8 **Abstract.** The sediment of alluvial riverbeds plays a significant role in river systems both in engineering and
9 natural processes. However, the sediment composition can show high spatial and temporal heterogeneity, even on
10 river reach scale, making it difficult to representatively sample and assess. Conventional sampling methods are
11 inadequate and time-consuming for effectively capturing the variability of bed surface texture in these situations.
12 In this study, we overcome this issue by adopting an image-based, Deep Learning (DL) algorithm. The algorithm
13 was trained to recognise main sediment classes in videos that were taken along cross-sections underwater in the
14 Danube river. 27 river bed samples were collected and analyzed for validation.. The introduced DL-based method
15 is fast, i.e., the videos of 300-400-meter-long sections can be analysed within minutes, with continuous spatial
16 sampling distribution (i.e., the whole riverbed along the path is mapped with images, in cca. 0.3 – 1 m² sized,
17 overlapping windows). The quality of the trained algorithm was evaluated i) mathematically by dividing the
18 annotated images into test and validation sets, and also via ii) intercomparison with other direct (sieving of
19 physical samples) and indirect sampling methods (wavelet-based image processing of the riverbed images),
20 focusing on the percentages of the detected sediment fractions. For the final evaluation, the sieving analysis of the
21 collected physical samples were considered as the ground truth. After correcting for samples affected by bed
22 armouring, comparison of the DL approach with 14 physical samples yielded a mean classification error of
23 4.5%. Besides, the spatial trend in the fraction changes was also well captured along the cross-sections, based upon
24 the visual evaluation of the footages. Suggestions for performing proper field measurements are also given,
25 furthermore, possibilities for combining the algorithm with other techniques are highlighted, briefly showcasing
26 the multi-purpose of underwater videos for hydromorphological assessment.

28 image-based

29 **1 Introduction**

30 The physical composition of a riverbed plays a crucial role in fluvial hydromorphological processes, as a sort of
31 boundary condition in the interaction mechanisms between the flow and the solid bed. Within these processes, the
32 grains on the riverbed are responsible for multiple phenomena, such as flow resistance (Vanoni and Hwang, 1967;
33 Zhou et al., 2021), stability of the riverbed (Staudt et al., 2018; Obodovskiy et al., 2020), development of bed
34 armour (Rákóczi, 1987; Ferdowski et al., 2017), sediment clogging (Rákóczi, 1997; Fetzer et al., 2017), fish shelter
35 (Scheder et al., 2015), etc. Through these physical processes, the bed material composition has a determining
36 effect on numerous river-uses, e.g., possibilities of inland waterway transport (Xiao et al., 2021), drinking water
37 supply through bank filtration (Cui et al., 2021), or the quality of riverine habitats (Muñoz-Mas et al., 2019)..

38 Knowledge of riverbed morphology and sediment composition (sand, gravel and cobble content) is therefore of
39 major importance in river hydromorphology. In order to gain information about riverbed sediments, in situ field
40 sampling methodologies are implemented.

41

42 Traditionally, bed material sampling methods are intrusive (i.e., sediment is physically extracted from the bed for
43 follow-up analysis) and carried out via collecting the sediment grains one-by-one (areal, grid-by-number and
44 pebble count methods, see e.g., Bunte and Abt, 2001; Guerit et al., 2018) or in a larger amount by a variety of
45 grab samplers (volumetric methods, such as WMO, 1981; Singer, 2008). This is then followed by measuring their
46 sizes individually on-site or transporting them to a laboratory for mass-sieving analysis (Fehr, 1987; Diplas, 1988;
47 Bunte and Abt, 2001). These sampling procedures are time- and energy consuming, especially in large gravel and
48 mixed bed rivers, where characteristic grain sizes can strongly vary both in time and space (Wolcott and Church,
49 1991; USDA, 2007), requiring a dense sampling point allocation. The same goes for critical river reaches, where
50 significant human impact led to severe changes in the morphological state of the rivers (e.g., the Upper section of
51 the Hungarian Danube; Török and Baranya, 2017). When assessing bed material composition on a river reach
52 scale, experts usually try to extrapolate from the samples, and describe larger regions of the bed (even several
53 thousand m²) by data gathered in a few, several dozen points (see e.g., USDA, 2007; Haddadchi et al., 2018;
54 Baranya et al., 2018; Sun et al., 2021). Gaining a representative amount of the sediment samples is also a critical
55 issue. For instance, following statistical criteria such as those of Kellerhals and Bray (1971) or Adams (1979), a
56 representative sample should weigh ten-to-hundred kg. Additionally, physical bed material sampling methods are
57 unable to directly quantify important, hydromorphological features such as roughness or bedforms (Graham et al.,
58 2005). Due to these constraints, surrogate approaches have recently been tested to analyse the riverbed. Examples
59 are introduced in the rest of this section. Unlike the conventional methods, these techniques are non-intrusive and
60 rely on computers and other instrumentation to decrease the need of human intervention and speed up the analyses.

61

62 One group of the surrogate approaches is the acoustic methods, where an acoustic wave source (e.g., an Acoustic
63 Doppler Current Profiler; ADCP) is pointed towards the riverbed from a moving vessel, emitting a signal. The
64 strength and frequency of this signal is measured while it passes through the water column, reflecting back to the
65 receiver from the sediment transported by the river, and finally from the riverbed itself. This approach is fast and
66 larger areas can be covered relatively quickly (Grams et al., 2013). While it has already become widely used for
67 describing sediment movement (i.e., suspended sediment, Guerrero et al., 2016; bedload, Muste et al., 2016; and
68 indirectly flow velocity; Shields and Rigby, 2005) and channel shape (Zhang et al., 2008), it has not reached
69 similar breakthrough for riverbed material analysis. Researchers experimented with the reflecting signal strength
70 [dB] from the riverbed (e.g., Shields, 2010) to establish its relationship with the riverbed material. Their hypothesis
71 was that the absorption (and hence the reflectance) of the acoustic waves reaching the bed correlates with the type
72 of bed sediment. Following initial successes, the method presented several disadvantages and limitations, hence
73 it could not establish itself as surrogate method for riverbed material measurements so far. For example, Shields
74 (2010) showed that it was necessary to apply instrument specific coefficients to convert the signal strength into
75 bed hardness, and these coefficients could only be derived by first validating each instrument using collected
76 sediment samples with corresponding ADCP data. Moreover, the method was sensitive to the bulk density of the
77 sediment and to bedforms. Based on his results and observations, the sediment classification could only extend to

78 differentiate between cohesive (clay, silt) and non-cohesive (sand, gravel) sediment patches, but gravel could not
79 be distinguished strongly from sand as they produced similar backscatter strengths. Buscombe et al. (2014a;
80 2014b) further elaborated on the topic and successfully developed a better, less limited, decision tree-based
81 approach. They showed that spectral analysis of the backscatter is much more effective for differentiating the
82 sediment types compared to the statistical analysis used by Shields. With this approach it became possible to
83 classify homogenous sand, gravel, and cobble patches. However, Buscombe et al. (2014a, 2014b) also emphasizes
84 that acoustic approaches are not capable of separating the effects of surface roughness from the effects of
85 bedforms, therefore the selection of an appropriate ensemble averaging window size is of great importance for
86 their introduced method. This size has to be small enough to not include morphological signal, for which however,
87 the a priori analyses of riverbed elevation profiles is needed at each site. Furthermore, they suggest their method
88 is sensitive to and limited by high concentrations of (especially cohesive) sediment, therefore its application to
89 heterogeneous riverbeds would require site specific calibrations. The above-mentioned studies also note that
90 acoustic methods in general inherently do not allow the measurement of individual sediment grains due to their
91 spatial averaging nature. The detected signal strength correlates with the median grainsize of the covered area,
92 information about other nominal grain sizes cannot be gained.

93
94 Another group of the surrogate approaches is the application of photography (Adams, 1979; Ibbekken and
95 Schleyer, 1986) and later computer vision or image-processing techniques. During the last two decades, two major
96 subgroups emerged: one uses object- and edge detection (by finding abrupt changes in intensity and brightness of
97 the image, segmenting objects from each other; Sime and Ferguson, 2003; Detert and Weitbrecht, 2013), and the
98 other one analyses the textural properties of the whole image, using autocorrelation and semi-variance methods
99 to define empirical relationship between image texture and the grain sizes of the photographed sediments (Rubin,
100 2004; Verdú et al., 2005). Both image processing approaches were very time consuming and required mostly site-
101 specific manual settings, however, a few transferable and more automated techniques have also been developed
102 recently (e.g., Graham et al., 2005; Buscombe, 2013). Even though there is a continuous improvement in the
103 applied image-based bed sediment analysis methods, there are still major limitations the users face with, such as:

- 105 • Most of the studies (all the ones listed above) focuses on gravel bed rivers, and only a few exceptions
106 can be found in the literature where sand is also accounted for (texture-based methods; e.g.:
107 Buscombe, 2013).
- 108 • The adaptation environment was typically non-submerged sediment, instead of underwater
109 conditions (a few exceptions: Chezar and Rubin, 2004; Warrick et al., 2009).
- 110 • The computational demand of the image processing is high (e.g., one to ten minutes per image;
111 Detert and Weitbrecht, 2013).
- 112 • The analysis requires operator expertise (higher than in case of any conventional method).
- 113 • There is an inherent pixel- and image resolution limit (Buscombe and Masselink, 2008 Cheng, 2015;
114 Purinton and Bookhagen, 2019). The finer the sediment, the higher resolution of the images is
115 required (higher calculation time), or they must be taken from a closer position (smaller area and
116 sample per image).

117

118 Nowadays, with the rising popularity of Artificial Intelligence (AI), several Machine Learning (ML) techniques
119 have been implemented in image recognition as well. The main approaches of segmentation contra textural
120 analysis still remain; however, an AI defines the empirical relationship between the object sizes (Igathinatane et
121 al., 2009; Kim et al., 2020) or texture types (Buscombe and Ritchie, 2018) in the images and their real sizes. In
122 the field of river sedimentology a few examples can already be found, where ML (e.g., Deep Learning; DL) was
123 implemented. For instance, Rozniak et al. (2019) developed an algorithm for gravel-bed rivers, performing
124 textural analysis. With this approach, information is not gained on individual grains (e.g., their individual shape
125 and position), but rather the general grain size distribution (GSD) of the whole images. At certain points of the
126 studied river basins, conventional physical samplings (pebble count) were performed to provide real GSD
127 information. Using this data, the algorithm was trained (with ~1000 images) to estimate GSD for the rest of the
128 study site, based on the images. The method worked for areas where grain diameters were larger than 5 mm, and
129 the sediment was well-sorted. The developed method showed sensitivity to sand coverage, blurs, reduced
130 illuminations (e.g., shadows) and white pixels. Soloy et al. (2020) presented an algorithm which used object
131 detection on gravel- and cobble covered beaches to calculate individual grain sizes and shapes. 46 images were
132 used for the model training, however, the number of images were multiplied with data augmentation (rotating,
133 cropping, blurring the images; see Perez and Wang, 2017) to enhance the learning session and increase the input
134 data. The method was able to reach a limited execution speed of a few seconds per m² and adequately measured
135 the sizes of gravels. Ren et al. (2020) applied an ensemble bagging-based Machine Learning (ML) algorithm to
136 estimate GSD along the 70 km long Hanford Reach of the Columbia River. Due to its economic importance, a
137 large amount of measurement data has been accumulated for this study site over the years, making it ideal for
138 using ML. By the time of the study, 13,372 scaled images (i.e., their millimetre/pixel ratio was known) were taken
139 both underwater and in the dry zones, covering approx. 1 m² area each. The distance between the image-sampling
140 points was generally between 50-70 m. An expert defined the GSD (8 sediment classes) of each image by using a
141 special, visual evaluation-classification methodology (Delong and Brusven, 1991; Geist et al., 2000). This dataset
142 was fed to a ML algorithm along with their corresponding bathymetric attributes and hydrodynamic properties,
143 simulated with a 2D hydrodynamic model. Then, it was tested to predict the sediment classes based on the
144 hydrodynamic parameters only. The algorithm performed with a mean accuracy of 53%. Even though this method
145 was not image-based (only indirectly, via the origin of the GSD data), it highlighted the possibilities of an AI for
146 a predictive model, using a high-dimensional dataset. Having such a large data of grain size information can be
147 considered exceptional and takes a huge amount of time to gather, even with the visual classification approach
148 they adapted. Moreover, this was still considered spatially sparse information (point-like measurements, 1 m²
149 covered area/image dozens of meters away from each other). Buscombe (2020) used a set of 400 scaled images
150 to train an AI algorithm on image texture properties, using another image-processing method (Barnard et al., 2007)
151 for validation. The algorithm reached a good result for not only gravel, but sand GSD calculation as well,
152 outperforming an earlier, but promising, texture-based method (wavelet analysis; Buscombe, 2013). In addition,
153 the method required fewer calibration parameters than the wavelet image-processing approach. The study also
154 foresaw the possibility to train an AI which estimates the real sizes of the grains, without knowing the scale of
155 one pixel (mm/pixel ratio) if the training is done properly. The AI might learn unknown relationships between the
156 texture and sizes if it is provided with a wide variety (images of several sediment classes) and scale (mm/pixel
157 ratio)) of dataset (however, it is also prone to learn unwanted biases). Recently, Takechi et al. (2021) further

158 elaborated on the importance of shadow- detection and removal, using a dataset of 500 pictures for training a
159 texture-based AI, with the help of an object-detecting image-processing technique (Basegrain; Detert and
160 Weitbrecht, 2013). The previously presented studies, applying ML and DL techniques, significantly contributed
161 to the development and improvement of surrogate sampling methods, incorporating the great potential in AI.
162 However, there are still several shortcomings to these procedures. Firstly, none of the image-based AI studies
163 used underwater recordings, even though the underwater environment offers completely different challenges.
164 Secondly, the training images were always scaled, i.e., the sizes of the grains could be easily reconstructed, which
165 is again complicated to accomplish in a river. Lastly, they were not adapted for continuous (i.e., spatially dense)
166 measurement, but rather focused on a sparse grid-like approach.

167

168 The goal of this study is to further investigate the applicability of image processing as a surrogate method, and
169 attempt solve the shortcomings of previous AI-based approaches. Hence, we introduce a riverbed material
170 analysing, DL algorithm and field measurement methodology, along with our first set of results. The introduced
171 technique can be used to measure the gravel and sand content of the submerged riverbed surface. It aims to
172 eventually become a practical tool for exploratory mapping, by detecting sedimentation features (e.g., deposition
173 zones of fine sediment, colmation zones, bed armour) and helping decision making for river sedimentation
174 management. Also, the long-term hypothesis of the authors includes the creation of an image-based measurement
175 methodology, where underwater videos of the riverbed could serve multiple sediment related purposes
176 simultaneously. Part of which is the current approach for mapping the riverbed material texture and composition.
177 Others include measuring the surface roughness of the bed (Ermilov et al., 2020) and detecting bedload movement
178 (Ermilov et al., 2022).

179

180 Compared to the studies introduced earlier, the main novelty of our study is that both the training and analysed
181 videos are recorded underwater, continuously along cross-sections of a large river. Furthermore, the training is
182 unscaled, i.e., the camera-riverbed distance varies while recording the videos, without considering image-scale.
183 Moreover, compared to the relatively low number of training images in most previous studies, we used a very
184 large dataset (~15000) of sediment images for the texture-based AI, containing mostly sand, gravel, cobble, and
185 to a smaller extent: bedrock together with some other, non-sediment related objects.

186

187 **2 Methods**

188 **2.1 Case studies**

189 The results presented in this study are based on riverbed videos taken during three measurement campaigns, in
190 sections of the Danube River, Hungary. The first campaign was at Site A, Ercsi settlement (~ 1606 rkm) where 3
191 transects were recorded, the second one was at Site B, Gönyű settlement (~ 1791 rkm) with 2 transects, and the
192 third was at Site C, near to Göd settlement (~ 1667 rkm) with 2 transects (Fig. 1). Each transect was recorded
193 separately (one video per transect), therefore our dataset included a total of 8 videos.

194
195
196

Figure 1: The location of the riverbed videos, where the underwater recordings took place. All sites were located in Hungary, Central Europe. The surveys were carried out on the Danube River, Hungary’s largest river.

203

The training of the DL algorithm was done using the video images of Site C and a portion of A (test set; see later in Section 2.3), while Site B and the rest of the images from A served for validation. The measurements were carried out during daytime, at mid-water regime ($Q = 1900 \text{ m}^3/\text{s}$) in case of Site A, and low water regime ($Q = 1350 \text{ m}^3/\text{s}$) at Site B, and Site C ($Q = 700 \text{ m}^3/\text{s}$). This latter site served only for increasing the training image dataset (i.e., conventional samplings were not carried out at the time of recording the videos), thus we do not go into further details with it for the rest of the study, but the main characteristics are listed in Table 1.

	Site A	Site B	Site C
Q_{survey} [m^3/s]	1900	1350	700
B_{survey} [m]	300 – 450		
$H_{\text{mean, survey}}$ [m]	3.5 - 4.5		
S_{survey} [cm/km]	15		
SSC_{survey} [mg/l]	25	20	14
Characteristic sediment riverbed	gravel, sandy gravel	gravel, gravelly sand	gravel, sandy gravel
$Q_{\text{annual, mean}}$ [m^3/s]	2000	2200	1400
$Q_{1\%}$ [m^3/s]	5300	5500	4700

204 **Table 1: Main hydromorphological parameters of the measurement sites. Q_{survey} : discharge during survey; B_{survey} : river**
205 **width during survey; $H_{\text{mean, survey}}$: mean water depth during the survey; S_{survey} : riverbed slope during survey; SSC_{survey} :**
206 **mean suspended sediment concentration during the survey; $Q_{\text{annual, mean}}$: annual-mean of the discharge at the site; $Q_{1\%}$:**
207 **flood with 1% annual exceedance probability.**

208 As underwater visibility conditions are influenced by the suspended sediment (SSC_{survey} – susp. sed.
209 concentration), the characteristics of this sediment transport is also included in Table 1. The highest water depths
210 were around 6-7 m in all cases. In Site A, measurements included mapping of the riverbed with a camera along
211 three separate transects (Fig. 2a). At Site B, two transects were recorded (Fig. 2b).

221

222

223

224

225

226

Fig. 3 presents a sketch of the measurement process with the equipment and a close-up of the underwater instrumentation. During the field measurements, the camera was attached to a streamlined weight (originally used as an isokinetic suspended sediment sampler) and lowered into the water from the vessel by an electric reel. The camera was positioned perpendicularly to the water and the riverbed, in front of the nose of the weight. Next to the camera, two diving lights worked as underwater light sources, focusing into the camera's field of view (FoV). In addition, four laser pointers were also equipped in hand-made isolation cases to provide possible scales for secondary measurements. They were also perpendicular to the bottom, projecting their points onto the underwater

227 camera field of view. Their purpose was to ensure a visible scale (mm/pixel ratio) in the video footages for
228 validation. During the measurement procedure, a vessel crossed the river slowly through river transects, while the
229 position of the above detailed equipment was constantly adjusted by the reel. Simultaneously, ADCP and RTK
230 GPS measurement were carried out by the same vessel, providing water depth, riverbed geometry, flow velocity,
231 ship velocity and position data. Based on this information and by constantly checking the camera's live footage
232 on deck, the camera was lowered or lifted to keep the bed in camera sight and avoid colliding with it. The sufficient
233 camera – riverbed distance depended on the suspended sediment concentration near the bed and the used
234 illumination. The reel was equipped with a register, with its zero adjusted to the water surface. This register was
235 showing the length of cable already released under the water, effectively the rough distance between the water
236 surface and the camera (i.e., the end of the cable). Due to the drag force this distance was not vertical, but this
237 value was continuously compared to the water depth measured by the ADCP. Differencing these two values, an
238 approximation for the camera – riverbed distance was given all time. The sufficient difference could be established
239 by monitoring the camera footage while lowering the device towards the bed. This value was then to be maintained
240 with smaller corrections during the survey of the given cross-section, always supported by observing the camera
241 recording, and adjusting to environmental changes. The vessel's speed was also adjusted based on the video and
242 slowed down if the video was blurry or the camera got too far away from the bed (see later in Section 3.3). The
243 measurements required three personnel to i) drive the vessel, ii) handle the reel, adjust the equipment position,
244 and monitor the camera footage, iii) monitor the ADCP data, while communicating with the other personnel (see
245 Fig. 3).

246
 247 **Figure 3: Left: sketch of the measurement process. The vessel was moving perpendicular to the riverbank along a cross-**
 248 **section (i). A reel was used to lower a camera close to the riverbed (ii). Simultaneously, the bed topography and water**
 249 **depth were measured by an ADCP (iii). Right: Close-up sketch of the underwater instrumentation.**

250 The video recordings were made with a GOPRO Hero 7 and a Hero 4 commercial action cameras. Image
 251 resolutions were set to 2704x2028 (2.7K) with 60 frame per second (fps) and 1920x1080 (1080p) with 48 fps,
 252 respectively. Other parameters were left at their default (see GOPRO 2014; 2018), resulting in slightly different
 253 quality of produced images between the two cameras. We found that a 0.2-0.45 m/s vessel speed with 60 fps
 254 recording frequency was ideal to retrieve satisfactory images in a range of 0.4-1.6 m camera-bed distances. This
 255 meant approximately 15 minutes long measurements per transects. Further attention needed to be paid to the reel
 256 and its cable during the crossing when the equipment was on the upstream side of the boat. If the flow velocities
 257 are relatively high (compared to the total submerged weight of the underwater equipment), the cable can be pressed
 258 against the vessel-body due to the force from the flow itself, causing the reel cable to jump to the side and leave
 259 its guide. This results in the equipment falling to the riverbed and the measurement must be stopped to reinstall
 260 the cable. For illumination, a diving light with 1500 lumen brightness and 75° beam divergence, and one with
 261 1800 lumen and 8° were used. The four lasers for scaling had 450-520 nm (purple and green) wavelength and 1-
 262 5 mW nominal power. Power supply was ensured with batteries for all instruments.

263
 264 At Site A and Site B, conventional bed material (physical) samplings were also carried out by a grabbing (bucket)
 265 sampler along the analysed transects. At each cross-section 4-5 samples were taken, with one exception where we
 266 had 10. The measured GSDs were used to validate results of the AI algorithm. Separately, a visual evaluation of
 267 the videos was also carried out, where a person divided the transects into subsections based on their dominant
 268 sediment classes, after watching the footages.

269 2.3 Image analysis: Artificial Intelligence and the wavelet method

270 In this study, we built on the former experiences of the authors, using Benkó et al., 2020 as a proof-of-concept,
271 where the developed algorithm was applied for analysing drone videos of a dry riverbed. The same architecture
272 was used in this study, which is based on the widely used Google's DeeplabV3+ Mobilnet, in which many novel
273 and state-of-the-art solutions are implemented (e.g., Atrous Spatial Pyramid Pooling; Chen et al., 2018). The
274 model was implemented with Pytorch, exploiting its handy API and backward compatibility. The main goal was
275 to build a deep neural network model which can recognise and categorise (via semantic segmentation; Chen et al.,
276 2018) at least three main sediment size classes, i.e., sand, gravel and cobble, in the images, while being quickly
277 deployable. The benefit of the introduced method compared to conventional imagery methods lies in the potential
278 of automation and increased speed. If the annotation and training is carried out thoroughly, analysing further
279 videos can run effortlessly, while the computation time can be scaled down either vertically (using stronger GPUs)
280 or horizontally (increasing the number of GPUs; if parallel analysis of images is desired). In this study a TESLA
281 K80 24GB GDDR5 348bit GPU, an Intel Skylake Intel® Xeon® Gold 6144 Processor (24.75M Cache, 3.50 GHz)
282 CPU with 13GB RAM was used. Also, contrary to other novel image-processing approaches in riverine sediment
283 research (Buscombe, 2013; Detert and Weitbrecht, 2013), the deep convolutional neural network is much less
284 limited by image resolution and mm/pixel ratios, because it does not rely on precise pixel count. This is an
285 important advantage to be exploited here, as we perform non-scaled training and measurements with the DL, i.e.,
286 camera-bed distance constantly changed, and size-reference was not used in the images by the DL.

287
288 Fig. 4 presents the flowchart of our DL-based image processing methodology. The first step after capturing the
289 videos was to cut them into frames, during which the videos were exploded into sequential images. Our
290 measurement setup proved to be slightly nose-heavy. Due to this, and the drag force combined, the camera tilted
291 forward during the measurements. As a result, the lower parts of the raw images were sometimes too dark, as the
292 camera was looking over the riverbed, and not at the lit part of the bed. In this study, this problem was handled by
293 simply cutting out the lower 25% of the images as this was the region usually containing the dark, unlit areas.
294 Brightening and sharpening filters were applied on the remaining part of the images to improve their quality. Next,
295 the ones with clearest outlines and best visibility were chosen. This selection process was necessary because this
296 way the delineation process (learning the prominent characteristics of each class) can be executed accurately,
297 without the presence of misleading or confusing images, e.g., blurry or dark pictures where the features are hard
298 to recognise. For training purposes, we chose three videos from different sections each being ~15 minutes long
299 with 60 fps and 48 fps, resulting in 129 600 frames. In fact, such a large dataset was not needed due to the strong
300 similarity of the consecutive frames. The number of images to be annotated and augmented were therefore

decreased to ~2000. We also performed a white balance correction on some of the images to improve visibility, making it even easier to later define the sediment class boundaries. We used an additional algorithm to generate more data, with the so-called Simplest Colour Balance method (Limare et al., 2011). It is a simple, but powerful histogram equalisation algorithm which helps to equalise the roughness in pixel distribution.

These steps were followed by the annotation, where we distinguished ten classes: silt-clay, sand, gravel, cobble, boulder (mainly riprap), bedrock, clam-upside, clam-downside, vegetation, unidentified (e.g., wreckages). Annotation was carried out by a trained personnel, not by the authors, and performed with the help of an open-source software called PixelAnnotationTool (Breheret, 2017), which enables the user to colour mask large parts of an image based on colour change derivatives (i.e., colour masking part of the images which belong to the same class, e.g., purple/red – sand, green – gravel, yellow – cobble, etc.). The masks and outlines were drawn manually, together with the so-called watershed annotation. That is, when a line was drawn, the algorithm checked for similar pixels in the vicinity and automatically annotated them with the same class. The annotation was followed by a data augmentation step where beside mirroring, cropping, rotating the images (to decrease the chance of overfitting), we also convolved them with different filters. These filters added normally distributed noise to the photos to influence the watershed algorithm and applied sharpening, blurring, darkening, and white balance enhancement. Thus, at the data level, we tried to ensure that any changes in water purity, light, and transparency, as well as colour changes, were adequately represented during training. Images were uniformly converted to 960x540 resolution, scaling them down to make them more usable to fit in the GPU's memory. The next step was to convert all the images from RGB (Red-Green-Blue) based colour to grayscale. This is important because colour images have 3-channels, so that they contain a red, a green, and a blue layer, while grayscale images' pixel can only take one value between 0 and 255. With this colour conversion we obtained a threefold increase in computational speed. In total, a dataset of 14,784 human-annotated images was prepared (from the ~2000 images of the 3 training videos). The next step was to separate this dataset into training and validation sets. In this study, we used 80% of it for training the DL algorithm, while 20% was withheld and reserved for the validation of the training. It was important to mix the images so that the algorithm selects batches in a pseudorandom manner during training, thus preventing the model from being overfitted. Finally, after

Figure 4: Flowchart of the applied methodology.

341 several changes in the hyperparameters (i.e., tuning), the evaluation and visualisation of the training results were
342 performed. Tuning is a general task to do when building DL Networks, as these hyperparameters determine the
343 structure of the network and the training process itself. Learning rate, for example, describes how fast the network
344 refreshes, updates itself during the training. If this parameter is set too high, the training process finishes quickly,
345 but convergence may not be reached. If it is too low, the process is going to be slow, but it converges. For this
346 reason, nowadays the learning rate decay technique is used, where one starts out with a large learning rate, then
347 slowly reduces it. The technique generally improves optimization and generalization of the DL Networks (You et
348 al., 2019). In our case, learning rate was initialised to 0.01, with 30000 iteration steps, and the learning rate was
349 reset after every 5000 iterations with a decay of 0.1. Another important parameter was the batch size, which sets
350 the number of samples fed to the network before it updates itself. Theoretical and empirical evidence suggest that
351 learning rate and batch size are highly important for the generalization ability of a network (He et al., 2019). In
352 our study, a batch size of 16 was used (other general values in the literature are 32, 64, 128, 256). We used a cross-
353 entropy loss function.

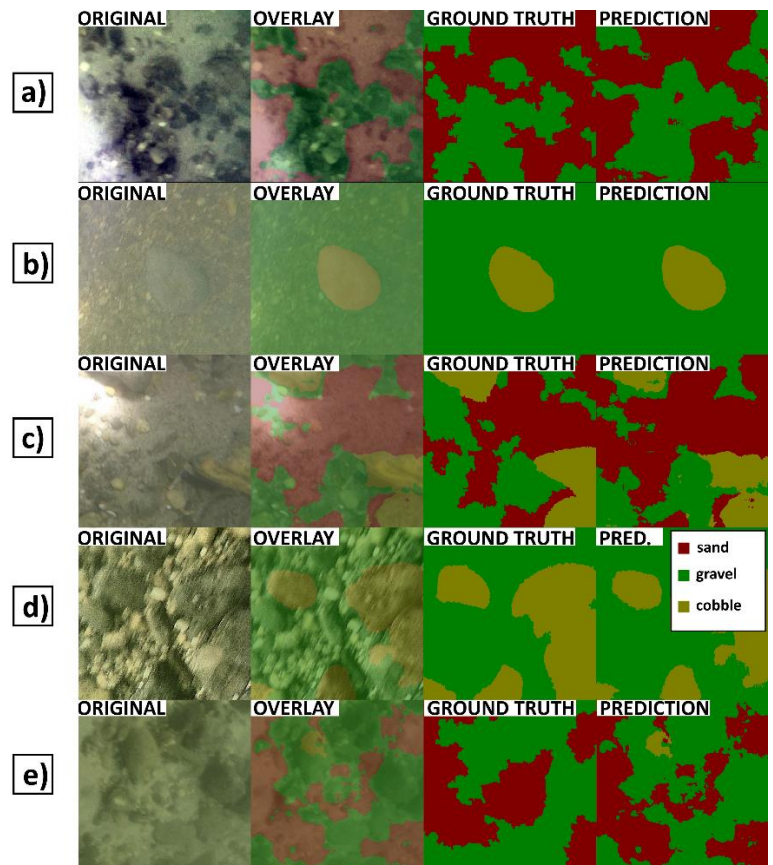

354
355 As previously discussed, the training of the deep learning (DL) algorithm proceeded without the application of
356 scaling, obviating the need for the laser equipment. Nevertheless, our original intention was to employ laser
357 pointers to establish a spatial scale for the recorded videos, serving as a supplementary validation measure.
358 Regrettably, the lasers did not operate as initially anticipated, rendering their continuous utilization during the
359 cross-sectional surveys and the pursuit of transactional scaling and validation unfeasible. Consequently, we shifted
360 our focus to validation at specific physical sampling points, where we could utilize the lasers properly. We adopted
361 a textural image-processing approach to analyse the video images captured at these sampling locations. In this
362 regard, we opted for the previously mentioned, transferable wavelet-based signal- and image-processing
363 technique. This method allows for the computation of the image-based grain size distribution from the selected
364 images. The analysis entails examining the grey-scale intensity along the pixel-rows and -columns within the
365 image, treating them as individual signals. This technique utilises the less-constrained wavelet transform, instead
366 of the Fourier transform, to decompose these signals. Ultimately, by computing the power spectra and determining
367 the sizes (firstly in pixel, then changing to millimeter, using the scale) of the wavelet components (each
368 corresponding to an individual grain), the user can derive the grain size distribution for the given image. Prior to
369 this study, this methodology had demonstrated its efficiency as a non-DL image-processing technique for mixed
370 sediments (Buscombe, 2013; 2020) and had previously been tested by us, under underwater conditions as well
371 (Ermilov et al., 2020).

372 **3 Results and discussion**

373 **3.1 Evaluation of the training**

374 To evaluate the training process, the 2957 images of the validation set were analysed by the developed DL
375 algorithm and its results were then compared to their human-annotated counterparts. Fig. 5a-d shows results of
376 original images (from the validation set), their ground truth (annotation by the training personnel), as well as the
377 DL prediction (result of the model). The overlays of the original and the predicted images are also shown for
378 better visualization. Calculating the overall pixel accuracy (i.e., the percent of pixels that were correctly classified

379 during validation) returned a satisfactory result with an average 96% match (over the 2957 validation images,
 380 each having 960x540 resolution, adding up to a total of 1 532 908 800 pixels as 100%). As this parameter in object
 381 detection and DL is not a stand-alone parameter (i.e., it can still be high even if the model performs poorly), the
 382 mean IoU (intersection-over-union or Jaccard index) was also assessed, indicating the overlap of ground truth
 383 area and prediction area, divided by their union (Rahman and Wang, 2016). This parameter showed a much
 384 slighter agreement of 41.46%. Interestingly, there were cases, where the trained model gave better result than the
 385 annotating personnel. While this highlighted the importance of thorough and precise annotation work, it also
 386 showcased that the number of poor annotations was relatively low, so that the algorithm could still carry out
 387 correct learning process and later detections, while not being severely affected by the mistake of the training
 388 personnel. Fig. 5e showcases an example for this: the correct appearance of cobble (yellow) in the prediction,
 389 even though the user (ground truth) did not define it during annotation. As a matter of fact, these false errors also
 390 decrease the IoU evaluation parameter, even though they increase the performance of the DL algorithm on the
 391 long term. Hence, this shows that pure mathematical evaluation may not describe the model performance entirely.
 392 Considering that others also reported similar experience with DL (Lu et al., 2018) and the fact that 40% and 50%
 393 are generally accepted IoU threshold values (Yang et al., 2018; Cheng et al., 2018; Padilla et al., 2020), we
 394 considered the 41.46% acceptable, while noting that the annotation and thus the model can further be improved.
 395 The general quality of our underwater images may have also played a role in lowering the IoU result.
 396

397
 398 **Figure 5: a-d) Example comparisons of ground truth (drawn by the annotating personnel, 3rd column) and DL**
 399 **predicted (result of analysing the raw image by the previously trained DL model, 4th column) during the validation**
 400 **process. The 1st column shows raw images, while the 2nd column overlays the result of the DL detection on the raw**
 401 **image for better visual context. e) Example of training personnel mistake during the annotation (i.e., lack of**
 402 **cobble/yellow annotation in ground truth) and how the DL performed better by hinting at the presence of the cobble**
 403 **fraction, leading to a false negative result during validation.**

One of these quality issues for the DL algorithm was associated with the illumination. Using a diving light with small beam divergence proved counterproductive. The high intensity, focused light occasionally caused overexposed zones (white pixels) in the raw bed image, misleading the DL algorithm and resulting in detection of incorrect classes there (Fig. 6a). In darker zones, where the suspended sediment concentration was higher and at the same time, the effect of camera tilting was not completely removed by preprocessing, the focused light sometimes reflected from the suspended sediment itself and resulted in brighter patches in the images (Fig. 6b). This also caused false positive detections.

In each masked image, the occurring percentage of the given class (i.e., the percentage of the pixels belonging to that class/colour mask, compared to the total number of pixels in the image) was calculated and used as the fraction percentage in that given sampling point. These sediment classes reconstructed by the DL algorithm were then compared to three alternative results: i) visual estimation, ii) GSD resulted from conventional grab sampling, iii) wavelet-based image-processing. In the followings, results from two cross-sections will be highlighted, one from Site A, the video used for the training, and one from Site B, being new for the DL. An averaging window of 15 m was applied on each cross-sectional DL result to smoothen and despike the dataset. The interval of physical sample collection in wider rivers can range anywhere between 20-200 m within a cross-section, depending on the river width and the homogeneity of riverbed composition. The averaging window size was chosen to be somewhat lower than our average applied physical sampling intervals in this study, but still in the same order of magnitude. The scope of the present study did not include further sensitivity analysis of the window size. In the followings, the reader is led through the comparison process via the example of two transects, and is given the over-all evaluation of the accuracy of the method.

431 3.2.1 Visual evaluation and physical samples

432 In Fig. 7a, we depict the vessel's trajectory within Section A – II at Site A. The path is color-coded based on our
433 visual assessment of the riverbed images, with distinct colors representing the prevalent sediment type at each
434 specific location on the riverbed. Additionally, we have marked the positions of physical bed material samples
435 with yellow markers for reference. App. Fig. A1 presents the unprocessed results of the DL detection for each
436 analysed image along Section A – II, prior to any moving-average smoothing. It's important to note that our current
437 approach is highly sensitive, occasionally resulting in substantial fluctuations in DL detection between successive,
438 slightly displaced video frames. Owing to this sensitivity and the inherent uncertainty in the coordinates of the
439 underwater photos and their corresponding physical samples, we discourage making direct comparisons by
440 selecting a specific image and its DL detection. Instead, we have implemented a moving-average-based smoothing
441 technique for each raw, cross-sectional DL detection, using a window size of 15 meters at each site. These moving
442 averages serve as the basis for comparisons with the physical sampling data and the wavelet method. For the sake
443 of clarity, we have included the raw DL detections of all sampling point images in the Appendix, although these
444 results may not precisely reflect their corresponding moving-average values. In Fig. 7b, we present a comparison
445 between the cross-sectional visual classification and the DL-detected sediment fractions in percentage after
446 applying the moving-average smoothing (i.e., the smoothed version of App. Fig. A1). Any noise observed in these
447 results is primarily attributable to abrupt changes in lighting conditions, which can occur either when visual
448 contact with the riverbed is momentarily lost due to sudden bathymetrical changes or as a result of increased
449 suspended sediment concentration. Overall, our DL results exhibit a commendable concordance with human
450 evaluations. For instance, in the vicinity of 100 meters from the left bank, between sampling points AII-1 and AII-
451 2, the DL algorithm correctly identifies a peak with approximately 70% sand and 30% gravel. Moreover, on either
452 side of this peak, a steep transition to gravel and a decline in sand content are observed, consistent with visual
453 observations, which we have labelled as "sandy gravel" and "gravelly sand." The DL algorithm also accurately
454 identifies mixed sediment zones on both riverbanks.

455

456

457 **Figure 7: a)** The path of the vessel and camera in Section A – II, Site A. The polyline is coloured based on the sediment
 458 features seen during visual evaluation of the video. Yellow markers are the locations of physical bed material samplings.
 459 (Map created with Google Earth Pro). **b)** The visual evaluation of the dominant sediment features in the video (top)
 460 compared to sediment fraction percentage, recognised by the DL algorithm (bottom). DL result after applying moving-
 461 averaging. The visual evaluation included four classes: gravel – G, sandy gravel – sG, gravelly sand – gS, sand – S).
 462 The fractions of the physical samples are shown as verticals.

463

464 At site B (Fig. 8a) the river morphology is more complex compared to Site A as a groyne field is located along
 465 the left bank (see Fig. 2b). As such, the low flow regions between the groynes yield the deposition of fine
 466 sediments, and much coarser bed composition in the narrowed main stream. As it can be seen, the DL algorithm
 467 managed to successfully distinguish these zones: the extension of fine sediments in the deposition zone at the left
 468 bank were adequately estimated and showed a good match with the visual evaluation for the whole cross-section
 469 (see Fig. 8b).

470

471
 472 **Figure 8:** a) The path of the vessel and camera in Section-B – II, Site B. The polyline is coloured based on the sediment
 473 seen during visual evaluation of the video. Yellow markers are the locations of physical bed material samplings. (Map
 474 created with Google Earth Pro). b) Sediment fraction percentages in Section-B – II, recognised by the AI. The visual
 475 evaluation included two classes: gravel – G, sand – S). The fractions of the physical samples are shown as verticals.

476
 477 Results of the other measurements can be found in the Appendix. App. Fig. C2, D2 and E2 show that the trend of
 478 riverbed composition from the visual evaluation is well-captured by the DL algorithm in the other cross-sections
 479 of the study as well.

480
 481 Next, the physically measured and DL-detected relative proportion of sand, gravel and cobble fractions were
 482 compared in each of the 27 sampling points. Firstly, however, outliers or incomparable data had to be identified.
 483 In our case, this meant the separation of sampling points where the differences between the results of the two
 484 methods were independent from the efficiency and performance of the DL algorithm. This selection was carried
 485 out after analysing the grainsize distribution curves of the weight-sieved physical samples (App. Fig. F1) and the
 486 riverbed images around the sampling points (App. Fig. A3, B1, C4, D4, E4). Based on our findings, the outliers

487 have been identified and separated into Outlier Type A, and Outlier Type B categories. First category included
 488 the sampling points where the GSD curves showcased bimodal (gap graded) distributions. This type of riverbed
 489 sediment distribution is a typical sign of riverbed armouring (Rákóczi, 1987; Marion & Fraccarollo, 1997), where
 490 a coarse surface layer protects the underlying finer subsurface substrate (see e.g., Wilcock, 2005). While the
 491 camera only sees the upper layer, the bucket sampler can penetrate the surface and gather sample from the
 492 subsurface as well. As a result, the two methods cannot be compared solely on the surface distribution. In App.
 493 Fig. A2, supportive images of bed armouring are provided, taken during our surveys in the Upper section of the
 494 Hungarian Danube. Out of the 27 sampling points, 11 were affected by armouring and categorised as Outlier Type
 495 A. The category of Outlier Type B consisted of points from the opposite case: where the riverbed image contained
 496 fine sediment, but the physical samples did not. In these cases, a relatively thin layer of fine sediment covered the
 497 underlying gravel particles. 2 sampling points were categorised as Outlier Type B, both of which were near to the
 498 borderline between a deposition zone behind a groyne, and the gravel bedded main channel. In these cases, the
 499 bucket sampler probably either stirred up the deposited fine sediment and washed it down during its lifting or was
 500 dragged through purely gravel bedded patch during sampling, as the surface composition was rapidly changing
 501 on this before-mentioned borderline. It is important to highlight that the analysis of physical samples involves
 502 measuring and weighing various sediment size classes, leading to weight distribution. In contrast, imaging
 503 methods offer surface distributions, and as a consequence, the presence of a thin layer of fine sediments on the
 504 surface can significantly skew the resulting composition (Bunte and Abt, 2001; Sime and Ferguson, 2003; Rubin
 505 et al., 2007).

506

	Comparable data	Outlier Type A	Outlier Type B	Σ
No. sampling points	14	11	2	27

507 **Table 2: After evaluating the results of the sieving analyses and riverbed surface images, out of the 27 sampling points,**
 508 **14 were defined as comparable between the applied sampling methods. 11 points were categorised as Outlier Type A,**
 509 **because their GSD curves were bimodal. 2 points were defined as Outlier Type B, since their images showed the**
 510 **presence of fine sediment, while the sieve analyses did not.**

511

512 Overall, the DL-based classification agreed well within the comparable sampling points, with an average error of
 513 4.5% (Fig. 9). It can be seen that even though in outlier points AII-1 and AI-3 the DL algorithm coincidentally
 514 gave good match with the sieving analysis, in the rest of the outlier points the DL- and physical-based results
 515 systematically differ from each other, supporting our outlier selection methodology.

522

Figure 9: Comparison of relative sediment fractions between the DL detection and physical samples. The three main sediment types (sand-gravel-cobble) are marked with different colour and symbols. The name of the sampling points where the given relative proportion was measured/detected is also written for gravel and sand (cobble was negligible). The proportions of outlier sampling points are marked with white/grey, while the symbol represents the sediment type respectively. The comparable points have their proportions with green (gravel) and red (sand) symbols.

523 3.2.2 Wavelet analysis

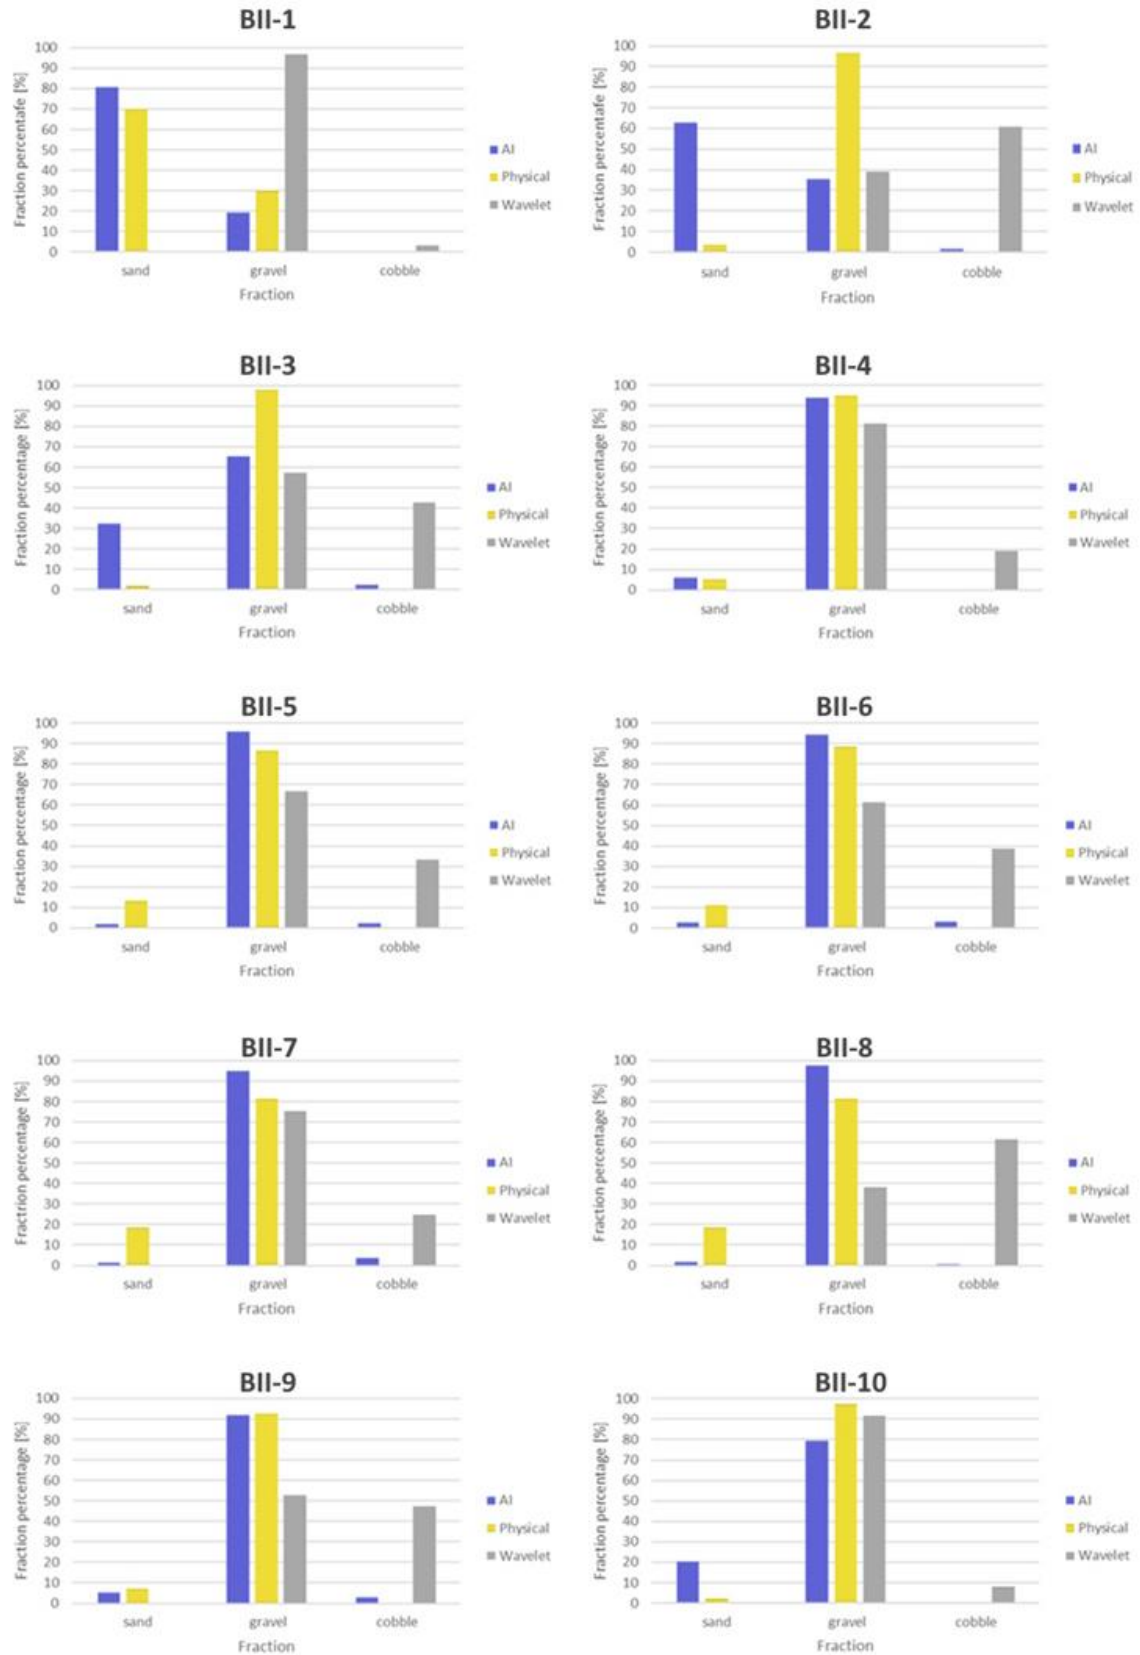

524 Regarding the wavelet analysis-based imaging technique, it is evident that there is a slight overall overestimation
525 of coarse particles, and the accurate reconstruction of sand classes is not achieved. This observation aligns with
526 our earlier field experiences reported in Ermilov et al. (2020), where we highlighted the wavelet technique's
527 pronounced sensitivity to image resolution. We demonstrated that to successfully detect a grain, its diameter must
528 be at least three times larger than a pixel. In the subsequent analysis, we compare the sediment proportions
529 determined by the wavelet-based method to those obtained earlier through DL and physical-based approaches,
530 presenting the results in bar plots (Fig. 10, 11). For instance, when the camera was positioned closer to the riverbed
531 at sampling points AII-1 and AII-4, resulting in a more favourable mm/pixel ratio, the wavelet algorithm was able
532 to detect coarse sand accurately. However, it struggled to identify finer sand, leading to lower sand percentage
533 estimates (Fig. 10). In other sampling points where sand particles were below the resolution limit, the wavelet
534 method consistently identified the presence of cobbles instead (Fig. 10), a distinction not made by the other two
535 methods. This pattern broadly characterizes the wavelet method's performance during our study. For illustrative
536 purposes, we provide an example highlighting the differences in the capabilities of these two methods in Figure
537 12. While both methods detect the presence of two major sediment categories, the wavelet technique interprets

538 the information as a mixture of gravel and cobbles, whereas the DL algorithm recognizes the presence of sand
 539 coverage and gravel particles.
 540

541 **Figure 10: Comparison of relative sediment fraction proportions [%] at the sampling locations from the moving-**
 542 **averaged DL detection, conventional sieving and the wavelet-based image processing method. Section A – II.**

548
 549 **Figure 12: a) Wavelet analysis result of the underwater image in BII-2. b) DL detection result of the same image.**

550
 551 Overall, the comparison between the two image-based method showed greater discrepancies (Fig. 13), due to the
 552 limitations of the wavelet approach, discussed earlier. The same sampling points were labelled as outliers as
 553 earlier. As it can be seen, the wavelet significantly differed in the points where the physical samples and DL-
 554 detections matched (green data points), due to its excessive, false cobble detections. However, it showed good
 555 agreement with the DL in most of the outlier points, supporting the earlier observation: the surface in those points
 556 was composed of solely gravel, and the finer fractions of the physical samples must have come from the
 557 subsurface. Hence, the outlier selection process was well based.

558
 559 **Figure 13: Comparison of sediment fractions between the DL detection and the wavelet approach, for the selected**
 560 **sampling points. The three main sediment types (sand-gravel-cobble) are marked with different colour (red-green-**
 561 **yellow) and symbols (diamond-circle-square) respectively. The name of the sampling points where the given relative**
 562 **proportion was measured/detected is also written for gravel. The proportions of outlier sampling points are marked**
 563 **with white/grey, while the symbol represents the sediment type respectively. The comparable points have their**
 564 **proportions with green (gravel), red (sand) symbols.**

565
566 Based on the results presented in this study, it could be established that the DL algorithm managed to recognise
567 the main features of the riverbed material composition from underwater videos with satisfactory accuracy in the
568 comparable sampling points (based on the sieving analysis of physical samples) and along cross-sections (based
569 on the visual evaluation). The method showed good potential for mapping heterogenous riverbeds along river
570 cross-sections. Furthermore, the wavelet proved to be a limited comparison tool with the introduced field
571 measurement methodology, as this latter did not provide it with the sufficient resolution most of the time.

572

573 **3.3 Implementation challenges**

574

575 The power supply for the entire imaging infrastructure, including the camera, diving lights, and lasers, relied on
576 batteries. However, due to the lower temperatures at the river bottom, the battery depletion rate was significantly
577 accelerated compared to typical conditions. To address this issue, we explored the option of a direct power supply
578 from the motorboat. Ensuring the camera's optimal positioning posed challenges as well. Proximity to the riverbed
579 risked damage to the equipment, while excessive camera-bed distances compromised image quality. To maintain
580 a clear view of the riverbed while avoiding blurry images, we utilized real-time ADCP water depth data to adjust
581 the camera's position, while simultaneously optimizing the boat's velocity. Increasing the recording frequency and
582 reducing exposure time emerged as potential solutions to mitigate this limitation. Lower vessel velocities were
583 not feasible, as they would have caused the vessel to drift out of the desired section. Alternatively, moving along
584 longitudinal (streamline) paths rather than transects may present the opportunity for slower vessel speeds,
585 potentially resulting in higher-quality images in the future. However, the conventional approach for river
586 bathymetry surveys typically involves transversal paths due to lower spatial variations along streamlines
587 compared to the transverse direction (Benjankar et al., 2015; Kinsman, 2015). Therefore, implementing
588 longitudinal paths may require a denser network to obtain sufficient data, thus increasing time demands. Hence,
589 careful consideration of path selection and interpolation methods becomes critical for this alternative approach.
590 Another challenge pertained to the impact of drag force on the measurement setup. Although the main body had
591 a streamlined design, the addition of other tools disrupted the setup's geometry. Additionally, we encountered a
592 slight imbalance in weight distribution. Long-term solutions could involve constructing a streamlined container
593 (e.g., a 3D-printed body or a body resembling unmanned underwater vehicles) with designated slots for each
594 device and improving weight distribution. Furthermore, we hypothesized that using lasers (as originally planned
595 in this study) during measurements could assist in orthorectifying the images, leveraging the known structure and
596 positioning of laser points' projections when the setup is perpendicular to the riverbed. This could reduce the
597 impact of occasional tilting, which may affect size analysis if scaling is included. In our specific case, we
598 demonstrated that the wavelet method had inherent limitations (e.g., image resolution limits) when applied within
599 our methodology, issues not attributable to camera tilting, as these would have had a significantly lower error
600 magnitude.

601

602 As for the training of the DL algorithm with the underwater images, the illumination is indeed a more crucial
603 aspect, compared to normal imagery methods. In many cases only the centre areas of the images were clearly
604 visible, whereas the remaining parts were rather dark and shady. Determining the boundaries between distinct

605 sediment classes for these images was challenging even for experienced eyes. This quality issue generated
606 incorrect annotations at first. To overcome this issue, manually varying the white balance thus enhancing the
607 visibility of the sediment could improve the results of the training. It is known that when DL methods are to be
608 used, most of the problems arise from the data side (Yu et al., 2007), whereas issues related to the applied
609 algorithms and hardware are rare. This is because data is more important from an accuracy perspective than the
610 actual technical infrastructure (Chen et al., 2020). The time demand of image annotation (data preparation) is
611 relatively high, i.e., a trained person could analyse roughly 10 images per hour. On the other hand, as introduced
612 earlier, a great advantage of using DL is the capability of improving the quality of training itself, often yielding
613 better agreement with reality, compared to the manual annotation. Similar results have been reported by Lu et al.,
614 (2018). This at the same time proves that with the introduced approach, there is no need for very precise manual
615 training, thus a fast and effective training process can eventually be achieved.

616

617 The validation of the DL algorithm is far from straightforward. In this study, four approaches were adopted: a
618 mathematical approach, and comparison with three other measurement methods, respectively. The mathematical
619 approach was based on calculating pixel accuracy and the Intersection-over-union parameter, as it is usually done
620 in case of DL methods to describe their efficiency (e.g., Rahman and Wang, 2016). However, the DL model in
621 some cases overperformed, and provided more accurate results for the sediment composition than the human
622 annotator did. This meant the calculated difference between the annotated validation images and their responding
623 DL-generated result was not solely originated from underperformance of the DL-model, but from human error as
624 well. Consequently, using only the mathematical evaluation in this study could not describe adequately the model
625 performance. Hence, the results were compared to those of three other methods: i) visual evaluation of the image
626 series, ii) a wavelet-based image-processing method (using the method of Buscombe, 2013) and iii) riverbed
627 composition data from physical samples. Considering the features of the applied methods, the first one, i.e., the
628 visual observation, is expected to be the most suitable for the model validation. Indeed, when assessing the bed
629 surface composition by eye, the same patterns are sought, i.e., both methods focus on the uppermost sediment
630 layer. On the other hand, the physical sampling procedure inherently represents subsurface sediment layers,
631 leading to different grain size distributions in many cases. For instance, as shown earlier, if bed armour develops
632 in the riverbed and the sampler breaks-up this layer, the resulted sample can contain the finer particles from the
633 subsurface. On the contrary, in zones where a fine sediment layer is deposited on coarse grains, i.e., a sand layer
634 on the top of a gravel bed, the physical samples represent the coarse material too, moreover, considering that the
635 sieving provides weight distribution this sort of bias will even enhance the proportion of the coarse particles.
636 Attempts were made to involve a third, wavelet-based method for model validation. However, this method failed
637 when finer particles, i.e., sand, characterized the bed. This is an inherent limitation of these type of methods, as
638 discussed earlier, i.e., when the pixel size is simply not fine enough to reconstruct the small grain diameters in the
639 range below fine gravel. Lastly, the most comparable sample points were selected to quantify the performance of
640 the DL. Holding the sieved physical samples as ground truth, the DL algorithm showed promising results. The
641 average error (difference) between DL-detected and physically measured relative sediment fraction portion
642 percentages was 4.5%. Furthermore, the DL algorithm successfully detected the trend of changing bed
643 composition along complete river cross-sections.

644

645 As it is known, the ML and DL models can learn unknown relationships in datasets, but unwanted biases as well.
646 With our current dataset, these biases would be the darker tones of visible grain texture and the lack of larger grain
647 sizes. This way our model in its current state is only applicable effectively in the chosen study site, until the dataset
648 is not expanded with additional images from other rivers or regions. However, the purpose of the study was to
649 introduce the methodology itself and its potential in general and not to create a universal algorithm.

650 **3.4 Novelty and future work**

651 The introduced image-based DL algorithm offers novel features in the field of sedimentation engineering. First,
652 to the authors' knowledge, underwater images of the bed of a large river have not yet been analysed by AI. Second,
653 the herein introduced method enables extensive mapping of the riverbed composition, in contrast to most of the
654 earlier approaches, where only several points or shorter sections were assessed with imagery methods. Third, the
655 method is much faster compared to conventional samplings or non-DL-based image-processing techniques. The
656 field survey of a 400 m long transect took ~15 minutes, while the DL analysis took 4 minutes (approx. 7 image/s).
657 The speed range of 0.2-0.45 m/s of the measurement vessel and the 15 minutes per transect complies with the
658 operating protocol of general ADCP surveys on rivers (e.g., RD Instruments, 1999; Simpson, 2002; Mueller and
659 Wagner, 2013). Hence, the developed image-based measurement can be carried out together with the conventional
660 boat-mounted ADCP measurements, further highlighting its time efficiency. Hence, the method offers an
661 alternative approach for assessing riverbed material on-the-go, in underwater circumstances. As an extensive and
662 quick mapping tool, it can support other types of bed material samplings in choosing the sampling locations and
663 their optimal number. Furthermore, it can be used for quickly detecting areas of sedimentation and their extent,
664 as we showed in Section 3.2. (e.g., Fig. 12b). This way, it can support decision-making regarding the maintenance
665 of the channel or the bank-infiltrated drinking water production (detecting colmation zones). Fourth, a novel
666 approach was used for the imaging and model training. As the camera-bed distance was constantly changing, the
667 mm/pixel ratio also varied. Hence, no scale was defined for the algorithm beforehand. As we discussed in Section
668 1., earlier DL methods for sediment analysis (e.g., Soloy et al., 2020) all applied fixed camera heights and/or
669 provided scaling for the AI. Furthermore, these studies were based on airborne measurements, mapping the dry
670 zone of the rivers. In an underwater manner, it is extremely challenging to keep a fixed, constant camera height
671 due to the spatially varying riverbed elevations. By avoiding the need for a scale, our method is faster and simpler
672 to use. As a drawback, our method does not reconstruct detailed grainsize distributions, but rather measures the
673 relative portions of the main sediment classes: sand, gravel, cobble. In short, this study showcased a fast bed
674 material mapping tool, with a much denser spatial resolution than the conventional methods, saving up significant
675 resources.

676
677 Originally, beside the three classes of main sediment types introduced in the study, others were also defined during
678 annotation (e.g., bedrock, clams), but due to class imbalance (i.e., dominance of the three sediment classes), these
679 were not discriminated successfully. In the future, improving the method through transfer learning (Zamir et al.,
680 2018) using broader dataset and involving other sediment types will be considered. Another option for developing
681 the method is to counter imbalance with the use of so-called weighted cross entropy (see Lu et al., 2019) on the
682 current dataset, which will also be investigated.

683

684 Since the introduced method offers a quick way to provide extensive, spatially dense bed material information of
685 its composition, it can be used to boost the training dataset of predictive, ensemble bagging-based Machine
686 Learning techniques (e.g., Ren et al., 2020) and improve their accuracy. Furthermore, the method can support the
687 implementation of other imaging techniques. For instance, using one of the training videos of this study the authors
688 managed to reconstruct the grain-scale 3D model of a riverbed section with the Structure-from-Motion technique
689 (Ermilov et al., 2020), enabling the quantitative estimation of surface roughness. Underwater field cameras can
690 also be used for monitoring and estimating bedload transport rate (Ermilov et al., 2022) by adapting Large-scale
691 – Particle Image Velocimetry and the Statistical Background Model approach. This latter videography technique
692 may also be used with moving cameras (e.g., Hayman and Ekhlund, 2003), which enables its adaptation into our
693 method by e.g., detecting bedload movement in the cross-section.

694
695 The statistical representativity of the introduced method, as a surface sampling technique, needs to also be
696 addressed in future work. Following and building upon the experience of conventional, surface sampling
697 procedures (e.g., grid sampling; Diplas, 1988) may prove to be beneficial, where they provided the exact number
698 of gravel particles needed to be included (Wolman, 1954) to satisfy the representativity criteria. Then, using edge-
699 and blob-detection would enable to calculate and compare the number of gravel particles in the images to this
700 value. Furthermore, we intend to apply 2 cameras, with overlapping FOVs for increasing the covered area (and
701 the representativity) during surveys. Besides, it would also improve the accuracy of the Structure-from-Motion
702 technique mentioned earlier.

703 **4 Conclusion**

704 We introduced a novel, AI-based method for riverbed sediment analysis. The method uses underwater images to
705 reconstruct spatial variations in sediment grain sizes. Trained and validated with ~15.000 underwater images
706 collected in a section of the Danube in Hungary, we showed that the method can map the riverbed along the
707 vessel's route at a high spatial density of approximately 60-100 overlapping sample images per meter. The method
708 does not require a scale and thus allows the distance between the camera and the riverbed to vary. In contrast to
709 conventional point samples of river-bed substrate, our method provides spatially continuous data, that can be
710 further enhanced (e.g., by interpolation) to 2D maps. The method can be applied in studies where dense
711 information about river-bed composition is required, such as riverine habitat studies, computational hydro- and
712 morphodynamic models, or analyses of river-restoration measures. **Financial support.** The first author
713 acknowledges the support of the ÚNKP-21-3 New National Excellence Programme of the Ministry for Innovation
714 and Technology, and the National Research, Development and Innovation Fund, Hungary.

715 **Code availability.** The code written and used in this study is available [here](#).

716 **Data availability.** The dataset and results can be accessed using the following links:
717 [link1](#); [link2](#); [link3](#).

718 **Author contributions.** GB developed the code and carried out the training process. AAE carried out the
719 fieldwork, evaluated the results, did the laboratory analysis, and collaborated with GB in improving the images.
720 SB oversaw and directed the project, while managing the financial- and equipment background.

721 **Competing interest.** The contact author has declared that none of the authors has any competing interest.

722 **Acknowledgements.** The authors would like to thank our students Dávid Koós, Gergely Tikász, Schrott Márton
723 and our technicians István Galgóczy, István Pozsgai, Károly Tóth and András ReháK for fieldwork support.

1137
1138 Figure E5: Riverbed video images overlapped with their raw, DL detection result, at the sampling points in Section B
1139 - I.

1140

1141 Appendix F

1142
1143 Figure F1: Grainsize distribution curves of the 27 sieved physical samples. 11 curves categorised as Outlier Type-A are
1144 showcased with dashed lines. The shapes of these curves are representing bimodal (gap graded) sediment distributions,
1145 which typically refers to bed armouring (i.e., excess of a certain particle size, a coarser surface layer protects a finer
1146 subsurface layer from being washed away). Hence, analysing images of the surface layer could not represent these
1147 complex distributions inherently.
