sim 1 \text{ g}$  of dried sediment sample was added to 15 ml of distilled water,  
129 placed in a shaker, and shaken at a speed of 4000 rpm for 5 minutes. The centrifuged supernatant was  
130 then poured out and these steps were repeated 3 times. To remove organic matter, 10 ml of a 15%  
131  $\text{H}_2\text{O}_2$  solution was added to the sediment and placed in an ultrasonic oscillator for 24 hours. After  
132 adding a second 10 ml of  $\text{H}_2\text{O}_2$  (15%) to confirm the completion of the reaction, the mixture was  
133 centrifuged and the supernatant containing the organic matter was removed. The sediment was then  
134 washed by adding 30 ml of distilled water, and the supernatant was again removed after centrifugation.  
135 This washing step was repeated 3 times to remove residual  $\text{H}_2\text{O}_2$  in the centrifuge tube. To remove the

136 carbonates, we added 10 ml of 10% HCl solution to the centrifuge tube and allowed the acid to react  
137 with the sediments for 24 hours. An additional 10 ml of HCl was then added to confirm the  
138 completeness of the reaction. The sample was then centrifuged, and the supernatant was decanted to  
139 remove the carbonates. The sample was then rinsed with 30 ml of distilled water, centrifuged, and  
140 decanted. This step was performed 3 times to remove any residual HCl.

141

142 To disperse sediment agglomeration, we added 10 ml of 1%  $\text{Na}(\text{PO}_3)_6$  solution to the sediment and let  
143 the sample react for more than half a day. The grain size of the sediment samples was obtained by  
144 Laser Diffraction Particle Size Analyzer LA950 at the GFZ German Research Centre for Geosciences.  
145 By using LA950, we measured grains in the size range of between 100 nm to about 3 cm.

146

#### 147 3.4 Calculation of the enriched ratio and sodium adsorption ratio (SAR)

148 In order to classify the supply of different ion sources during the typhoon event, we used the enriched  
149 ratio of concentration as a reference. The enriched ratio is the ion concentration at a certain time  
150 divided by the ion concentration at the first observation. A value greater than 1 represents a point in  
151 time when the sample is more concentrated relative to the first observation, whereas a value smaller  
152 than 1 represents a point in time when the sample is more diluted relative to the first observation. The  
153 first observation was sampled 6 hours before the typhoon which represents the background value of  
154 river water chemistry in this study.

155

156 Dissolved calcium and magnesium can stabilize soil aggregates and therefore enhance water  
157 permeability (Nadler et al., 1996). By contrast, excess sodium can disperse soil particles through  
158 deflocculation, thereby reducing water permeability (Hanson et al., 1999). The potential for material  
159 dispersion in badlands is generally determined by measuring the presence and behavior of sodium and  
160 is quantified by the sodium absorption ratio (SAR), (1):

161 
$$SAR = \frac{Na^+}{\sqrt{\left(\frac{Ca^{2+}+Mg^{2+}}{2}\right)}} \quad (1)$$

162 Here, the cation measurements are expressed in milliequivalents per liter (meq/L). For pore water,  
 163 when SAR is greater than 13, the excess sodium causes soil particles to repel each other, preventing  
 164 the formation of soil aggregates (Seelig, 2000; Horneck et al., 2007). Given the influence of soil  
 165 structure, SAR value for irrigation water smaller than 3 is low, from 3 to 9 is medium and above 9 is  
 166 high (Ayers and Westcot, 1985).

167

### 168 3.5 Calculation of TDS and chemical weathering rate

169 Riverine TDS is widely used to estimate chemical weathering rates of river catchments (e.g. Gaillardet  
 170 et al. 1999). In this study, riverine TDS (in units of  $\mu\text{mol/L}$ ) is expressed as:

171 
$$TDS = TDS_{rain} + TDS_{evaporite} + TDS_{sil} + TDS_{carb} \quad (2)$$

172 where the contributions from precipitation ( $TDS_{rain}$ ), evaporite ( $TDS_{evaporite}$ ), silicate weathering  
 173 ( $TDS_{sil}$ ) and carbonate weathering ( $TDS_{carb}$ ) are considered. We calculated the proportions of ion  
 174 contributions from rainwater, evaporite, silicate and carbonate for Ca, Mg, Na, Cl, and  $SO_4$  with the  
 175 MEANDIR inversion model (Kemeny and Torres, 2021), a MATLAB script for inverting fractional  
 176 contributions of end-members, and for constraining the chemical compositions of those end-members  
 177 with Monte Carlo propagation of uncertainty. To exclude the input of precipitation ( $TDS_{rain}$ ) from  
 178 riverine TDS, we used local rainwater  $Cl^-$  concentrations with an average value of  $68 \mu\text{mol/L}$  (Lu,  
 179 2014), and also the ratios of  $SO_4/Cl$ ,  $Na/Cl$ ,  $K/Cl$ ,  $Mg/Cl$ ,  $Ca/Cl$  in rainfall based on the rainfall  
 180 chemistry from 2007 to 2013 reported by Lu (2014) (Table 1).

181 
$$[X]_{norain} = [X]_{river} - [X]_{rain} \quad (3)$$

182 
$$TDS_{rain} = \sum [X]_{rain} \quad (4)$$

183 Here  $[X]_{norain}$  reflects the remaining concentration of ion X after the removal of atmospheric inputs;

184  $[X]_{river}$  is the concentration of ion X in river water, and  $[X]_{rain}$  is the concentration of ion X from

185 atmospheric deposition. In the second step, we corrected for evaporite inputs ( $TDS_{\text{evaporite}}$ ) using the  
 186 following equation:

$$187 \quad [X]_{\text{NSS}} = [X]_{\text{norain}} - [X]_{\text{evap}} = [X]_{\text{norain}} - \left( [Cl]_{\text{norain}} \times \left( \frac{X}{Cl} \right)_{\text{evap}} \right) \quad (5)$$

$$188 \quad TDS_{\text{evaporite}} = \sum [X]_{\text{evap}} \quad (6)$$

189 where  $[X]_{\text{NSS}}$  is the concentration of ion X after the removal of ions attributed to evaporites,  $[X]_{\text{evap}}$ .  
 190  $[X/Cl]_{\text{evap}}$  is the ratio of ion X and Cl by using the end-member molar ratios of evaporite reported by  
 191 Burke et al. (2018), of which K/Cl is referred to Chao et al., (2011) (Table 1)). Then, after the correction  
 192 for evaporite, the chemical weathering budget can be divided into contributions by silicate ( $TDS_{\text{sil}}$ )  
 193 and carbonate weathering ( $TDS_{\text{carb}}$ ), expressed as:

$$194 \quad TDS_{\text{sil}} = [Na]_{\text{sil}} + [K]_{\text{sil}} + [Mg]_{\text{sil}} + [Ca]_{\text{sil}} + [SiO_2]_{\text{sil}} \quad (7)$$

$$195 \quad TDS_{\text{carb}} = [Mg]_{\text{carb}} + [Ca]_{\text{carb}} + [HCO_3]_{\text{carb}} \quad (8)$$

$$196 \quad [HCO_3]_{\text{carb}} = \frac{1}{2} ([Mg]_{\text{carb}} + [Ca]_{\text{carb}}) \quad (9)$$

197 where  $[Na]_{\text{sil}}$  and  $[K]_{\text{sil}}$  are riverine  $[Na]_{\text{NSS}}$  and  $[K]_{\text{NSS}}$  concentrations, respectively. We used  
 198 endmember values for silicate- and carbonate-dominated rocks reported by Gaillardet et al. (1999)  
 199 (Table 1). We agree that the use of global endmembers leads to a larger range of estimations, but is  
 200 still appropriate in discussing trends in weathering rates.

201 Considering the hydrological response, we use flow weighted method to calculate the flux of solute  
 202 (Huang et al., 2012), expressed as:

$$203 \quad Flux_{(\text{rain, evap, sil, carb})} = \frac{\left( m \times \frac{\sum_{i=1}^n TDS_{(\text{rain, evap, sil, carb})i}}{\sum_{i=1}^n Q_i} \times Q_t \right)}{\text{catchment area}} \quad (10)$$

204 where m is the conversion factor for a specific unit (ton/km<sup>2</sup>/yr).  $Q_i$  is the hourly discharge  
 205 corresponding to sampling time.  $Q_t$  is total discharge during the year or during the typhoon.

206

207 **Table 1** Input end-members for the mixing model.

End-member	SO <sub>4</sub> /Cl	Na/ Cl	K/ Cl	Mg/Cl	Ca/Cl
Precipitation	0.35	0.90	0.09	0.18	0.35
Evaporites	0.6±0.6	1.0±0	0.026	0.1±0.08	0.5±0.5
	Ca/Na	Mg/Na			
Silicates	0.35±0.25	0.24±0.2			
Carbonates	60±30	30±15			

208

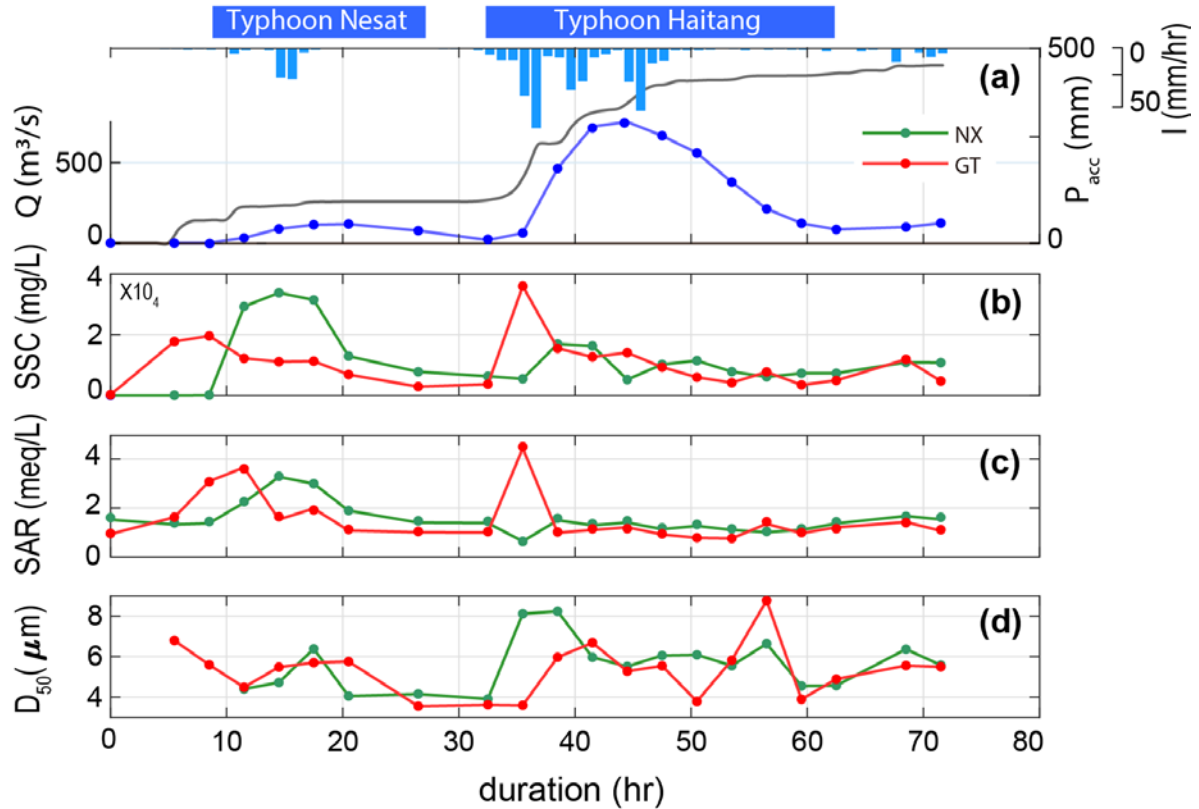

209 **4. Results**210 **4.1 Geochemistry of river water and suspended sediment**

211 In 2017, the Nesat and Haitang typhoons brought 579 mm of rainfall over three days, with a maximum  
 212 intensity of 74 mm/hr. The discharge at Nanxiong Bridge demonstrated that the climatic co-response  
 213 has two pulses (Fig. 2). Since the time interval between the two typhoons was less than 6 hours, we  
 214 define the two typhoons as one typhoon event and distinguish between a first and second discharge  
 215 pulse. We quantify time relative to the onset of the typhoon (0 hr). The first pulse occurred from 8.5 to  
 216 32.5 hr, with a mean water discharge of 66.2 m<sup>3</sup>/s. The second pulse that occurred from 32.5 to 62.5  
 217 hr had a 5.5 times higher mean discharge of 369.2 m<sup>3</sup>/s. The maximum discharge (753.2 m<sup>3</sup>/s) was  
 218 observed during the second pulse at 44.5 hr (July 31st, 2017, at 6:00 a.m.) (Fig. 2).

219

220 At Nanxiong Bridge, SSC has a statistically significant positive correlation with SAR ( $\rho = 0.51$ ,  $p <$   
 221  $0.05$ ). SSC has two peaks, one during each pulse, but SAR only shows a peak during the first pulse.  
 222 During the first pulse, SSC ranged from 10 to 33757 mg/L and SAR increased from 1.44 and to 3.14.  
 223 During the second pulse, SSC increased from 5445 to 16900 mg/L and SAR remained about 1.44.  
 224 The median grain size ( $D_{50}$ ) ranged from 3.9 to 8.2  $\mu\text{m}$ , with an average value of 5.6  $\mu\text{m}$  during the  
 225 second pulse, and exhibited a positive correlation with discharge ( $\rho = 0.40$ ). At Guting Bridge, SSC  
 226 has a statistically significant positive correlation with SAR ( $\rho = 0.69$ ,  $p < 0.05$ ) during the survey. SSC  
 227 ranged from 164 to 19538 mg/L before the first pulse and ranged from 2857 to 35920 mg/L during the  
 228 second pulse, while SAR showed a mean of 1.46 and two peaks with a value over 4 during both pulses.

229  $D_{50}$  ranged from 3.6 to 8.8  $\mu\text{m}$ , with an average value of 5.3  $\mu\text{m}$  during the second pulse, (Fig. 2). In  
 230 terms of sediment chemistry at Guting Bridge, major elements of the two selected sediment samples  
 231 show that calcium and sodium accounted for about 10% of the mass loss between the typhoon event  
 232 (5.5 hr of duration) and the peak of discharge (41.5 hr of duration) (Table. S4).

233  
 234 **Figure 2.** Timeseries SSC, SAR and median grain size of suspended sediment ( $D_{50}$ ) at two sampling  
 235 sites. The blue line denotes hourly discharge ( $Q$ ) at Nanxiong Bridge, and the blue bar denotes hourly  
 236 precipitation ( $I$ ) at Gutingkeng station. The gray line denotes precipitation accumulation ( $P_{\text{acc}}$ ), the  
 237 green line denotes the Nanxiong Bridge (NX) dataset, and the red line denotes the Guting Bridge (GT)  
 238 dataset.

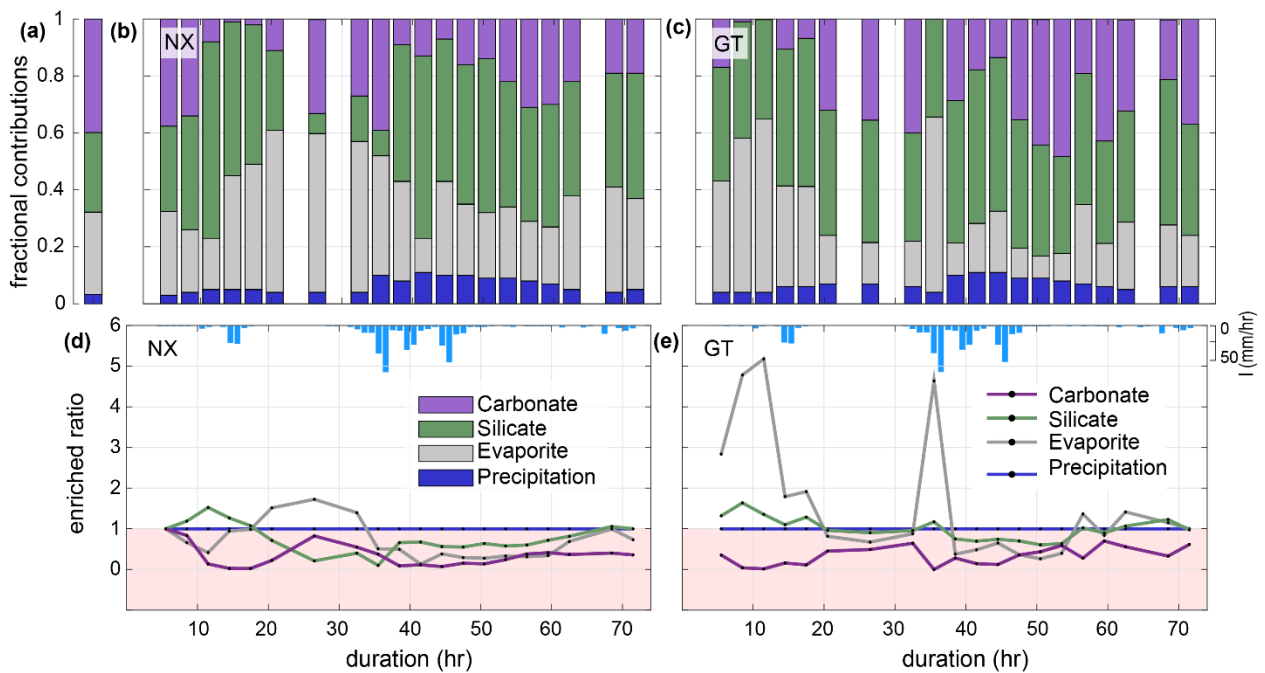

239  
 240 The fractional proportions of TDS at Nanxiong Bridge during baseflow show that precipitation,  
 241 evaporites, silicates, and carbonates contribute  $3.0 \pm 1.1\%$  (uncertainty gives the standard error of the  
 242 mean),  $28.7 \pm 14.6\%$ ,  $26.9 \pm 6.5\%$ , and  $41.4 \pm 13.2\%$ , respectively (Fig. 3a). During the typhoon event,  
 243 the proportion of TDS at Nanxiong Bridge attributed to  $\text{TDS}_{\text{rain}}$  is  $6.3 \pm 2.4\%$ .  $\text{TDS}_{\text{evaporite}}$  contributes  
 244  $32.4 \pm 13.6\%$  and increases from 27.4% to 61.1% at the incipient first pulse.  $\text{TDS}_{\text{sil}}$  contributes  
 245  $39.5 \pm 15.2\%$ , which is 12.6% higher than the non-typhoon period.  $\text{TDS}_{\text{carb}}$  contributes  $21.8 \pm 11.5\%$

246 (Fig. 3b), which is 19.6% lower than the non-typhoon period. The fractional proportions of TDS at the  
247 Guting Bridge show that  $6.5\pm 2.1\%$  of TDS is contributed by  $TDS_{rain}$ .  $TDS_{evaporite}$  contributes  
248  $24.8\pm 16.2\%$  and increases from 13.6% to 61.6% at the incipient second pulse, when the SSC and SAR  
249 peak simultaneously.  $TDS_{sil}$  and  $TDS_{carb}$  contribute  $39.5\pm 15.2\%$  and  $27.5\pm 16.7\%$ , respectively (Fig.  
250 3c).

251

252 Enriched ratios of less than one indicate dilution, and values greater than one indicate concentration.  
253 Since we set the ion concentration of rainfall to be constant during the typhoon event, the enriched  
254 ratio of precipitation is constant throughout the observation period. At Nanxiong Bridge, the evaporites  
255 enriched ratio increases from 0.4 to 1.7 between the two pulses and decreases to 0.1 at the discharge  
256 peak. The silicates enriched ratio increases from 1 to 1.5 before the first pulse and decreases to 0.1 at  
257 the peak of discharge, then returns to 1 before the observation ends. The concentration attributed to  
258 carbonates is always diluted. The evaporites and carbonates enriched ratio has a statistically significant  
259 negative correlation with discharge (evaporites:  $\rho = -0.67$ , carbonates:  $-0.60$ ,  $p < 0.05$ ) and the silicate  
260 enriched ratio has a negative correlation with discharge ( $\rho = -0.32$ ), indicating dilution by typhoon  
261 rainfall (Fig. 3d). At Guting Bridge, the evaporites enriched ratio has two peaks during the two pulses  
262 with a value of 5.2 at the first peak, a value of 4.7 at the second peak. After the event, the value returns  
263 to about 1.2. Notably, the evaporites enriched ratios during both pulses are similar, but the peak  
264 discharge of the second pulse is 5.5 times higher than that of the first pulse. The silicate enriched ratio  
265 has an analogous pattern with the evaporites enriched ratio, but the enriched ratio is smaller. Similar  
266 to Nanxiong Bridge, the carbonates enriched ratio is always diluted at Guting Bridge (Fig. 3e). The  
267 evaporite and silicate enriched ratio shows a statistically significant positive correlation ( $\rho = 0.96$ ,  
268  $p < 0.05$ ), and the evaporite and silicate enriched ratios have a statistically significant positive  
269 correlation with SAR ( $\rho = 0.86$ ,  $\rho = 0.84$ ,  $p < 0.05$ ). We also use the concentration–discharge (cQ)  
270 relationship of each ion at rising and recession limb, as well as baseflow at Nanxiong Bridge to assess  
271 the state of dilution behavior (Fig. S2). Overall, our results show that all ions are in a dilution, and the

272 dilution in recession limb is stronger than that in rising limb, except for SO<sub>4</sub> during baseflow ( $\theta=0.07$ ).  
273 The concentration of Na, Cl and K during baseflow have a higher variability than the values during  
274 the event. Additionally, Na, Cl, and SO<sub>4</sub> increase the concentration with increasing flow at the certain  
275 period of rising limb.

277

278 **Figure 3.** Timeseries illustrating TDS sources during the typhoon event at the two sampling sites.  
 279 Fig.3a shows the average proportion of TDS for the non-typhoon period from September 2014 to  
 280 December 2016 at Nanxiong Bridge; Fig.3b-c denotes the endmember contributions to TDS at  
 281 Nanxiong Bridge dataset and Guting Bridge dataset from the typhoon period; the purple bar denotes  
 282  $TDS_{carb}$  (Eq. 8); green denotes  $TDS_{sil}$  (Eq. 7); the gray bar denotes  $TDS_{evaporite}$  (Eq. 6); the blue bar  
 283 denotes  $TDS_{rain}$  (Eq. 4). Fig.3d-e denotes the enriched ratio of ion concentrations by TDS sources from  
 284 the Nanxiong Bridge dataset and Guting Bridge dataset during the typhoon period. The purple line  
 285 denotes  $TDS_{carb}$ , the green line denotes  $TDS_{sil}$ , the gray line denotes  $TDS_{evaporite}$ , the blue line denotes  
 286 the  $TDS_{rain}$ , and blue bar denotes hourly precipitation (I) at GTK station.

## 287 **4.2 Evaporite, silicate and carbonate dissolution over time**

288 We calculated the enriched ratios of ions (i.e.,  $\text{Na}^+$ ,  $\text{Cl}^-$ ,  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$ ) that are sourced from evaporites  
289 (i.e., halite ( $\text{NaCl}$ ) and gypsum ( $\text{CaSO}_4$ )). The variability in the concentrations of each of these ions  
290 reflects the overall trends in TDS (Fig. 3d-e & Fig. 4).

291

292 At Nanxiong Bridge, all evaporite and carbonate ions have a statistically significant negative  
293 correlation with discharge. The enriched ratios in evaporite  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$  have the same trend (Fig.  
294 4), which show an initial decrease during the first pulse, followed by an increase to 2 between the two  
295 pulses, and a final decrease during the second pulse. Evaporite  $\text{Ca}^{2+}$  shows a similar trend with  
296 evaporite  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2-}$ , but the values are below 1. The enriched ratios of silicate  $\text{Na}^+$ ,  $\text{Ca}^{2+}$  show  
297 an increase during the first pulse and a decrease to less than 1 before the rainfall peak, followed by an  
298 increase from about 0.06 to 1.11 at the end of observation. At Guting Bridge, all evaporite ions have a  
299 statistically significant positive correlation with the corresponding silicate ions ( $\text{Na}^+$ ,  $\rho = 0.98$ ;  $\text{Ca}^+$ ,  $\rho$   
300  $= 0.81$ ,  $p < 0.05$ ). Evaporite  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{SO}_4^{2-}$  each have two peaks that occur prior to the maximum  
301 rainfall and reflect a factor of 5 increase in the enriched ratio. Compared with Nanxiong Bridge  
302 (downstream), the enriched ratio in evaporite  $\text{Ca}^{2+}$  at Guting Bridge concentrates at the onset of the  
303 first pulse and after peak discharge. Additionally, the enriched ratios of carbonate at Guting Bridge are  
304 similar to Nanxiong Bridge, and are always below 1.

305

306 **Figure 4.** Time-series patterns in enriched ratio at two sampling sites. NX denotes the Nanxiong Bridge  
 307 dataset and GT denotes Guting Bridge dataset. The pink area indicates enriched values below 1. Blue  
 308 bar denotes hourly precipitation ( $I$ ) at Gutingkeng station.

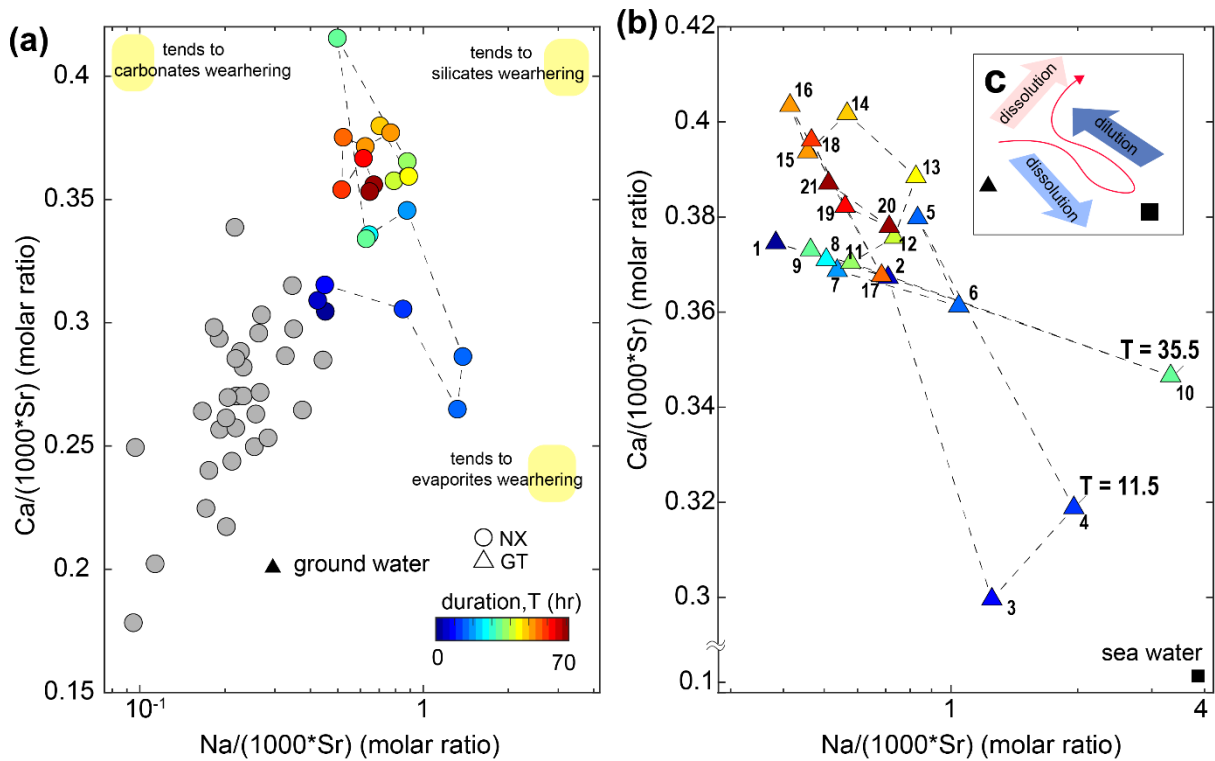

309

310 Gaillardet et al. (1999) documented that dissolved ions ratios of  $\text{Ca}/\text{Sr}$  and  $\text{Na}/\text{Sr}$  are distinct for  
 311 carbonates (low  $\text{Na}/\text{Sr}$ , high  $\text{Ca}/\text{Na}$ ) versus silicates or evaporites (high  $\text{Na}/\text{Sr}$ , low  $\text{Ca}/\text{Na}$ ). We use  
 312 these ratios to elucidate potential mixing between carbonates, silicates, and evaporite endmembers (Fig.  
 313 5). At Nanxiong Bridge, non-typhoon ratios of  $\text{Na}/(1000 \cdot \text{Sr})$  and  $\text{Ca}/(1000 \cdot \text{Sr})$  are 0.23–0.68 and  
 314 0.19–0.35, respectively (Table S4). These values increase markedly during the typhoon events, with  
 315 enriched– ratios of  $\text{Na}^+$  exceeding 5 at  $T = 11.5$  and  $35.5$  hr. The high concentration of  $\text{Na}^+$ ,  $\text{Cl}^-$  and  
 316  $\text{SO}_4^{2-}$  (as illustrated in the enriched ratio) indicate that there is enhanced dissolution of evaporites at  
 317 the onset of the typhoon event, especially at Guting Bridge. Subsequently, the concentration of  $\text{Na}^+$

318 decreased with sustained rainfall. Then, the ratios approach the silicates/carbonates weathering (high  
 319 Na/Sr, high Ca/Sr ratios ) after the peak discharge.

320

321

322 **Figure 5.** Molar ratio mixing diagrams of Erren River waters for (a-b) Na/(1000\*Sr) versus  
 323 Ca/(1000\*Sr), circles denote dataset at Nanxiong Bridge, and triangles denote dataset at Guting Bridge.  
 324 Colorbar denotes survey duration. Gray circles denote the dataset at Nanxiong Bridge during baseflow  
 325 conditions from 2014 to 2016. The black triangle illustrates the groundwater endmember (Chao et al.,  
 326 2011); the black square illustrates the seawater endmember. Numbers in the triangle represent the time  
 327 sequence, 1 represents the start point, and 21 represents the end point. Yellow areas indicate trends in  
 328 weathering types rather than the locations of endmember. (c) Illustration of dynamic weathering. The  
 329 red line indicates the direction of change with time. The light blue arrow denotes dissolution of  
 330 evaporite, the dark blue arrow denotes dilution from rainfall, and the red arrow denotes dissolution of  
 331 suspended sediment.

332

## 333 5. Discussion

### 334 5.1 Relationships between dissolved evaporite and river water chemistry

335 Before the survey, the monthly rainfall of the study area was 72.5 mm, which is only 18% of the

336 average monthly rainfall, implying that it provides a relatively dry environment for accumulating  
337 evaporites on the slope surface. Under maximum rainfall intensity,  $\text{Na}^+$ ,  $\text{Cl}^-$  and  $\text{SO}_4^{2+}$  at Guting Bridge  
338 show markedly increased concentrations at the onset of the typhoon, peaks in enriched ratios that  
339 exceed 5 (Fig. 4), and the greatest contribution of dissolved ions from evaporites (Fig. 3). Calculated  
340 with pore water chemistry during the dry season from the same study site, the sodium absorptions ratio  
341 (SAR) is 240.8 and exceeds the threshold value of 13. During the typhoon event, the river water SAR  
342 has a maximum value of 4.41 at Guting Bridge (3.14 at Nanxiong Bridge), suggesting soil  
343 deflocculation within river is weaker than on the hillslopes. However, the SAR has a statistically  
344 significant positive correlation with  $\text{TDS}_{\text{evaporite}}$  ( $\rho = 0.86$ ,  $p < 0.05$ ) at Guteng Bridge (upstream). This  
345 pattern indicates that excess sodium is effective at inducing material dispersion at hillslopes and thus,  
346 contributing to a higher suspended sediment load. The trend of river water SAR is able to reflect the  
347 extent of dissolved  $\text{Na}^+$  from hillslope. (Fig. 2).

348

349 These observations and results suggest that rainwater in the typhoon event rapidly dissolves the  
350 evaporites on the slope surface, which produces high measured concentrations of  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{SO}_4^{2+}$   
351 during the time of peak precipitation (30-40 hr of duration). Furthermore, the dissolution of the near-  
352 surface evaporite deposits should be most heavily influenced by runoff from the hillslopes, so we  
353 expect that excess sodium and enhanced erosion will be most significant on the hillslopes.

354

355 At Nanxiong Bridge, we observe a 10-hour delay in the peak enriched ratio relative to the SAR (Fig.  
356 3d) and overall lower enriched ratios relative to Guteng Bridge (Fig. 3d-e). We suggest that dilution  
357 and the transport distance from the badlands are responsible for this. The two catchments have a similar  
358 areal extent of badlands within the total catchment area, which is about 2.49% at Nanxiong Bridge  
359 catchment and 2.37 % in Guting Bridge catchment. Badlands contribute considerable evaporite solutes  
360 (Chou, 2008), but the higher downstream drainage area will result in dilution of the solutes without  
361 additional inputs. Additionally, Nakata and Chigira (2009) have observed that salt dissolution induces

362 an increase in electrical conductivity during intermittent rainfall events and decreases gradually after  
363 rainfall events when evaporation and salt precipitate. Therefore, re-crystallization during the  
364 transportation is to be expected.

365

## 366 **5.2 From evaporite dissolution to silicate weathering**

367 Our observations show that silicate weathering during the typhoon event contributes 16.8 ton/km<sup>2</sup>/yr,  
368 corresponding to 16.6% of the annual silicate weathering flux (Table S3). Additionally, we observed a  
369 change in dominant chemical weathering mechanism during the typhoon event. We rule out significant  
370 contributions from groundwater and deep seawater after peak discharge, since ratios shift to higher  
371 Na/Sr, and Ca/Sr ratios relative to the non-typhoon ratio (Fig. 5a–b), and the Ca/Sr ratio of mud  
372 volcanoes in the study site is one order of magnitude less than river water (Chao et al., 2011). Carbonate  
373 weathering is the primary contributor of Ca<sup>2+</sup> for most of the world's large rivers (Gaillardet et al.  
374 1999), but the increased Na<sup>+</sup> and consistently enriched ratio of carbonate Ca<sup>2+</sup> does not make this a  
375 likely main contributor to the Erren River during the typhoon. We thus suggest that the primary  
376 contributor to weathering is enhanced silicate dissolution. This interpretation is supported by the  
377 temporal evolution of the enriched ratio of silicate Ca<sup>2+</sup>, which gradually increases after the discharge  
378 peak, to approach a value of about 1 at the end of survey (Fig. 4e&f). As such, in the waning of the  
379 event, excess Ca<sup>2+</sup> originates from a silicate source. Therefore, we suggest that the ratios shift to higher  
380 Na/Sr, Ca/Sr ratios due to enhanced silicate weathering during the typhoon. We also observe that the  
381 masses of Na and Ca are reduced by 10.6% and 9.9%, respectively, in the suspended sediment during  
382 the course of the typhoon event (Table S6).

383

384 Given that the sediment transported in the channel is supplied by physical erosion, we suggest that  
385 physical erosion in our study site enhances silicate chemical weathering, which is consistent with  
386 previous studies (Chung, 2002; Chou, 2008). Moreover, we associate the change in weathering regime

387 during the course of the typhoon with abrasive erosion of silicate sediments in the channel. Mechano-  
388 chemical dissolution of weakly bound ions, e.g.,  $F^-$  from the fresh muscovite surfaces is driven by  
389 abrasion under high energy sediment transport with reorganization of the river bed (Andermann et al.,  
390 2022). Mudstones are mainly composed of silicate minerals (e.g., illite and chlorite minerals) (Tsai,  
391 1984a), and a few swelling clay minerals (e.g., montmorillonite), which provide an abundant silicate  
392 pool. We suggest that high suspended sediment concentrations, combined with high energy flow during  
393 the typhoon, caused increased silicate input from the weathered silicates in the suspended sediment.  
394 This trend can explain about 10% of the reduced mass and it has also been observed in typhoon-driven  
395 silicate chemical weathering from silicate minerals at surface (Meyer et al., 2017). Importantly, the  
396 global annual silicate weathering flux of rivers is 15.7 ton/km<sup>2</sup>/yr (Gaillardet et al. 1999), relative to  
397 our value of 16.8 ton/km<sup>2</sup>/yr., suggesting that individual stochastic events may have global relevance.

### 398 399 **5.3 Typhoon-controlled cycles of physical and chemical erosion**

400 Evaporites, including halite (NaCl) and gypsum (CaSO<sub>4</sub>), are found in few sedimentary environments,  
401 and they are often excluded from the estimation of CO<sub>2</sub> consumption (Gaillardet et al., 1999).  
402 Compared to silicate rocks, the relation between evaporites weathering and physical erosion has rarely  
403 been discussed. Through the interactions among riverine chemistry, suspended sediment properties,  
404 and previous soil water chemistry studies, we suggest a positive feedback cycle of physical-chemical  
405 erosion driven by mobile dissolved evaporite (Fig. 5). The feedback cycle includes three steps. (1)  
406 precipitation and deposition of evaporite during the dry season in near-surface mudstone desiccation  
407 cracks through capillary transport (Higuchi et al., 2013, 2015; Nakata and Chigira, 2009). In the dry  
408 season, exposed bedrock with low water content develops desiccation cracks (Allen, 1982; Goehring  
409 et al., 2010; Kindle, 1917; Seghir and Arscott, 2015; Xiaa and Hutchinson, 2000), providing space for  
410 the re-precipitation of evaporite minerals. Using evidence from core samples in mudstone bedrock at  
411 the study site, the depth of the crack of about 20 cm can be regarded as the thickness of the weathering  
412 layer. Higuchi et al. (2013) suggested that the weathering layer in the top 10 cm of mudstone can easily

413 be eroded by intense rainfall. Erosion exposes fresh bedrock, which would dry in the following dry  
414 season and further produce weatherable material.

415

416 (2) Rainfall dissolves the evaporites, producing sodic water that increases physical erosion during  
417 typhoon events. The resulting dissolved sodium causes higher hillslope erosion by deflocculation,  
418 leading to increased suspended sediment in the channels. In the study site, hillslope erosion rate is  
419 about 9-30 cm/year (Higuchi et al., 2013; Yang et al., 2021a). At Nanxiong Bridge, the denudation rate  
420 approaches about 142,857 ton/km<sup>2</sup>/yr, measured from river suspended load (Dadson et. al., 2003), and  
421 the chemical weathering flux is 124-237 ton/km<sup>2</sup>/yr (Chou, 2008; this study). The high hillslope  
422 erosion rate ensures a steady supply of freshly exposed bedrock, allowing for high chemical weathering  
423 rates.

424

425 (3) Physical erosion enhances silicate weathering and bedrock exposure on hillslopes. Clay minerals  
426 in mudstone deposits are abraded from the abundantly available sediment and provide material for  
427 silicate weathering in streams. Ultimately, with frequent typhoon events and high temperatures in the  
428 study area, this dynamic cycle could repeat several times a year.

429

430 **Figure. 6.** Cycle of feedback between physical erosion rate (PER) and solute flux in badlands  
 431 catchment. Red blocks represent dry season conditions. Blue region represents typhoon conditions.  
 432 Brown region represents the bedrock and indicates the type and proportion of minerals of mudstone  
 433 (Tsai, 1984b).

434

435 6. Conclusion

436 We presented major element compositions of stream water from two sites in the Erren River catchment  
 437 at three-hour intervals during a three-day typhoon event in 2017. At Guteng Station (upstream),  
 438  $TDS_{\text{evaporite}}$  is covariant with  $TDS_{\text{sil}}$ , the sodium adsorption ratio, and the suspended sediment  
 439 concentration, which can be assigned to dissolved evaporite (e.g., halite and gypsum). The excess  
 440 sodium in the evaporite deposits causes material dispersion through deflocculation, which enhances  
 441 the suspended sediment flux. Our observations show that the water chemistry of the typhoon event is  
 442 mainly contributed by silicate weathering at  $16.8 \text{ ton/km}^2/\text{yr}$  and evaporite weathering at  $10.9$

443 ton/km<sup>2</sup>/yr, in contrast with baseflow (non-typhoon) conditions that are mainly contributed by  
444 carbonate weathering. Moreover, during the course of the typhoon, we observed a shift from  
445 predominantly evaporite weathering during peak precipitation to silicate weathering at peak discharge.

446

447 Combining the observation of riverine chemistry, suspended sediment properties, and previous soil  
448 water chemistry studies, we propose a feedback cycle between physical erosion and chemical  
449 weathering in badlands topography, illustrating that precipitation of evaporites during the dry season  
450 produces sodic water during typhoon events and preferentially triggers higher local erosion. The  
451 enhanced hillslope erosion and abrasive effects of clay in a high discharge stream enhance bedrock  
452 exposure on hillslopes and silicate weathering, respectively. Newly exposed bedrock then produces  
453 more weathered material. Although measurements of bedrock mineral chemistry and Sr isotope are  
454 still needed for confirming sources of excess sodium and calcium (Fig. 5), we suggest that the  
455 conceptual model could provide an insight into landscape change of badlands. The results from our  
456 study suggest that high erosion rates in mudstone badlands of the Erren River catchment are due to  
457 both weakened lithology and the interaction between evaporites and hillslope erosion.
