Abstract. Chemical weathering driven by physical erosion is a natural process that strongly affects chemical and solid matter budgets at the Earth’s surface. However, the influence of extreme climatic erosion on chemical weathering dynamics is poorly understood. Badland landscapes formed in highly erodible substrates have the potential to respond to individual events on scales that are rapid enough for direct observation. Here, we assess the geochemical and grain-size composition of suspended sediment and riverine chemistry measurements collected from two catchments during the 2017 Nesat and Haitang typhoons in southwestern Taiwan. During the typhoons, the Na⁺ concentration covaried with suspended sediment concentration, which we attributed to sodium-induced deflocculation. Evaporite weathering at peak rainfall is succeeded by peak silicate weathering at maximum discharge. Overall, our observations suggest that initial weathering of near-surface evaporite enhances the physical erosion of silicate rock during extreme rainfall events.

21 **1. Introduction**

22 Chemical weathering induced by physical erosion controls nutrient supply to ecosystems (Milligan
23 and Morel, 2002), reflects dynamic surface processes (e.g., Calmels et. al., 2011; Clift et. al., 2014;
24 Emberson et. al., 2016; Meyer et. al., 2017), and regulates the global carbon cycle and the evolution
25 of Earth's long-term climate (Berner et al., 1983; Ram et al., 1992; Gaillardet et al., 1999). In most
26 landscapes, physical erosion and chemical weathering operate on geological timescales that may be
27 difficult to observe on human timescales (e.g., Maher et al., 2014). However, in many landscapes
28 erosion dominantly occurs during stochastic events, such as storms (e.g., Hartshorn et al., 2002; Lee
29 et al., 2020; Wang et al., 2021). In particular, typhoons are able to transport large volumes of water and
30 dissolved solids within hours to days, allowing us to observe the interactions between physical erosion
31 and chemical weathering in landscapes impacted by them. Nevertheless, observations of the interaction
32 between extreme physical erosion and chemical weathering dynamics are limited (Meyer et. al., 2017).
33 Furthermore, the lack of high-frequency stream water sampling leads to a fundamental difficulty in
34 constraining the dynamic behavior between physical erosion and chemical weathering during a high
35 discharge period (e.g., a typhoon), which could have key implications for our ability to quantify
36 topographic responses to these events.

37

38 Badlands are landscapes characterized by highly erodible and weathered substrates, that are largely
39 devoid of vegetation. The high erodibility of these landscapes provides a unique opportunity to
40 investigate and quantify denudation processes that operate at short timescales (Cheng et al., 2019;
41 Yang et al, 2019, 2021a; 2021b). Badlands is typically dominated by mudstones and clays, and soils
42 that contain clays saturated in sodium ions are particularly vulnerable to erosion by water. Sodium ions
43 alter the layer charge of double-layered clay minerals (i.e. smectite) and cause the clays to deflocculate,
44 which refers to the process of breaking up the clay (and ultimately the soil) into finer particles that are
45 more easily washed away by water (e.g., Faulkner et al., 2004; Mitchell et al., 1993; Rengasamy and
46 Olsson, 1991; Rengasamy et al.,1984; Sherard et al., 1976; Kašanin-Grubin et. al., 2018). Additionally,

47 mineral assemblage affects the stability of soil aggregates; for example, small amounts of smectite in
48 kaolinitic materials cause it to be more dispersive and unstable (Levy et al., 1993).

49

50 Previous studies in the badlands of southwestern (SW) Taiwan have revealed that halite and gypsum
51 dissolve at depth and migrate to the hillslope surface and deposit in desiccation cracks during the dry
52 season (Higuchi et al., 2013, 2015; Nakata and Chigira, 2009). Others have observed that pore waters
53 found in the near-surface mudstone have Na^+ concentrations of 1–3 million $\mu\text{mol/L}$ at 1–2 cm depth
54 (Nakata and Chigira, 2009). Mud cracks lead to the properties of the mudstone, e.g., rock density,
55 water permeability, and ion concentration between the surface (a few centimeters to 10 cm depth) and
56 bedrock are different (Fig. S1). For example, the bedrock hardly participates in physical erosion during
57 a rainfall event due to low permeability. We hypothesize that the dissolved halite and gypsum re-
58 crystallize in the near-surface and are deposited in the mudstone cracks through capillary action during
59 the dry season. Subsequent precipitation dissolves the evaporite, and the dissolved Na^+ enhances
60 erosion by clay dispersity and exposes more weatherable materials, forming a positive feedback cycle.
61 Assuming a mudstone substrate that is primarily comprised of silicate minerals, we expect that
62 concentration of evaporite ions should be consistent with changes in the sediment concentration and
63 the concentration of silicate ions.

64

65 To investigate this potential feedback between evaporite dissolution and erosion, we use suspended
66 sediment concentrations (SSC) and stream chemistry data from two catchments in the badlands of SW
67 Taiwan (Fig. 1), collected at a temporal resolution of 3 hours over 3 days. We interpret our observations
68 in the badlands to reflect how the excess sodium that re-precipitates at surface in dry season enhances
69 physical erosion and chemical weathering in the following typhoon event.

70

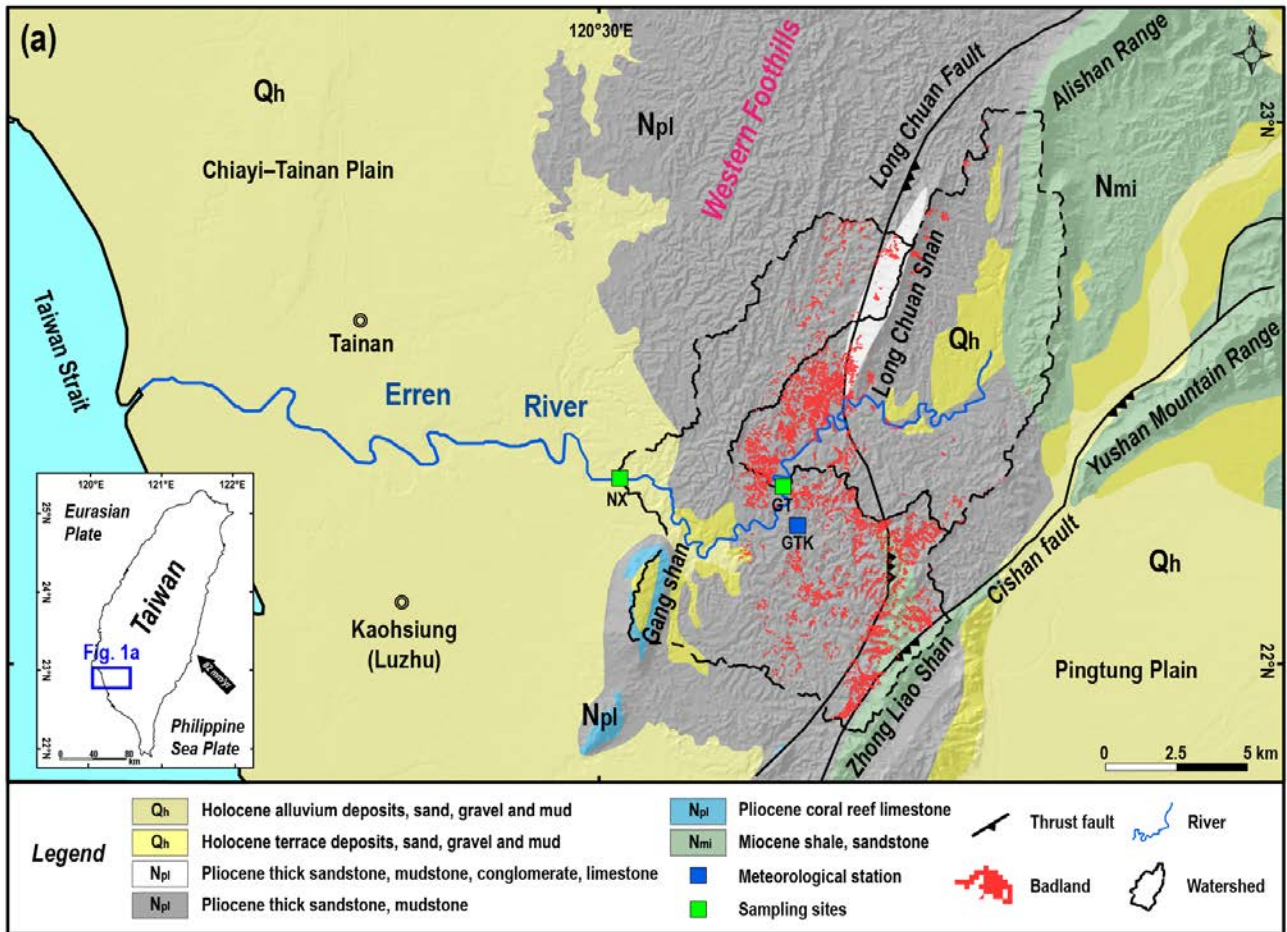

71 **2. Geological and Meteorological Setting**

72 In Taiwan's badlands, the annual precipitation is about 2 m, and 90% of the rainfall is concentrated in
73 the rainy season. The rainy season lasts from May to October and reaches its peak in August, with over
74 400 mm of precipitation within a single month. In contrast, less than 40 mm of average monthly rainfall
75 is measured from November to April. We collected river water samples from two sites downstream of
76 the studied badland areas. The first site, Nanxiong Bridge (NX), is located at the midstream of the
77 Erren River and has a drainage area of 175 km². This area includes badlands covering an area of 4.37
78 km², which accounts for 2.49% of the total catchment area (Fig.1). The Erren River catchment is
79 predominantly underlain by Plio-Pleistocene mudstones, which are several kilometers thick, and
80 mainly feature illite (30.54%) and chlorite (28.70%) minerals (Tsai, 1984a). During the dry seasons,
81 the pore water chemistry in the near-surface mudstones is mainly composed of Na⁺, Cl⁻, Ca²⁺ and SO₄²⁻
82 (Nakata and Chigira, 2009).

83

84 The gauging station at Nanxiong Bridge (NX) provides hourly discharge data for calculating sediment
85 and solute fluxes. The annual average discharge of Nanxiong Bridge station is 10.2 m³/s, and the
86 typhoon season accounts for 84% of the total discharge. The meteorological station at Gutingkeng
87 (GTK) is located 5.5 km from Nanxiong Bridge and provides hourly precipitation data. Our second
88 sampling site is Guting (GT) Bridge, with an upstream drainage area of 79 km² and a badlands area of
89 1.87 km², corresponding to 2.37% of the total area. Guting Bridge is located adjacent to a badlands
90 conservation area, so the riverine water chemistry reflects the weathering products derived from the
91 adjacent hillslopes. Due to a lack of stream discharge observations at Guting Bridge, we use hourly
92 precipitation data at GTK, which is less than 1 km from the sampling site, to quantify the impact of
93 the typhoon events.

94

95
 96 **Figure 1.** Location of sampling sites and geology of the study area. (a) The geological map of the
 97 study area (Source: Central Geological Survey, 2013). The green squares are sampling sites; hourly
 98 stream discharge data were obtained from the Nanxiong Bridge (NX) hydrometric station (Water
 99 Resources Agency). The blue square is the meteorological station, which provides hourly precipitation
 100 data (Central Weather Bureau, <https://dbar.pccu.edu.tw/>).
 101

102 **3. Methods and Materials**

103 **3.1 Water Sampling**

104 We collected 42 stream samples from the two sampling sites for the typhoon period of July 2017.
 105 During sample collection, two 1000 ml PE bottles were dropped 1 to 2 meters below the water surface
 106 of the river simultaneously. Suspended sediment concentration (SSC) was subsequently calculated
 107 from the water collected in one of the PE bottles, and riverine chemistry was determined from water
 108 collected in the other bottle. Samples were filtered *in situ*, and the filtrate was preserved in the
 109 refrigerator for laboratory analysis. Additionally, 31 samples were collected from September 2014 to

110 December 2016 in the second half of every month at Nanxiong Bridge for non-typhoon periods, using
111 the same sampling procedure.

112

113 3.2 Dissolved load and sediment chemistry analysis

114 For the riverine dissolved load, we measured major dissolved anions (Cl^- , SO_4^{2-} , NO_2^- , NO_3^- , F^-) on an
115 Ion chromatography (IC, Metrohm Basic-883 plus), and we measured major dissolved cations (Na^+ ,
116 K^+ , Mg^{2+} , Sr^{2+} , Ba^{2+} , Si^{4+}) on an ICP-OES (PerkinElmer, Optima 2100DV). We measured bulk
117 sediment chemistry from two samples of suspended sediment collected from Guting Bridge at low
118 flow before the typhoon event ($2.26 \text{ m}^3/\text{s}$) and at the peak of runoff ($724.32 \text{ m}^3/\text{s}$). About 0.7 g of dried
119 sediment sample was combusted in the muffle furnace at 650°C for 2 hours and then weighed to obtain
120 the loss on ignition (LOI). Afterward, an aliquot of $\sim 100 \text{ mg}$ from the residue was digested with a
121 mixture of concentrated HF and aqua regia. After digestion and drying, the sample was dissolved in
122 0.3 N HNO_3 for elemental determination. Major elemental concentrations of sediment samples were
123 obtained by ICP-OES (Varian 720-ES) at the GFZ German Research Centre for Geosciences.

124

125 3.3 Grain size of suspended load

126 Before measuring grain size, we removed the non-clastic deposition, i.e., sea salt, organic matter, and
127 carbonate. To remove sea salt, $\sim 1 \text{ g}$ of dried sediment sample was added to 15 ml of distilled water,
128 placed in a shaker, and shaken at a speed of 4000 rpm for 5 minutes. The centrifuged supernatant was
129 then poured out and these steps were repeated 3 times. To remove organic matter, 10 ml of a 15%
130 H_2O_2 solution was added to the sediment and placed in an ultrasonic oscillator for 24 hours. After
131 adding a second 10 ml of H_2O_2 (15%) to confirm the completion of the reaction, the mixture was
132 centrifuged and the supernatant containing the organic matter was removed. The sediment was then
133 washed by adding 30 ml of distilled water, and the supernatant was again removed after centrifugation.
134 This washing step was repeated 3 times to remove residual H_2O_2 in the centrifuge tube. To remove the

135 carbonates, we added 10 ml of 10% HCl solution to the centrifuge tube and allowed the acid to react
136 with the sediments for 24 hours. An additional 10 ml of HCl was then added to confirm the
137 completeness of the reaction. The sample was then centrifuged, and the supernatant was decanted to
138 remove the carbonates. The sample was then rinsed with 30 ml of distilled water, centrifuged, and
139 decanted. This step was performed 3 times to remove any residual HCl.

140

141 To disperse sediment agglomeration, we added 10 ml of 1% $\text{Na}(\text{PO}_3)_6$ solution to the sediment and let
142 the sample react for more than half a day. The grain size of the sediment samples was obtained by
143 Laser Diffraction Particle Size Analyzer LA950 at the GFZ German Research Centre for Geosciences.
144 By using LA950, we measured grains in the size range of between 100 nm to about 3 cm.

145

146 3.4 Calculation of the enriched ratio and sodium adsorption ratio (SAR)

147 In order to classify the supply of different ion sources during the typhoon event, we used the enriched
148 ratio of concentration as a reference. The enriched ratio is the ion concentration at a certain time
149 divided by the ion concentration at the first observation. A value greater than 1 represents a point in
150 time when the sample is more concentrated relative to the first observation, whereas a value smaller
151 than 1 represents a point in time when the sample is more diluted relative to the first observation. The
152 first observation was sampled 6 hours before the typhoon which represents the background value of
153 river water chemistry in this study.

154

155 Dissolved calcium and magnesium can stabilize soil aggregates and therefore enhance water
156 permeability (Nadler et al., 1996). By contrast, excess sodium can disperse soil particles through
157 deflocculation, thereby reducing water permeability (Hanson et al., 1999). The potential for material
158 dispersion in badlands is generally determined by measuring the presence and behavior of sodium and
159 is quantified by the sodium absorption ratio (SAR), (1):

$$SAR = \frac{Na^+}{\sqrt{\left(\frac{Ca^{2+}+Mg^{2+}}{2}\right)}} \quad (1)$$

Here, the cation measurements are expressed in milliequivalents per liter (meq/L). For pore water, when SAR is greater than 13, the excess sodium causes soil particles to repel each other, preventing the formation of soil aggregates (Seelig, 2000; Horneck et al., 2007). Given the influence of soil structure, SAR value for irrigation water smaller than 3 is low, from 3 to 9 is medium and above 9 is high (Ayers and Westcot, 1985).

166

3.5 Calculation of TDS and chemical weathering rate

Riverine TDS is widely used to estimate chemical weathering rates of river catchments (e.g. Gaillardet et al. 1999). In this study, riverine TDS (in units of $\mu\text{mol/L}$) is expressed as:

$$TDS = TDS_{rain} + TDS_{evaporite} + TDS_{sil} + TDS_{carb} \quad (2)$$

where the contributions from precipitation (TDS_{rain}), evaporite ($TDS_{evaporite}$), silicate weathering (TDS_{sil}) and carbonate weathering (TDS_{carb}) are considered. We calculated the proportions of ion contributions from rainwater, evaporite, silicate and carbonate for Ca, Mg, Na, Cl, and SO_4 with the MEANDIR inversion model (Kemeny and Torres, 2021), a MATLAB script for inverting fractional contributions of end-members, and for constraining the chemical compositions of those end-members with Monte Carlo propagation of uncertainty. To exclude the input of precipitation (TDS_{rain}) from riverine TDS, we used local rainwater Cl^- concentrations with an average value of $68 \mu\text{mol/L}$ (Lu, 2014), and also the ratios of SO_4/Cl , Na/Cl , K/Cl , Mg/Cl , Ca/Cl in rainfall based on the rainfall chemistry from 2007 to 2013 reported by Lu (2014) (Table 1).

$$[X]_{norain} = [X]_{river} - [X]_{rain} \quad (3)$$

$$TDS_{rain} = \sum [X]_{rain} \quad (4)$$

Here $[X]_{norain}$ reflects the remaining concentration of ion X after the removal of atmospheric inputs; $[X]_{river}$ is the concentration of ion X in river water, and $[X]_{rain}$ is the concentration of ion X from

184 atmospheric deposition. In the second step, we corrected for evaporite inputs ($TDS_{\text{evaporite}}$) using the
 185 following equation:

$$186 \quad [X]_{\text{NSS}} = [X]_{\text{norain}} - [X]_{\text{evap}} = [X]_{\text{norain}} - \left([Cl]_{\text{norain}} \times \left(\frac{X}{Cl} \right)_{\text{evap}} \right) \quad (5)$$

$$187 \quad TDS_{\text{evaporite}} = \sum [X]_{\text{evap}} \quad (6)$$

188 where $[X]_{\text{NSS}}$ is the concentration of ion X after the removal of ions attributed to evaporites, $[X]_{\text{evap}}$.
 189 $[X/Cl]_{\text{evap}}$ is the ratio of ion X and Cl by using the end-member molar ratios of evaporite reported by
 190 Burke et al. (2018), of which K/Cl is referred to Chao et al., (2011) (Table 1)). Then, after the correction
 191 for evaporite, the chemical weathering budget can be divided into contributions by silicate (TDS_{sil})
 192 and carbonate weathering (TDS_{carb}), expressed as:

$$193 \quad TDS_{\text{sil}} = [Na]_{\text{sil}} + [K]_{\text{sil}} + [Mg]_{\text{sil}} + [Ca]_{\text{sil}} + [SiO_2]_{\text{sil}} \quad (7)$$

$$194 \quad TDS_{\text{carb}} = [Mg]_{\text{carb}} + [Ca]_{\text{carb}} + [HCO_3]_{\text{carb}} \quad (8)$$

$$195 \quad [HCO_3]_{\text{carb}} = \frac{1}{2} ([Mg]_{\text{carb}} + [Ca]_{\text{carb}}) \quad (9)$$

196 where $[Na]_{\text{sil}}$ and $[K]_{\text{sil}}$ are riverine $[Na]_{\text{NSS}}$ and $[K]_{\text{NSS}}$ concentrations, respectively. We used
 197 endmember values for silicate- and carbonate-dominated rocks reported by Gaillardet et al. (1999)
 198 (Table 1). We agree that the use of global endmembers leads to a larger range of estimations, but is
 199 still appropriate in discussing trends in weathering rates.

200 Considering the hydrological response, we use flow weighted method to calculate the flux of solute
 201 (Huang et al., 2012), expressed as:

$$202 \quad Flux_{(\text{rain, evap, sil, carb})} = \frac{\left(m \times \frac{\sum_{i=1}^n TDS_{(\text{rain, evap, sil, carb})i}}{\sum_{i=1}^n Q_i} \times Q_t \right)}{\text{catchment area}} \quad (10)$$

203 where m is the conversion factor for a specific unit (ton/km²/yr). Q_i is the hourly discharge
 204 corresponding to sampling time. Q_t is total discharge during the year or during the typhoon.

205

206 **Table 1** Input end-members for the MEANDIR inversion model.

End-member	SO ₄ /Cl	Na/ Cl	K/ Cl	Mg/Cl	Ca/Cl
Precipitation	0.35	0.90	0.09	0.18	0.35
Evaporites	0.6±0.6	1.0±0	0.026	0.1±0.08	0.5±0.5
	Ca/Na	Mg/Na			
Silicates	0.35±0.25	0.24±0.2			
Carbonates	60±30	30±15			

207

208 **3.6 Calculation of total loss of mobile elements**

209 The non-dimensional mass transfer coefficient ($\tau_{j,i}$) is used to quantify the loss or accumulation of a
 210 mobile element (Anderson et al., 2002). Notably, we use the suspended sediment before the typhoon
 211 event as the reference, instead of parent materials.

$$212 \tau_{i,j} = \frac{C_{j,p}C_{i,b}}{C_{j,b}C_{i,p}} - 1 \times 100 \quad (11)$$

213 Here, the concentration of an immobile element, Ti (C_i) or of a mobile element (C_j) in suspended
 214 sediment is denoted for the time before peak discharge ($C_{i,b}$) or at peak discharge ($C_{i,p}$). When the τ
 215 values approach -100, it indicates depletion, while values close to 100 indicate accumulation.

216

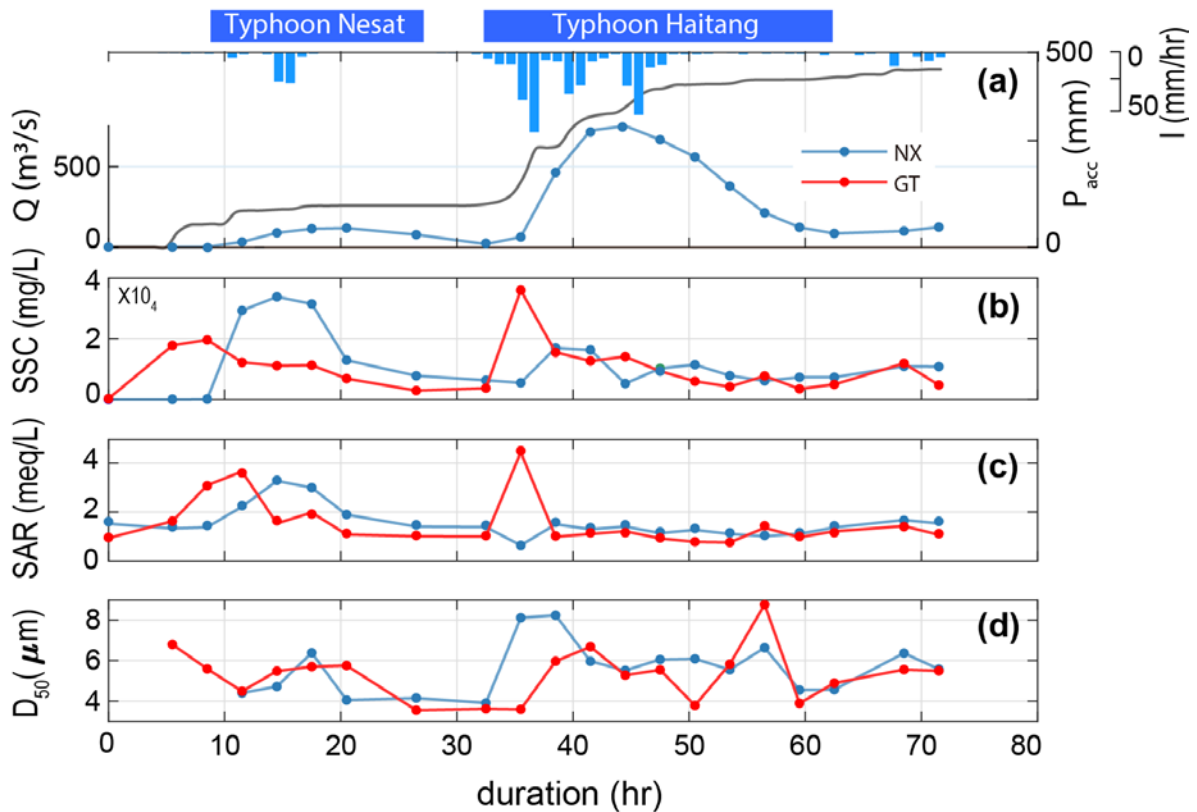

217 **4. Results**218 **4.1 Geochemistry of river water and suspended sediment**

219 In 2017, the Nesat and Haitang typhoons brought 579 mm of rainfall over three days, with a maximum
 220 intensity of 74 mm/hr. The discharge at Nanxiong Bridge demonstrated that the climatic co-response
 221 has two pulses (Fig. 2). Since the time interval between the two typhoons was less than 6 hours, we
 222 define the two typhoons as one typhoon event and distinguish between a first and second discharge
 223 pulse. We quantify time relative to the onset of the typhoon (0 hr). The first pulse occurred from 8.5 to
 224 32.5 hr, with a mean water discharge of 66.2 m³/s. The second pulse that occurred from 32.5 to 62.5
 225 hr had a 5.5 times higher mean discharge of 369.2 m³/s. The maximum discharge (753.2 m³/s) was
 226 observed during the second pulse at 44.5 hr (July 31st, 2017, at 6:00 a.m.) (Fig. 2).

227

228 At Nanxiong Bridge, SSC has a statistically significant positive correlation with SAR ($\rho = 0.51$, $p <$
 229 0.05). SSC has two peaks, one during each pulse, but SAR only shows a peak during the first pulse.

230 During the first pulse, SSC ranged from 10 to 33757 mg/L and SAR increased from 1.44 and to 3.14.
 231 During the second pulse, SSC increased from 5445 to 16900 mg/L and SAR remained about 1.44.
 232 The median grain size (D_{50}) ranged from 3.9 to 8.2 μm , with an average value of 5.6 μm during the
 233 second pulse, and exhibited a positive correlation with discharge ($\rho = 0.40$). At Guting Bridge, SSC
 234 has a statistically significant positive correlation with SAR ($\rho = 0.69$, $p < 0.05$) during the survey. SSC
 235 ranged from 164 to 19538 mg/L before the first pulse and ranged from 2857 to 35920 mg/L during the
 236 second pulse, while SAR showed a mean of 1.46 and two peaks with a value over 4 during both pulses.
 237 D_{50} ranged from 3.6 to 8.8 μm , with an average value of 5.3 μm during the second pulse, (Fig. 2). In
 238 terms of sediment chemistry at Guting Bridge, major elements of the two selected sediment samples
 239 show that calcium and sodium accounted for about 10% of the mass loss between the typhoon event
 240 (5.5 hr of duration) and the peak of discharge (41.5 hr of duration) (Table. S4).

241
 242 **Figure 2.** Timeseries SSC, SAR and median grain size of suspended sediment (D_{50}) at two sampling
 243 sites. The blue line denotes hourly discharge (Q) at Nanxiong Bridge, and the blue bar denotes hourly
 244 precipitation (I) at Gutingkeng station. The gray line denotes precipitation accumulation (P_{acc}), the blue
 245 line denotes the Nanxiong Bridge (NX) dataset, and the red line denotes the Guting Bridge (GT) dataset.

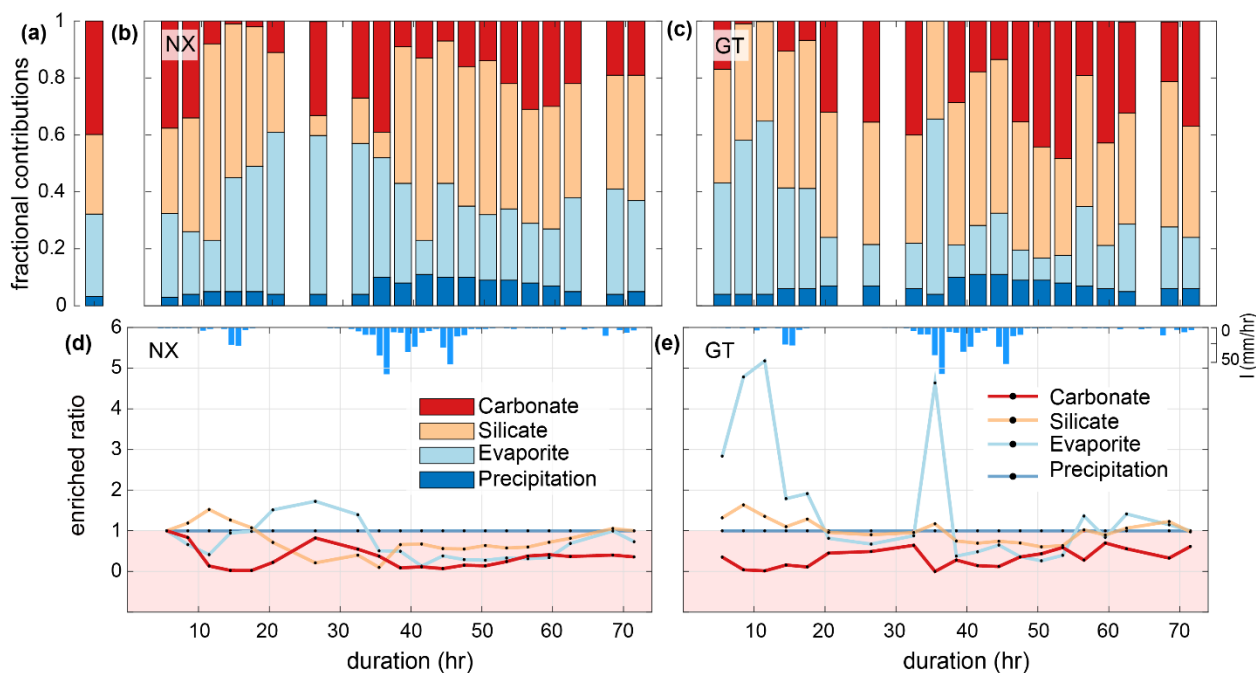

246

247 The fractional proportions of TDS at Nanxiong Bridge during baseflow show that precipitation,
248 evaporites, silicates, and carbonates contribute $3.0\pm 1.1\%$ (uncertainty gives the standard error of the
249 mean), $28.7\pm 14.6\%$, $26.9\pm 6.5\%$, and $41.4\pm 13.2\%$, respectively (Fig. 3a). During the typhoon event,
250 the proportion of TDS at Nanxiong Bridge attributed to TDS_{rain} is $6.3\pm 2.4\%$. $TDS_{evaporite}$ contributes
251 $32.4\pm 13.6\%$ and increases from 27.4% to 61.1% at the incipient first pulse. TDS_{sil} contributes
252 $39.5\pm 15.2\%$, which is 12.6% higher than the non-typhoon period. TDS_{carb} contributes $21.8\pm 11.5\%$
253 (Fig. 3b), which is 19.6% lower than the non-typhoon period. The fractional proportions of TDS at the
254 Guting Bridge show that $6.5\pm 2.1\%$ of TDS is contributed by TDS_{rain} . $TDS_{evaporite}$ contributes
255 $24.8\pm 16.2\%$ and increases from 13.6% to 61.6% at the incipient second pulse, when the SSC and SAR
256 peak simultaneously. TDS_{sil} and TDS_{carb} contribute $39.5\pm 15.2\%$ and $27.5\pm 16.7\%$, respectively (Fig.
257 3c).

258

259 Enriched ratios of less than one indicate dilution, and values greater than one indicate concentration.
260 Since we set the ion concentration of rainfall to be constant during the typhoon event, the enriched
261 ratio of precipitation is constant throughout the observation period. At Nanxiong Bridge, the evaporites
262 enriched ratio increases from 0.4 to 1.7 between the two pulses and decreases to 0.1 at the discharge
263 peak. The silicates enriched ratio increases from 1 to 1.5 before the first pulse and decreases to 0.1 at
264 the peak of discharge, then returns to 1 before the observation ends. The concentration attributed to
265 carbonates is always diluted. The evaporites and carbonates enriched ratio have a statistically
266 significant negative correlation with discharge (evaporites: $\rho = -0.67$, carbonates: -0.60 , $p < 0.05$) and
267 the silicate enriched ratio has a negative correlation with discharge ($\rho = -0.32$), indicating dilution by
268 typhoon rainfall (Fig. 3d). At Guting Bridge, the evaporites enriched ratio has two peaks during the
269 two pulses with a value of 5.2 at the first peak, a value of 4.7 at the second peak. After the event, the
270 value returns to about 1.2. Notably, the evaporites enriched ratios during both pulses are similar, but
271 the peak discharge of the second pulse is 5.5 times higher than that of the first pulse. The silicate

272 enriched ratio has an analogous pattern with the evaporites enriched ratio, but the enriched ratio is
273 smaller. Similar to Nanxiong Bridge, the carbonates enriched ratio is always diluted at Guting Bridge
274 (Fig. 3e). The evaporite and silicate enriched ratio shows a statistically significant positive correlation
275 ($\rho = 0.96$, $p < 0.05$), and the evaporite and silicate enriched ratios have a statistically significant positive
276 correlation with SAR ($\rho = 0.86$, $\rho = 0.84$, $p < 0.05$). We also use the concentration–discharge (cQ)
277 relationship of each ion at rising and recession limb, as well as baseflow at Nanxiong Bridge to assess
278 the state of dilution behavior (Fig. S2). Overall, our results show that all ions are in a dilution, and the
279 dilution in recession limb is stronger than that in rising limb, except for SO_4 during baseflow ($\theta = 0.07$).
280 The concentration of Na, Cl and K during baseflow have a higher variability than the values during
281 the event. Additionally, Na, Cl, and SO_4 increase the concentration with increasing flow at the certain
282 period of rising limb.

284

285 **Figure 3.** Timeseries illustrating TDS sources during the typhoon event at the two sampling sites.

286 Fig.3a shows the average proportion of TDS for the non-typhoon period from September 2014 to

287 December 2016 at Nanxiong Bridge; Fig.3b-c denotes the endmember contributions to TDS at

288 Nanxiong Bridge dataset and Guting Bridge dataset from the typhoon period; the red bar denotes

289 TDS_{carb} (Eq. 8); orange denotes TDS_{sil} (Eq. 7); the azure bar denotes $TDS_{evaporite}$ (Eq. 6); the blue bar290 denotes TDS_{rain} (Eq. 4). Fig.3d-e denotes the enriched ratio of ion concentrations by TDS sources from

291 the Nanxiong Bridge dataset and Guting Bridge dataset during the typhoon period. The red line denotes

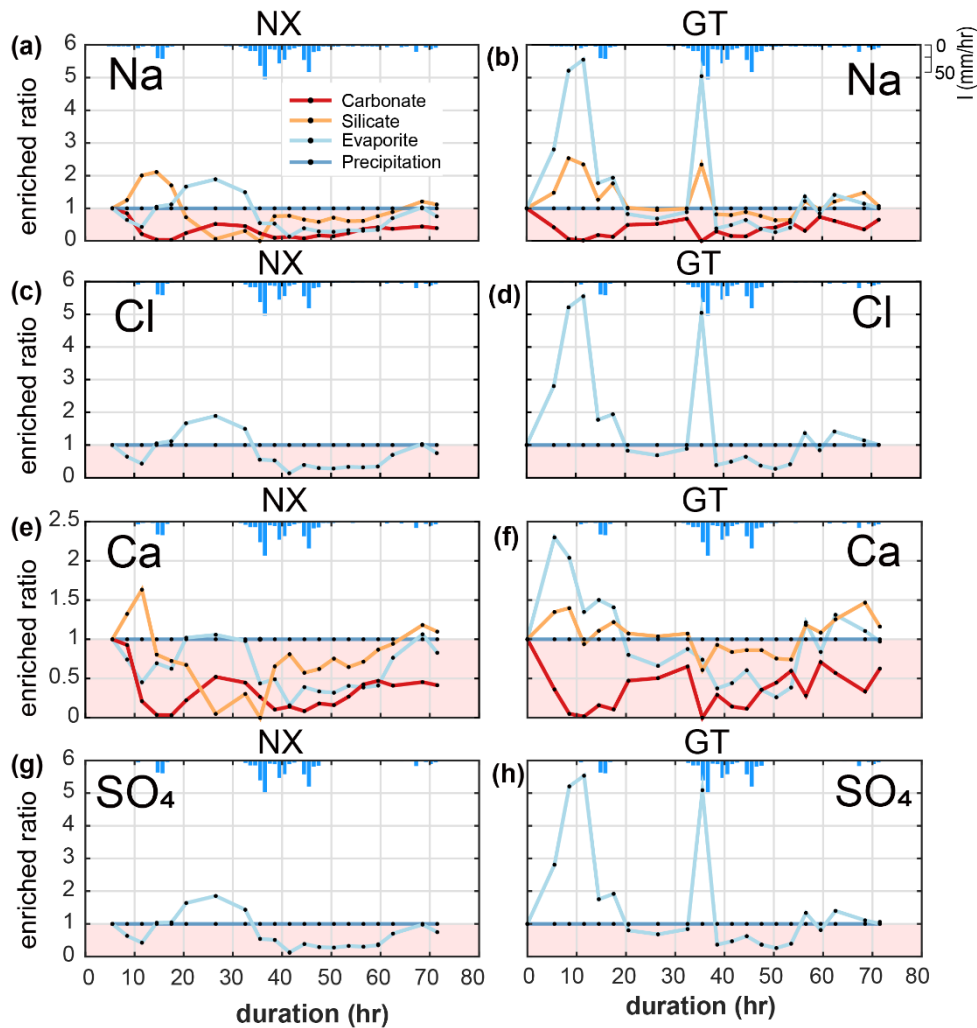

292 TDS_{carb} , the orange line denotes TDS_{sil} , the azure line denotes $TDS_{evaporite}$, the blue line denotes the293 TDS_{rain} , and blue bar denotes hourly precipitation (I) at GTK station.

294 **4.2 Evaporite, silicate and carbonate dissolution over time**

295 We calculated the enriched ratios of ions (i.e., Na^+ , Cl^- , Ca^{2+} and SO_4^{2-}) that are sourced from evaporites
296 (i.e., halite (NaCl) and gypsum (CaSO_4)). The variability in the concentrations of each of these ions
297 reflects the overall trends in TDS (Fig. 3d-e & Fig. 4).

298

299 At Nanxiong Bridge, all evaporite and carbonate ions have a statistically significant negative
300 correlation with discharge. The enriched ratios in evaporite Na^+ , Cl^- and SO_4^{2-} have the same trend (Fig.
301 4), which show an initial decrease during the first pulse, followed by an increase to 2 between the two
302 pulses, and a final decrease during the second pulse. Evaporite Ca^{2+} shows a similar trend with
303 evaporite Na^+ , Cl^- and SO_4^{2-} , but the values are below 1. The enriched ratios of silicate Na^+ , Ca^{2+} show
304 an increase during the first pulse and a decrease to less than 1 before the rainfall peak, followed by an
305 increase from about 0.06 to 1.11 at the end of observation. At Guting Bridge, all evaporite ions have a
306 statistically significant positive correlation with the corresponding silicate ions (Na^+ , $\rho = 0.98$; Ca^+ , ρ
307 $= 0.81$, $p < 0.05$). Evaporite Na^+ , Cl^- , and SO_4^{2-} each have two peaks that occur prior to the maximum
308 rainfall and reflect a factor of 5 increase in the enriched ratio. Compared with Nanxiong Bridge
309 (downstream), the enriched ratio in evaporite Ca^{2+} at Guting Bridge concentrates at the onset of the
310 first pulse and after peak discharge. Additionally, the enriched ratios of carbonate at Guting Bridge are
311 similar to Nanxiong Bridge, and are always below 1.

312

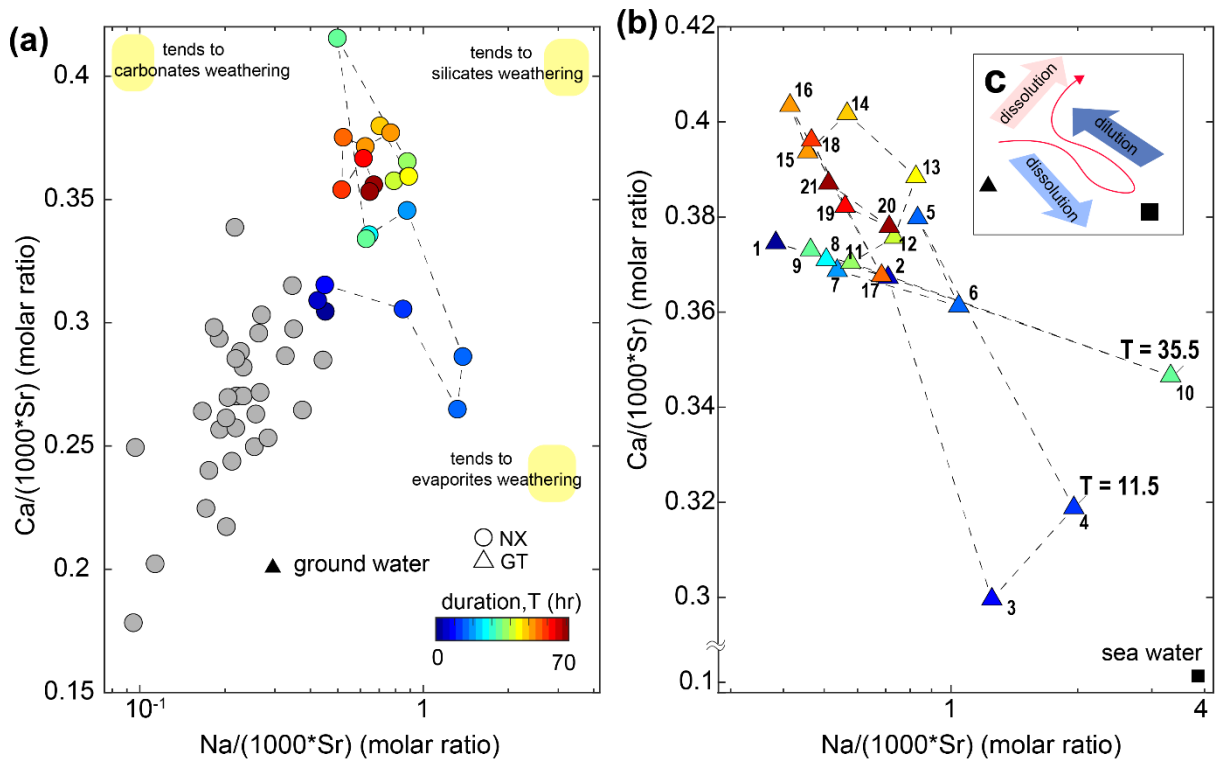

313 **Figure 4.** Time-series patterns in enriched ratio at two sampling sites. NX denotes the Nanxiong Bridge
 314 dataset and GT denotes Guting Bridge dataset. The pink area indicates enriched values below 1. Blue
 315 bar denotes hourly precipitation (I) at Gutingkeng station.

316

317 Gaillardet et al. (1999) documented that dissolved ions ratios of Ca/Sr and Na/Sr are distinct for
 318 carbonates (low Na/Sr, high Ca/Na) versus silicates or evaporites (high Na/Sr, low Ca/Na). We use
 319 these ratios to elucidate potential mixing between carbonates, silicates, and evaporite endmembers (Fig.
 320 5). At Nanxiong Bridge, non-typhoon ratios of Na/(1000*Sr) and Ca/(1000*Sr) are 0.23–0.68 and
 321 0.19–0.35, respectively (Table S4). These values increase markedly during the typhoon events, with
 322 enriched– ratios of Na⁺ exceeding 5 at T = 11.5 and 35.5 hr. The high concentration of Na⁺, Cl⁻ and
 323 SO₄²⁻ (as illustrated in the enriched ratio) indicate that there is enhanced dissolution of evaporites at
 324 the onset of the typhoon event, especially at Guting Bridge. Subsequently, the concentration of Na⁺

325 decreased with sustained rainfall. Then, the ratios approach the silicates/carbonates weathering (high
 326 Na/Sr, high Ca/Sr ratios) after the peak discharge.

327

328

329 **Figure 5.** Molar ratio mixing diagrams of Erren River waters for (a-b) Na/(1000*Sr) versus
 330 Ca/(1000*Sr), circles denote dataset at Nanxiong Bridge, and triangles denote dataset at Guting Bridge.
 331 Colorbar denotes survey duration. Gray circles denote the dataset at Nanxiong Bridge during baseflow
 332 conditions from 2014 to 2016. The black triangle illustrates the groundwater endmember (Chao et al.,
 333 2011); the black square illustrates the seawater endmember. Numbers in the triangle represent the time
 334 sequence, 1 represents the start point, and 21 represents the endpoint. Yellow areas indicate trends in
 335 weathering types rather than the locations of endmember. (c) Illustration of dynamic weathering. The
 336 red line indicates the direction of change with time. The light blue arrow denotes dissolution of
 337 evaporite, the dark blue arrow denotes dilution from rainfall, and the red arrow denotes dissolution of
 338 suspended sediment.

339

340 5. Discussion

341 5.1 Relationships between dissolved evaporite and river water chemistry

342 Before the survey, the monthly rainfall of the study area was 72.5 mm, which is only 18% of the

343 average monthly rainfall, implying that it provides a relatively dry environment for accumulating
344 evaporites on the slope surface. Under maximum rainfall intensity, Na^+ , Cl^- and SO_4^{2+} at Guting Bridge
345 show markedly increased concentrations at the onset of the typhoon, peaks in enriched ratios that
346 exceed 5 (Fig. 4), and the greatest contribution of dissolved ions from evaporites (Fig. 3). Calculated
347 with pore water chemistry during the dry season from the same study site, the sodium absorptions ratio
348 (SAR) is 240.8 and exceeds the threshold value of 13. During the typhoon event, the river water SAR
349 has a maximum value of 4.41 at Guting Bridge (3.14 at Nanxiong Bridge), suggesting soil
350 deflocculation within river is weaker than on the hillslopes. However, the SAR has a statistically
351 significant positive correlation with $\text{TDS}_{\text{evaporite}}$ ($\rho = 0.86$, $p < 0.05$) at Guting Bridge (upstream). This
352 pattern indicates that excess sodium is effective at inducing material dispersion at hillslopes and thus,
353 contributing to a higher suspended sediment load. The trend of river water SAR is able to reflect the
354 extent of dissolved Na^+ from hillslope. (Fig. 2).

355

356 These observations and results suggest that rainwater in the typhoon event rapidly dissolves the
357 evaporites on the slope surface, which produces high measured concentrations of Na^+ , Cl^- , and SO_4^{2+}
358 during the time of peak precipitation (30-40 hr of duration). Furthermore, the dissolution of the near-
359 surface evaporite deposits should be most heavily influenced by runoff from the hillslopes, so we
360 expect that excess sodium and enhanced erosion will be most significant on the hillslopes.

361

362 At Nanxiong Bridge, we observe a 10-hour delay in the peak enriched ratio relative to the SAR (Fig.
363 3d) and overall lower enriched ratios relative to Guting Bridge (Fig. 3d-e). We suggest that dilution
364 and the transport distance from the badlands are responsible for this. The two catchments have a similar
365 areal extent of badlands within the total catchment area, which is about 2.49% at Nanxiong Bridge
366 catchment and 2.37 % in Guting Bridge catchment. Badlands contribute considerable evaporite solutes
367 (Chou, 2008), but the higher downstream drainage area will result in dilution of the solutes without
368 additional inputs. Additionally, Nakata and Chigira (2009) have observed that salt dissolution induces

369 an increase in electrical conductivity during intermittent rainfall events and decreases gradually after
370 rainfall events when evaporation and salt precipitate. Therefore, re-crystallization during the
371 transportation is to be expected.

372

373 **5.2 From evaporite dissolution to silicate weathering**

374 Our results show that the typhoon is responsible for mobilizing 16.8 ton/km²/yr of dissolved solutes
375 derived from silicate weathering during the course of the event, and this flux corresponds to 16.6% of
376 the annual silicate weathering flux (Table S3). Additionally, we observed a change in the dominant
377 chemical weathering mechanism during the typhoon event. We rule out significant contributions from
378 baseflow and deep seawater after peak discharge, since ratios shift to higher Na/Sr, and Ca/Sr ratios
379 relative to the non-typhoon ratio (Fig. 5a–b), and the Ca/Sr ratio of mud volcanoes in the study site is
380 one order of magnitude less than river water (Chao et al., 2011). Carbonate weathering is the primary
381 contributor of Ca²⁺ for most of the world's large rivers (Gaillardet et al. 1999), but the increased Na⁺
382 and consistently enriched ratio of carbonate Ca²⁺ does not make this a likely main contributor to the
383 Erren River during the typhoon. We thus suggest that the principal source of dissolved solutes is likely
384 to be silicate weathering. This interpretation is supported by the temporal evolution of the enriched
385 ratio of silicate Ca²⁺, which gradually increases after the discharge peak, to approach a value of about
386 1 at the end of survey (Fig. 4e&f). Therefore, we suggest that the ratios shift to higher Na/Sr, Ca/Sr
387 ratios due to enhanced silicate weathering during the typhoon. We also observe a 10–18% loss in the
388 individual concentrations of Ca, Na, Al, and Sr in the suspended sediment during the course of the
389 typhoon event, whereas concentrations of Fe, K, Mg, and Mn increase by 3-10% (Table S6). The
390 dissolution kinetics of silicate weathering are multiple orders of magnitude slower than carbonate or
391 evaporite weathering (Meybeck, 1987), suggesting that significant weathering of fresh silicate
392 minerals over the course of a single typhoon event is unlikely. Thus, the observed changes in ion
393 concentrations during the event are likely to arise from heterogeneities in the bedrock composition or

394 the input of previously weathered silicate minerals from a deeper groundwater reservoir (Calmels et
395 al., 2011), which is different from groundwater source of baseflow during non-typhoon period.
396 However, quantifying the role of a deeper groundwater inputs is difficult in the absence of isotope data.

397

398 Given that the sediment transported in the channel is supplied by physical erosion, we suggest that
399 physical erosion in our study site enhances silicate chemical weathering, which is consistent with
400 previous studies (Chung, 2002; Chou, 2008). Moreover, we associate the change in weathering regime
401 during the course of the typhoon with abrasive erosion of silicate sediments in the channel. Mechano-
402 chemical dissolution of weakly bound ions, e.g., F^- from the fresh muscovite surfaces is driven by
403 abrasion under high energy sediment transport with reorganization of the river bed (Andermann et al.,
404 2022). Mudstones are mainly composed of silicate minerals (e.g., illite and chlorite minerals) (Tsai,
405 1984a), and a few swelling clay minerals (e.g., montmorillonite), which provide an abundant silicate
406 pool. We suggest that high suspended sediment concentrations, combined with high energy flow during
407 the typhoon, caused increased silicate input from the weathered silicates in the suspended
408 sediment, which has also been observed in typhoon-driven silicate chemical weathering from silicate
409 minerals at surface (Meyer et al., 2017). Importantly, the global annual silicate weathering flux of
410 rivers is 15.7 ton/km²/yr (Gaillardet et al. 1999), relative to our value of 16.8 ton/km²/yr., suggesting
411 that individual stochastic events may have global relevance.

412

413 **5.3 Typhoon-controlled cycles of physical and chemical erosion**

414 Evaporites, including halite (NaCl) and gypsum (CaSO₄), are found in few sedimentary environments,
415 and they are often excluded from the estimation of CO₂ consumption (Gaillardet et al., 1999).
416 Compared to silicate rocks, the relation between evaporites weathering and physical erosion has rarely
417 been discussed. Through the interactions among riverine chemistry, suspended sediment properties,
418 and previous soil water chemistry studies, we suggest a positive feedback cycle of physical-chemical
419 erosion driven by mobile dissolved evaporite (Fig. 5). The feedback cycle includes three steps. (1)

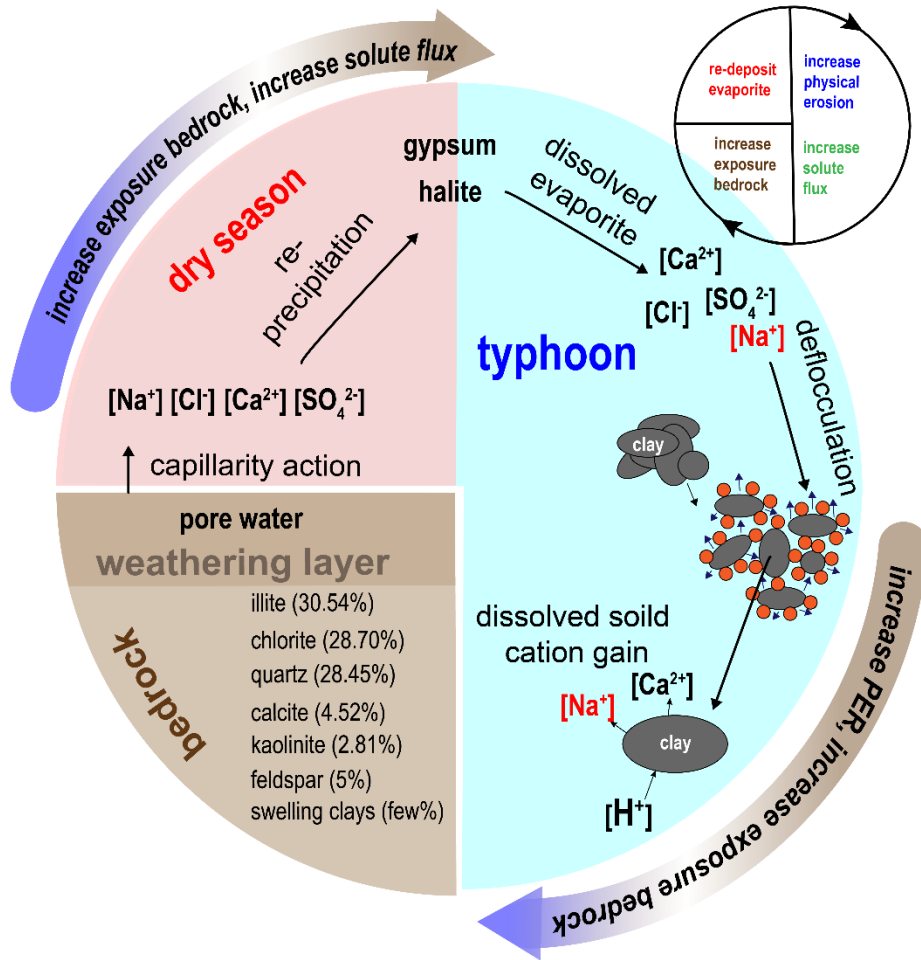

420 precipitation and deposition of evaporite during the dry season in near-surface mudstone desiccation
421 cracks through capillary transport (Higuchi et al., 2013, 2015; Nakata and Chigira, 2009). In the dry
422 season, exposed bedrock with low water content develops desiccation cracks (Allen, 1982; Goehring
423 et al., 2010; Kindle, 1917; Seghir and Arscott, 2015; Xiaa and Hutchinson, 2000), providing space for
424 the re-precipitation of evaporite minerals. Using evidence from core samples in mudstone bedrock at
425 the study site, the depth of the crack of about 20 cm can be regarded as the thickness of the weathering
426 layer. Higuchi et al. (2013) suggested that the weathering layer in the top 10 cm of mudstone can easily
427 be eroded by intense rainfall. Erosion exposes fresh bedrock, which would dry in the following dry
428 season and further produce weatherable material.

429

430 (2) Rainfall dissolves the evaporites, producing sodic water that increases physical erosion during
431 typhoon events. The resulting dissolved sodium causes higher hillslope erosion by deflocculation,
432 leading to increased suspended sediment in the channels. In the study site, hillslope erosion rate is
433 about 9-30 cm/year (Higuchi et al., 2013; Yang et al., 2021a). At Nanxiong Bridge, the denudation rate
434 approaches about 142,857 ton/km²/yr, measured from river suspended load (Dadson et. al., 2003), and
435 the chemical weathering flux is 124-237 ton/km²/yr (Chou, 2008; this study). The high hillslope
436 erosion rate ensures a steady supply of freshly exposed bedrock, allowing for high chemical weathering
437 rates.

438

439 (3) Physical erosion enhances silicate weathering and bedrock exposure on hillslopes. Clay minerals
440 in mudstone deposits are abraded from the abundantly available sediment and provide material for
441 silicate weathering in streams. Ultimately, with frequent typhoon events and high temperatures in the
442 study area, this dynamic cycle could repeat several times a year.

443

444 **Figure. 6.** Cycle of feedback between physical erosion rate (PER) and solute flux in badlands
 445 catchment. Red blocks represent dry season conditions. Blue region represents typhoon conditions.
 446 Brown region represents the bedrock and indicates the type and proportion of minerals of mudstone
 447 (Tsai, 1984b).

448

449 **6. Conclusion**

450 We presented major element compositions of stream water from two sites in the Erren River catchment
 451 at three-hour intervals during a three-day typhoon event in 2017. At Guting Station (upstream),
 452 $TDS_{\text{evaporite}}$ is covariant with TDS_{sil} , the sodium adsorption ratio, and the suspended sediment
 453 concentration, which can be assigned to dissolved evaporite (e.g., halite and gypsum). The excess
 454 sodium in the evaporite deposits causes material dispersion through deflocculation, which enhances
 455 the suspended sediment flux. Our observations show that the water chemistry of the typhoon event is
 456 mainly contributed by silicate weathering at $16.8 \text{ ton/km}^2/\text{yr}$ and evaporite weathering at 10.9

457 ton/km²/yr, in contrast with baseflow (non-typhoon) conditions that are mainly contributed by
458 carbonate weathering. Moreover, during the course of the typhoon, we observed a shift from
459 predominantly evaporite weathering during peak precipitation to silicate weathering at peak discharge.

460

461 Combining the observation of riverine chemistry, suspended sediment properties, and previous soil
462 water chemistry studies, we propose a feedback cycle between physical erosion and chemical
463 weathering in badlands topography, illustrating that precipitation of evaporites during the dry season
464 produces sodic water during typhoon events and preferentially triggers higher local erosion. The
465 enhanced hillslope erosion and abrasive effects of clay in a high discharge stream enhance bedrock
466 exposure on hillslopes and silicate weathering, respectively. Newly exposed bedrock then produces
467 more weathered material. Although measurements of bedrock mineral chemistry and Sr isotope are
468 still needed for confirming sources of excess sodium and calcium (Fig. 5), we suggest that the
469 conceptual model could provide an insight into landscape change of badlands. The results from our
470 study suggest that high erosion rates in mudstone badlands of the Erren River catchment are due to
471 both weakened lithology and the interaction between evaporites and hillslope erosion.
