16

17 **Abstract.** Rock fracturing comprises a key component of a broad array of Earth surface processes due to its direct control on rock
18 strength as well as rock porosity and permeability. However, to date, there has been no standardization for the quantification of
19 rock fractures in surface processes research. In this work, we make the case for standardization within fracture-focused research
20 and review prior work to identify various key datasets and methodologies. We then present a suite of standardized methods that
21 we propose as ‘baseline’ for fracture-based research in surfaces processes studies. These methods have been shown in preexisting
22 work from structural geology, fracture mechanics, and surface processes disciplines to comprise best practices for the
23 characterization for cracks, clasts, and outcrops. These practical, accessible and detailed methods can readily be employed across
24 all fracture-focused weathering and geomorphology applications. The wide adoption of a baseline of data, all collected using the
25 same methods, will enable comparison and compilation of data among studies globally, and ultimately will lead to a better
26 understanding of the links and feedbacks between rock fracture and landscape evolution.

27 1 Introduction

28 Rock fracture in surface and near-surface environments plays a key role in virtually all Earth surface processes. The propagation
29 of opening-mode cracks (versus shear- or compression-mode) in bedrock and loose clasts occurs universally at or near the surface
30 of Earth (e.g. within ~500 m - Moon et al., 2020) and on other terrestrial bodies (Molaro et al., 2020). It epitomizes mechanical
31 weathering and the development of ‘critical zone architecture’, i.e., the evolving porosity, permeability, and strength of near-
32 surface rock (e.g., Riebe et al., 2021). Herein, we use the terms crack and fracture interchangeably to refer to any planar, *open* void
33 in rock, regardless of origin or scale (more details below), acknowledging that a large body of geologic literature also refers to
34 veins or dikes - filled with secondary minerals - as ‘fractures’. The size, number, and/or orientation of fractures exert enormous
35 influence on both rock mechanical properties (Ayatollahi and Akbaridoost, 2014) and rock hydrological properties (e.g., Leone et
36 al., 2020; Snowdon et al., 2021). Fractures therefore influence a wide array of natural and anthropogenic landscape features and
37 processes including channel incision (e.g., Shobe et al., 2017), sediment size and production (e.g., Sousa, 2010), hillslope erosion
38 (e.g., DiBiase et al., 2018; Neely et al., 2019), built environment degradation (Hatir, 2020), landslide and rockfall hazards (e.g.,
39 Collins and Stock, 2016), groundwater and surface water processes (e.g., Maffucci et al., 2015; Wohl, 2008), and vegetation
40 distribution (e.g., Aich and Gross, 2008). Additionally, crack propagation and coalescence produce clastic sediment. The resultant
41 physical properties of that sediment (i.e., clast size distribution, mass, porosity, etc.) control both hillslope and stream processes
42 (e.g., Chilton and Spotila, 2020; Glade et al., 2019).

43
44 With fractures so clearly central to so many surface processes, it is crucial to understand the factors that control rock fracturing
45 rates and processes. To fully do so requires a large body of data quantifying fracture-related characteristics and phenomena in a
46 variety of subaerial environments; however, to date, no standardized set of field methods has been established to quantify cracks
47 in the modern surface processes realm. Consequently, data collected across studies cannot be readily compared or coalesced. The
48 purpose of this paper is therefore to define such standards for surface processes research by combining prior fracture methodology
49 studies from other geoscience disciplines with methods that have been developed, tested and refined during more than 20 years of
50 field-based crack-observations for surface processes-related research (Aldred et al., 2015; Eppes and Griffing, 2010; Eppes et al.,
51 2018; Eppes et al., 2010; McFadden et al., 2005; Moser, 2017; Shobe et al., 2017; Weiserbs, 2017).

52
53 Building on this combination of past work, here, we first define the benefits of establishing a standard procedure for fracture-
54 focused surface processes field research, describing how our chosen methods outperform other approaches. We then provide the

55 methods themselves including: 1) a set of guiding principles that should be employed for all surface processes research involving
56 rock fractures; 2) a list of crack and rock data measurements that constitute “basic” field-based metrics; and 3) detailed methods
57 that comprise best practices for collection of these data. Finally, we provide some suggestions for data analyses, and demonstrate
58 a real case example of how the proposed methods lead to reproducible results across users. We limit ourselves to field observations
59 on subaerially exposed rock, i.e., cracks that can be observed with the naked eye or basic hand lens on exposed outcrops or clasts.
60 We do not address measurement of smaller cracks (e.g., those visible with microscopy) or of buried fractures (e.g., those visualized
61 in bore-holes or with indirect geophysical methods). In providing these standardized methods to the surfaces processes community,
62 we hope to accelerate the overall characterization and conceptualization of how a most basic feature of all rock – its open fractures
63 – contributes to the processes and evolution of Earth’s surface and critical zone.

64 1.1 The value of a standardized approach

65 Particularly within the fields of geomorphology and weathering sciences, no common suite of data, methods, or terminology has
66 been defined or described that comprises an analysis of fractures. Although some crack characterization field methods exist in the
67 context of structural geology and aquifer and reservoir characterization (e.g., Watkins et al., 2015; Wu and Pollard, 1995; Zeeb et
68 al., 2013), they diverge significantly in their approaches because they were largely developed for the specific application of each
69 unique study. Furthermore, the terminology and methods used to describe natural fractures across this existing research are largely
70 limited to only those fractures loosely interpreted to be tectonically induced ‘joints’, and published works rarely provide clear
71 criteria, even for choosing which fractures to measure. This lack of consistency severely limits the ability of the geomorphic
72 community to reproduce methods, or to combine, compare, or interpret different fracture datasets.

73
74 The dearth of standardized methodology in quantifying natural fractures is in contrast with methods available for other components
75 of Earth systems. The development of consistent methods undergirds most quantitative Earth sciences. For example, the fields of
76 sedimentology and soil science have clear, standardized methods to acquire what constitutes the “basic” data for their observations.
77 Sedimentologists have long shared common metrics and methods for quantifying grain size, sorting, rounding, and stratigraphic
78 records (e.g., Krumbein, 1943). Similarly, soil scientists share common methods, metrics, and nomenclature for describing soil
79 profiles and horizons (e.g., Birkeland, 1999 Appendix A; Soil Survey Staff, 1999). The realization of the need for standard methods
80 has also remained constant in lab based rock mechanics over the last several decades, driving the American Society for Testing
81 and Materials (ASTM) and International Society for Rock Mechanics (ISMR) to publish ongoing standards and methods papers
82 (e.g., Ulusay and Hudson, 2007).

83
84 Standards like those mentioned above exist because workers have long recognized and reaped the the benefits of standardized
85 methods. Standardized methods can frequently lead to major step-change innovations when data are combined. For example,
86 standardized soil methods allowed for 100 m scale mapping across the US, enabling detailed human–landscape models that can
87 aid in preserving vital soil resources (Ramcharan et al., 2018). Another major example arises from the field of rock mechanics.
88 Prior to the 1950s, theoretical developments of rock failure and plasticity lagged behind other branches of geophysics and
89 engineering, limited both by technology and, arguably more so, by lack of consistent methods. Across rock mechanics, methods
90 for repeatable failure testing were then developed, largely in the groups led by Knoppf, Griggs, and Turner in the USA and Australia
91 (Wenk, 1979). This standardization culminated in the landmark series of papers that made the observations driving the next 50
92 years of experimental rock mechanics (Borg and Handin, 1966; Handin et al., 1963; Handin and Hager, 1958, 1957; Heard, 1963;

93 Mogi, 1971, 1967; Turner et al., 1954), as well as continued methods development in field and laboratory methods linking structural
94 geology and experimental rock mechanics (Wenk, 1979).

95

96 Across the limited studies where field observation crack methods have been standardized, major advances have also occurred as a
97 result. For example, noting the similarity of crack data collected with standardized methods across a range of climates (McFadden
98 et al., 2005; Eppes et al., 2010; Eppes et al., 2015; Aldred et al., 2016) was foundational in motivating and validating the
99 construction of a predictive model of how and why moisture impacts rates of crack evolution (e.g., Eppes and Keanini, 2017).
100 This work has led to a greater appreciation within surface processes research that rock cracking is a complex, time- and climate-
101 dependent, non-linear process. How can we begin to understand it across teams without a standard set of observation methods?

102

103 **1.2 Development of the Standardized Crack Measurement Approach**

104 Particularly for the case of fracture-focused research outside of geomorphology applications, the need for standardized methods
105 has already been established. Within this prior body of research, the methods we propose below have been shown to outperform
106 other approaches. In one case example, study participants were asked to measure fractures with no particular instructions given for
107 how to collect the data other than where to collect it. The wide variance in resulting datasets collected by different users led to the
108 conclusion that, without common and clearly established measurement criteria, fracture characterization is rife with subjective bias
109 that severely impacts interpretations of results (Andrews et al., 2019). Then, based on post-data collection interviews and
110 workshops, Andrews et al., (2019) scrutinized the source of the variance and provided a list of suggested best-practices that would
111 serve to best eliminate the subjectivity of data collection that was leading to the bias.

112

113 In another case example, Zeeb et al. (2013) sought to determine how different sampling approaches leads to censoring bias of
114 different crack sizes from outcrop data by applying different sampling methods to artificially generated fracture networks that had
115 known parameters. Analysis of data collected using scanline, window, and circular estimator methods revealed that the window
116 approach resulted in the lowest uncertainty for most parameters and required the fewest measurements to provide representative
117 datasets.

118

119 We incorporate the suggested best-practices from the two case examples above as well as from other published research in the
120 methods we describe below. For example, our approach of measuring any continuous open fracture as a single fracture is preferable
121 over trying to interpret separate linked fractures, which can vary significantly depending on the scale of observation (e.g., Ortega
122 and Marrett, 2000), and thus tends to amplify selective bias of the user (Andrews et al., 2019). Similarly, the use of a crack size
123 cut-off has been shown in other studies to be crucial to maintaining reproducibility of results (e.g., Ortega et al., 2006), and window
124 sampling was chosen as it provides the most accurate representation of the rock mass (e.g., Zeeb et al., 2013), and results in the
125 least user-variance in results (Andrews et al., 2019). Measuring fracture apertures with a crack-comparator (section 8.4.2) provides
126 better constrained aperture-size distributions than other techniques, particularly for sub mm widths (e.g., Ortega et al., 2006).
127 Several studies have shown that measuring all fractures – i.e., a complete inventory as described in section 4.2 – provides the most
128 accurate representation of the full fracture characteristics of a rock body (e.g., Wu and Pollard, 1995).

129

130 The standardized methods below were also chosen by us to optimize data collection as it relates to modern geomorphology
131 questions. We focus on open fractures found in surface outcrops and clasts because these fractures can represent both surface and
132 subsurface fracture processes, and impact rock strength and hydrology. Other geoscience research frequently employs crack

133 characteristic data from natural rock exposures. Outcrop fracture measurements are commonly employed to explain lithofacies
134 variability observed in subsurface wireline logs for hydrocarbon production (e.g., Milad and Slatt, 2019) and structural modeling
135 (e.g., Hennings et al., 2000), or to validate shallow geophysical measurements inferred to reflect fracture density (e.g., Flinchum
136 et al., 2018; Novitsky et al., 2018). A major distinction between geomorphology and weathering fracture-focused research
137 compared to other fracture-based geosciences is the recognition and interest in environmentally-driven cracking (see section 2.2
138 below for examples). Fracture data from loose clasts can serve to isolate environmentally-driven processes like thermal stress
139 cracking from those related to gravity or tectonics (e.g., McFadden et al., 2005; see section 2.3 below). Thus, we describe methods
140 for both outcrop and clast data collection.

141 **2 Standardized methods: Guiding principles**

142 **2.1 Natural rock cracking background**

143 The design of any fracture-related study must arise from consideration of the general factors that influence how and if a rock will
144 crack. Here, we provide a very brief overview of some key rock fracture mechanics concepts behind these factors. Eppes and
145 Keanini (2017) and Eppes (2022) provide more detailed reviews of rock fracture processes in the context of surface processes.

146
147 Rocks fracture in response to the complex sum of all tectonic (e.g., Martel, 2006), topographic (e.g., St. Clair et al., 2015; Moon
148 et al., 2020; Molnar, 2004), biological (e.g., Brantley et al., 2017), and environment-related (e.g., Matsuoka and Murton, 2008;
149 Gischig et al., 2011) stresses they experience. Fracturing can occur when stresses exceed the failure criteria (i.e., rock's material
150 strength). More commonly, however, because critical stresses are only rarely reached in nature, fractures can also propagate
151 *subcritically* at stresses as low or lower than 10% of the rock's strength (see textbooks like Schultz, 2019; Atkinson, 1987).

152
153 Overall, subcritical cracking processes and rates are strongly dependent on stress magnitude, but they are *also* strongly influenced
154 by the size of the fracture that is under stress, as well as the environmental conditions that impact crack tip bond breaking (see
155 fracture mechanics textbooks like Anderson, 2005). Stresses applied to the rock body are concentrated at crack tips proportional
156 to the length of the crack (a concept embodied by the term 'stress intensity'), effectively increasing the stresses experienced directly
157 in that location. The environmental factors known to impact subcritical rock cracking -- in a manner separate from their influence
158 on stresses -- include vapor pressure, temperature, and pore-water chemistry (Eppes and Keanini, 2017; Eppes et al., 2020; Brantut
159 et al., 2013). Therefore, in the context of surface processes, climate matters twice for rock cracking: 1) as it contributes to the
160 stresses that the rock experiences, and 2) as it contributes to the chemo-physical processes that break bonds at crack tips as they
161 propagate.

162
163 Just as other common physical properties like tensile strength can be measured, rocks can be tested for their propensity to crack
164 subcritically by the measurement of subcritical cracking parameters such as the subcritical cracking index (e.g., Paris and Erdogan,
165 1963). These parameters influence both the rate and the characteristics (e.g., crack density or length) of subcritical cracking in rock
166 (e.g., Olson, 2004). In sum, natural rock cracking is not necessarily the singular, catastrophic event as it is typically portrayed; but
167 rather may be a slowly evolving process that progresses over geologic time that is influenced by complex amalgamations and
168 feedbacks between rock and fracture properties, as well as environmental, topographic, and tectonic factors.

169 **2.2 Site selection and study design using a State Factor approach**

170 Due to their influence on rock cracking as described above, all potential driving stresses and variations in crack environments must
171 be considered in site selection and study design for any fracture-related research. We recommend employing the ‘State Factor’
172 approach (Jenny, 1941) that has been well-vetted in the weathering and soil science disciplines. Here, we assert that applying this
173 soil science paradigm to fracture research is relevant because fracturing processes are influenced by each of these factors, just as
174 are all other chemical processes acting on rock and soil. This is particularly true when the subcritical nature of rock fracture is
175 considered (section 2.1). Thus, by employing a State Factor approach to fracture-based research, all factors that could contribute
176 to fracture propagation styles and rates are considered and controlled for as much as possible within the aims and scope of the
177 research for any given site. These ‘State Factors’ - long categorized as they relate to overall soil development, of which physical
178 weathering is a component (e.g., Jenny, 1941) - are equally applicable to fractures alone: climate (cl, both regional climate and
179 microclimate), organisms (o, flora and fauna), relief (r, topography at all scales), parent material (p, rock properties) and time (t,
180 exposure age or exhumation rate). For rock fracture, tectonics (T) should be added to this list, making cl,o,r,p,t,T.

181
182 Hereafter, we employ the term ‘site’ to refer to a single location, of either a group of rock clasts or a group of outcrops, whereby
183 all clasts or outcrops within the ‘site’ could be reasonably assumed to have experienced similar State Factors over their exposure
184 history. For example, a site might comprise a single boulder bar on an alluvial fan surface or a single ridgeline with several outcrops.
185 Once the specific State Factors, including the internal variability of each site, are identified for all the sites within a given field
186 area, a series of sites can be selected whose State Factors are known and controlled for as much as possible. This enables a study
187 of the influence of a single factor across the sites, i.e., fracture chronosequences, climosequences, toposequences, or lithosequences.

188
189 As outlined in the background above, for rock fracture, it is important to understand how each cl,o,r,p,t,T factor may contribute
190 both to stresses that give rise to cracking, and/or to the molecular-scale processes that serve to subcritically break bonds at crack
191 tips. Each has the potential to independently impact cracking rates, styles, and processes. In the following paragraphs, we briefly
192 provide examples of how each of the State Factors may influence rock fracture.

193 2.2.1 Climate (cl)

194 *Climate (cl)* as a State Factor refers not just to regional mean annual precipitation or temperature, but also the local microclimate
195 of a site, which may be influenced by site characteristics such as runoff or aspect. The presence of liquid water increases the
196 efficacy of water-related stress-loading processes like those related to freezing (Girard et al., 2013) or chemical precipitation of
197 salts or oxides (e.g., Buss et al., 2008; Ponti et al., 2021). Moisture – particularly vapor pressure – can also serve to accelerate rock
198 cracking rates independent of any stress-loading (e.g., Eppes et al., 2020; Nara et al., 2017). Temperature cycling can produce
199 thermal stresses (through differential expansion and contraction of both adjacent minerals as well as different portions of the rock
200 mass; e.g., Ravaji et al., 2019), and also can influence rates and processes of crack-tip bond breaking (e.g., Dove, 1995).

201 2.2.2 Organisms (o)

202 *Organisms (o)* refers to both flora and fauna - everything from overlying vegetation and large animals to roots and microorganisms,
203 all of which may provide a source of rock stress and/or may influence water availability or chemistry. These relationships can be
204 complex and unexpected. For example, tree motion during wind, and root swelling during water uptake, both exert stresses on rock
205 directly (Marshall et al., 2021). Organism density and type can impact rock water and air chemistry (Burghelca et al., 2015), both
206 of which may impact the rates and processes of subcritical cracking (e.g. review in Brantut et al., 2013).

207 2.2.3 Relief (*r*)

208 In the context of State Factors, *relief* (*r*) refers generically to all metrics related to topography including aspect, slope, and
209 convexity. Topography impacts the manifestation of both gravitational stresses as well as tectonic stresses within the rock body
210 (Molnar, 2004; Moon et al., 2020; Martel, 2006). The directional aspect of a particular outcrop or boulder face may also influence
211 insolation and water retention, translating into differences in micro climate and vegetation, and thus weathering overall (e.g.,
212 Burnett et al., 2008; West et al., 2014; McAuliffe et al., 2022) including fracturing (Persico et al., 2021).

213 2.2.4 Parent material (*p*)

214 The *parent material* (*p*) factor in the context of a fracture study refers not only to the specific rock type being fractured, but also
215 to the size and shape of the clast or outcrop. For example, angular corners generally concentrate stresses more than rounded edges
216 (Anderson, 2005). Also, clasts or outcrops of different sizes experience different magnitudes of thermal stresses related to diurnal
217 heating and cooling (Molaro et al., 2017). In addition to rock shape or size, rock material properties directly influence the rates and
218 styles of fracture propagation (Atkinson, 1987) due both to how they respond to stresses but also due to how they allow stresses to
219 arise. For example, different minerals are characterized by different coefficients of thermal expansion. As a result, rocks with
220 different mineral constituents will be more or less sensitive to thermal stresses than others depending on the contrasts between
221 adjacent grains. There is significant variance in this and many other material properties within any given category of rock type,
222 such as ‘granite’ or ‘sandstone’. Grain size, porosity, sedimentary features, and metamorphic fabrics all influence the rates and
223 characteristics of fracture growth and susceptibility to different environmental stresses.

224 2.2.5 Time (*t*)

225 *Time* (*t*) likely plays a role in rock fracturing rates just as it does in chemical weathering, whereby outcrops found in slowly-eroding
226 environments or clasts found on old surfaces may be subject to different cracking rates and processes (e.g., Mushkin et al., 2014).
227 Over time, rock mechanical properties can also change as rocks weather (e.g., Cuccuru et al., 2012). Although the time factor has
228 not been well-studied in the context of natural rock fracture, preliminary data suggest that it should be considered (Berberich, 2020;
229 Rasmussen et al., 2021).

230 2.2.6 Tectonics (*T*)

231 Finally, in a fracture-related study, *tectonic* (*T*) setting must also be considered as a State Factor. Joint sets that have formed in the
232 deep subsurface inevitably become exhumed and further increase in both number density (total cracks per area) and intensity (total
233 crack length per area) as they approach the surface. Also, even very low magnitude tectonic stresses can translate to fracture
234 propagation in very near-surface bedrock, especially when interacting with local topography (e.g., Martel, 2011; Moon et al.,
235 2020).

236 2.3 Bedrock outcrops versus deposited clasts

237 The fracture characteristics of outcrops have long been employed as proxies for subsurface fracture networks, and there is a
238 reasonably large body of literature addressing these relationships and their potential pitfalls (e.g., Ukar et al., 2019; Al-Fahmi et
239 al., 2020; Sharifigaliuk et al., 2021). Overall, we emphasize that the researcher should be aware that for any outcrop of *in situ*
240 bedrock, tectonic stresses are likely not the only cause of fractures observed there. Importantly, fractures of all scales that may
241 have initiated in response to rock crystallization, diagenesis, or tectonic stresses in the subsurface continue to propagate and evolve
242 in the near-surface and once exposed subaerially. Thus, topographic and environmental stresses have likely both contributed to

243 any subaerially observed fracture network. For example, a commonly employed criterion for identifying what are interpreted as
244 tectonically formed joints is that there are ‘several in parallel’ (e.g., Ewan et al., 1983). Yet, environmental stresses also produce
245 parallel fractures (e.g., Aldred et al., 2015; Eppes et al., 2010; Mcfadden et al., 2005), as do those related to the morphology of the
246 eroding landscape (Leith et al., 2014).

247

248 For studies that aim to isolate fractures associated with environmental stresses, measurements from clasts may be more useful than
249 outcrops. Clasts that have been transported by fluvial, glacial, or mass-wasting processes have experienced abrasion, and therefore
250 it is highly likely that pre-existing superficial fractures have been removed. Thus, clasts may be more reasonably considered ‘fresh’
251 than an outcrop with an unknown exhumation history, allowing clearer linkages between environmental exposure and observed
252 fractures. This idea of “resetting” fractures within clasts through transport is supported by data showing clasts of identical rock
253 type that have experienced more transport (i.e., rounded river rocks) having higher strength than those found in, for example, recent
254 talus slopes (Olsen et al., 2020).

255 **3 Standardized method: Selecting the clasts, outcrops, or rock surface locations that will comprise the fracture** 256 **observation area**

257 Carefully selecting the rock surface area(s) on which fractures will be observed and measured within a site is equally as important
258 as selecting the site or the fractures themselves. Hereafter, we employ the term ‘observation area’ to refer to the specific portion(s)
259 of rock surface(s) for which cracks are being measured. Observation areas may comprise the entire exposed surface of individual
260 clasts, outcrops, or portions of either (Fig. 1). In the following sections, instructions for selecting these observation areas in the
261 field are provided.

262 **3.1 Establishing outcrop or clast selection criteria**

263 Before observation areas can be identified, outcrops or clasts must be selected. The first step of that selection process is to establish
264 criteria for determining which outcrops or surface clasts within the site are acceptable for measurement. Similar to site selection,
265 variability in c,l,o,r,p,t factors that may influence cracking (temperature, moisture availability, rock shape, and rock type) should
266 be controlled for as much as possible.

267

268 In general, characteristics of the clasts or outcrops that might impact mechanical properties, moisture, or thermal stress-loading
269 should be most heavily considered. The rock type properties that should be considered when developing selection criteria include
270 not only heterogeneities like bedding or foliation, but also grain size and mineralogy, all of which can influence fracture rates and
271 style characteristics. For example, perhaps only outcrops with no visible veins or dikes will be employed; or only outcrops greater
272 than 1 m in height; or only north facing outcrop faces. In past work, for example, we have focused on upward facing surfaces of
273 outcrops or large clasts (e.g., Berberich, 2020; Eppes et al., 2018).

274

275 For loose clasts, only clasts of a particular size or rock type might be employed for measurement. For example, we have found that
276 below approximately 5 cm diameter in semi-arid and arid environments (Eppes et al., 2010), and 15 cm in more temperate
277 environments with vegetation (Aldred et al., 2015), the long-term stability of the positioning of the clast on the surface becomes
278 questionable.

279 **3.2 Non-biased selection of clasts or outcrops for measurement**

280 Once criteria are defined, clasts or outcrops meeting those criteria must be chosen for the fracture measurements. A procedure such
281 as the well-vetted Wolman Pebble Count style transect (Wolman, 1954) should be employed to avoid sampling bias. For landforms
282 with other geometries, a grid may be used instead of a transect line. In either case, a tape transect or net grid is laid out on the
283 ground at each site, and the clast or outcrop closest to specified intervals on the tape (or at the points of the grid meeting the criteria)
284 is selected (Fig. 1a). The interval or grid spacing should be adjusted to the overall size and abundance of clasts or outcrops found
285 on the surface. If there are relatively few meeting the criteria at a site, all within the site (e.g., on a particular boulder bar or
286 ridgeline) meeting the criteria can be measured.

287
288 A similar technique can be applied for selecting more sparsely spaced outcrops. For locations where outcrops are common and
289 vegetation relatively sparse, a grid of a set dimension (e.g., 100 m) is overlain on aerial imagery, and the closest outcrop to each
290 grid intersection meeting the outcrop criteria are selected (Watkins et al., 2015). In sites where outcrops are few, all outcrops might
291 be employed. For areas where outcrops are not visible in aerial imagery, a measured or paced transect can be employed where the
292 user walks along a bearing and chooses the closest outcrop meeting the selection criteria at each interval, e.g., 30 paces.

293
294 In all of the above, transect locations and orientations should be selected following consistent criteria and being mindful of the
295 State Factors *cl, o, r, p, t, T*. For example, all transects or grids might be placed uniformly along backslopes with a certain upslope
296 distance from the crest; or along the latitudinal center or crest of a landform. Alternatively, the transect might be orientated
297 perpendicular or oblique to a paleo-flow direction so that it is not constrained only to bars or swales. The coordinates and bearing
298 of all transects or grids should be recorded, enabling tracking and avoiding repetition.

299 **3.3 Observation areas comprising the entire clast or outcrop surface**

300 The observation area for small clasts and outcrops can be their entire exposed surface. When clasts or outcrops selected for
301 measurements are less than ~50 cm in maximum dimension, we recommend making measurements on all cracks visible on the
302 clast or outcrop exposed surface, without disturbing the rock. This non-disturbance practice is particularly crucial for maintaining
303 Earth's geodiversity (Brilha et al., 2018) and preserving sites for future workers to revisit. Further, research examining acoustic
304 emission localization of rocks naturally cracking found that the large majority of crack 'foci' were located in the upper hemispheres
305 of boulders (Eppes et al., 2016). Thus, we assert that the potential insight gained by moving clasts does not warrant its damage to
306 geoheritage.

307 **3.4 Establishing 'windows' as the observation area for larger clasts and outcrops**

308 When it is not feasible to measure every crack on an outcrop or clast (in our experience this becomes true for most outcrops or
309 boulders greater than 50 cm maximum diameter), the observation area may comprise predetermined 'windows' (Fig. 1b). This
310 window selection method for the area of observation has been demonstrated to result in the most accurate representation of fractures
311 on an entire outcrop (e.g., Zeeb et al., 2013) and is the least affected by subjective bias (Andrews et al., 2019). These windows
312 comprise representative decimeter- to meter-scale square or rectangular areas of the rock surface. Other techniques that require
313 measurements of all cracks that intersect a line (scanlines) tend to under-sample small cracks (La Pointe, 2002), making the scanline
314 approach particularly inappropriate for geomorphology and weathering applications. For areas with large outcrop exposures,
315 circular scanlines combined with a window approach have proven effective (Watkins et al., 2015). Here, we outline a 'window'
316 approach that can be employed regardless of outcrop size or fracture density. We also detail an expansion of crack length

317 measurements – similar to that proposed by Weiss (2008) – so that long fractures are not underrepresented (see length methods
318 below).

319

320 Importantly, the number and size of windows observed on each outcrop or at each site will depend on the typical number and size
321 of cracks present on the surface of the rock (see section 4.2). It is preferable to strike a balance between window size and number
322 so that during data analysis, variance can be quantified by comparing data collected between windows on the same outcrops and
323 at the same site.

324

325 Choosing the placement of windows on the outcrop should entail a stratified random sampling approach. In other words, cl,o,r,p,t,T
326 factors like aspect should be taken into consideration and controlled for as much as possible in the window placement strategy by,
327 for example, only using upward facing surfaces. Then, window placement determination is made to avoid sampling bias and edge
328 effects. For example, if upward facing outcrop surfaces are to be characterized, then the total length and width of the face could be
329 employed to align sufficient numbers of windows along even intervals of those measurements (e.g., for example, three windows
330 whose centers are located along the center axis of the rock, with even spacing between the edges and each box; Fig. 1b).

331

332 For the placement of each window, we recommend employing a simple cardboard template of the appropriate window size with a
333 center hole and trace the outline with chalk directly on the clast or outcrop. Then, all crack measurements are made in the
334 window(s). Each window should be numbered and photographed in the context of each outcrop or clast. Detailed photo-
335 documentation and coordinates to 0.00000 dd are also recommended.

336 3.5 How many observation areas?

337 The number of clasts, outcrops, or windows required to measure sufficient cracks will vary with the study goals, site complexity,
338 and the variables for which the data are being tested or controlled. Importantly, for each study, the required number of observation
339 areas must be established based on the amount that is necessary to gain a statistically sufficient number of crack observations to
340 represent the rocks in question for that setting (see section 4.2). As yet, no rule-of-thumb can be employed, because there has not
341 been sufficient standard fracture data collected to establish such a rule – an illustration of the motivation of this paper! Rocks or
342 outcrops with lower crack density (number of cracks per area) will require that larger areas of their surface be examined in order
343 to measure sufficient cracks for statistical significance (see section 4.2). Thus, as an example only, we note that in past work, when
344 State Factors were carefully controlled for, relationships between rock material properties and rock cracking properties were
345 evident from about three to ten 10⁰-meter scale outcrops per rock type on ridge-forming quartz rich rocks (Eppes et al., 2018).
346 However, we emphasize that until sufficient magnitude of datasets has been collected, the amount of observation area must be
347 established based on the number of fractures available uniquely at each study site.

348 4 Standardized method: Selecting fractures for measurement

349 4.1 Rules-based criteria for selecting fractures in surface processes research

350 The term ‘fracture’ is employed with a wide variety of meaning across the geosciences, potentially resulting in large variations in
351 the range of features that two individuals might study on a single outcrop (Long et al., 2019). Therefore, it is crucial to employ
352 clear and repeatable rules-based criteria (e.g., Table 1) for what constitute measurable ‘cracks’ within any fracture-related research.
353 To not do so consistently results in a high variance of subjective bias that is more reflective of worker personality than of the

354 variance in fracture of the outcrop (Andrews et al., 2019). Thus, consistency and documentation are required for deriving
355 interpretable and repeatable results.

356

357 Our proposed rules (Table 1) for determining which fractures to measure at any given field site were developed in the context of
358 surface processes research and through iterations with numerous non-expert users (undergraduate students) to arrive at criteria that
359 provide consistency in observations across users. Because surface processes are frequently and largely dependent both on rock
360 erodibility and water within a rock body, we limit our recommended criteria to apply only to open voids, which are known to
361 greatly impact both. Also, because other types of open voids like vesicles are common in rock, we employ the additional criteria
362 that the open void must be planar in shape, bounded by parallel or sub-parallel sides (hereafter fracture or crack ‘walls’), with a
363 visible opening that is deeper than it is wide. Fracture walls will pinch together at fracture terminations.

364

365 It is common for such planar voids in rock to have been filled with mineral solids during intrusion and metamorphism, diagenesis,
366 or weathering. Portions of fractures containing such cements do not meet the ‘open’ criteria and, thus, should not be included in
367 the fracture dataset. However, voids that fit the shape criteria that are filled with lichens, dust, or other permeable material that can
368 be readily brushed out with a fingernail or prodded with a needle should be included. If solid mineral cement forms a discontinuous
369 bridge between fracture walls fully connecting the two walls of the otherwise open, planar void, the open length of the fractures
370 on either side of the bridge would be treated as individual fractures. To distinguish this type of fracture truncation, a yes/no
371 indication may be added to the dataset collected.

372

373 Finally, we also propose the criteria that the planar void must be continuously open (no ‘bridges’ of cemented mineral material)
374 for a distance longer than 10 X the characteristic grain size dimension or 2 cm, whichever is greater. In most rock types, this
375 translates to a 2 cm minimum cutoff for countable cracks (Fig. 2a; See section 5.4.1 below for measuring lengths). We propose
376 this length threshold based on three features. First, past work has demonstrated that deriving precise (repeatable) detailed
377 information -- other than length -- for cracks <2 cm in length is challenging (e.g., Eppes et al., 2010). Second, temperature-
378 dependent acoustic emission measurements (Wang, et. al, 1989; Griffiths et al., 2017) and theoretical arguments suggest that on
379 single year time scales, cracks on single grain and smaller length scales exist in thermodynamic equilibrium, (randomly) opening
380 and closing under constant redistribution of ubiquitous diurnal to seasonal thermal stresses within surface rocks. The approximate
381 statistical mechanical ‘rule-of-ten’ states that well-defined equilibrium and nonequilibrium, continuum-scale properties, e.g.,
382 viscosity, density, stress and strain, each determined by myriad microscale random processes, are obtained on length scales
383 approximately 10 times an appropriate molecular length scale, e.g., average atomic size or mean free path length between colliding
384 (gas) molecules. This interpretation is consistent with recommendations for the number of grains the minimum diameter of a
385 sample is for repeatable testing of continuous rock properties such as rock strength and elastic moduli (ASTM, 2008 and 2017).

386

387 Last, and practically, the high abundance of cracks below this cutoff significantly increases the time required for crack
388 measurement. If these smaller cracks are of interest, they can be characterized with photographic analysis (not covered herein), or
389 subjected to semi-quantification via an index (see section 5.2). Importantly, in some applications it may be appropriate that a larger
390 minimum threshold in crack length is chosen. However, in that case, crack abundances in the rock will possibly dictate that
391 significantly larger observation areas of the rock exposure need to be employed in order to obtain sufficient numbers of cracks to
392 provide representative data (see section 4.2).

393

394 Regardless of the threshold length chosen for the study, two adjacent fractures separated by intact rock or bridges of cement are
395 considered two fractures, even if at a distance they appear to be continuous (Fig. 2b). This practice results in repeatable
396 measurement between multiple workers and provides the most accurate representation of past crack growth and crack connectivity
397 in the rock body.

398 4.2 Determining how many fractures to measure

399 Most published fracture-focused studies provide no justification for the number of fractures they measure, begging the question -
400 is the dataset representative of the rock body? However, it is a long-recognized concept in fracture and rock mechanics that crack
401 size distributions are highly skewed and characterized by scale-independent power law distributions (e.g. Davy et al., 2010; Hooker
402 et al., 2014). Thus, the expected power-law distribution of fracture size can be leveraged in most cases to ensure that a
403 representative crack population has been measured in any given dataset (Ortega et al., 2006).

404

405 Here, we recommend that to fully characterize the fractures for any site(s), outcrop(s), or feature(s) of interest, sufficient numbers
406 of cracks should be measured such that a statistically robust power-law distribution in crack length is evident in the data. While
407 other log normal, exponential, and Weibull distributions have been proposed for various fracture datasets (e.g., Baecher, 1983),
408 employing these distributions depends on preexisting knowledge of the expected dataset. Thus, unless there is prior documentation
409 of fracture distributions at a particular site, the power law distribution should suffice.

410

411 In practice, it is an iterative process to determine the number of fractures required for any given dataset, but generally, on the order
412 of 10^2 cracks are required (e.g., Zeeb et al., 2013) to reach a representative distribution (Fig. 3). When sufficient numbers of cracks
413 have been measured to result in such a distribution, then it can be assumed that the population of measured cracks is representative
414 of all cracks on the rock, outcrop, or group of rocks/outcrops with certain features. For example, if the goal of a study is to test the
415 influence of rock type on crack width, enough cracks must be measured to allow for a power-law distribution of crack lengths for
416 *each* of the rock types. That population of cracks can then be considered representative of the given rock type, and statistics on
417 other crack properties like width can also be reasonably interpreted as representative.

418

419 We provide an example of what that iterative process might look like in Fig. 3. In this example, all cracks were measured on the
420 surface of 15-50 cm diameter granitic boulders selected along transects across both a modern wash bar (with few overall cracks
421 per boulder) and a ~6 Ka alluvial fan bar (with many cracks per boulder). For the modern wash, after 5, 30, or 50 boulders, a
422 statistically significant power law distribution is not evident (Fig. 3). However, after 130 clasts, the fit of the power law falls below
423 a p-value threshold of 0.01. Thus, measurements from around 130 clasts were necessary to fully characterize cracks for that
424 particular site. In contrast, the threshold p-value is reached after only 5 boulders for clasts with high crack density on the mid-
425 Holocene age site; however, with more clasts examined, more variables per clast can be analyzed in the data. Thus, in order to
426 evaluate different variables (like clast size or shape), the iterative process would repeat, but limiting the analysis to cracks found
427 on clasts meeting the criteria of interest. In this example, a total of 130 clasts per surface were measured, enabling several subsets
428 of data to be examined in order to test the influence on a range of clast properties on cracking.

429

430 One notable exception to the scale independent power law rule of thumb may be if there are abundant fracture terminations in
431 infilling material. In this case, the size of the fracture (as defined by Table 1) is dictated by the spacing of the filled material bridges.
432 Thus, fracture sets in rocks that contain abundant varnish or secondary precipitates like calcium carbonate may not follow this rule.

433 5 Proposed standardized baseline field data for fracture-focused surface processes research

434 Here, we describe the minimum suite of data (Table 2) that should be collected for all observation areas and all cracks. Table 3
435 contains a list of recommended field equipment to make the measurements. The list of baseline data in Table 2 was developed with
436 the goal of allowing the worker to fully analyze their fracture data in the context of variables known from the literature to influence
437 or reflect cracking in exposed rocks. As overall knowledge of fractures in surface environments grows, the suggested set of
438 measured variables should also change, just as, for example, the components of the simple stream power equation has evolved in
439 fluvial geomorphology literature. The proposed fracture field methods list is also focused on direct ‘observables’ – without
440 interpretation – that should apply universally across field areas. We readily acknowledge that additional items can and should be
441 added to accommodate the needs of any specific study.

442

443 The metrics listed in Table 2 and the associated methods described below are designed to be applicable and translatable to both
444 natural outcrops and individual clasts. While they may also be applicable to fractures found in quarries and road-cuts, such outcrops
445 are prone to cracking that has been anthropogenically induced by blasting, exhumation, and new environmental exposure (e.g.,
446 Ramulu et al., 2009; He et al., 2012).

447 5.1 The ‘Crack Sheet’

448 We provide a data collection template comprising all the proposed standard data that allows efficient, complete, and detailed
449 recording of all parameters while in the field (e.g., a “crack sheet”, Fig. 4 with digital version provided in supplemental data). The
450 crack sheet can and should be modified to include additional parameters relative to any study. Ours is structured so that each
451 observation area’s information (e.g., that of each clast, outcrop, or window) shares a row with the first crack measured. Then,
452 subsequent rows are employed for additional measured cracks on the same observation area. Each observation area and crack are
453 assigned unique identifiers to enable unambiguous reference in subsequent data analysis. Employing a ‘window’ rather than an
454 entire clast or outcrop as the observation area necessitates slightly different data collection, so we provide two separate crack sheets
455 in the supplement.

456

457 The crack sheet provides a header space for site meta-data. Any observations that could elucidate the possible contributions of any
458 State Factor (c,l,o,r,p,t,T) acting at the site should be recorded (e.g., the vegetation or topography of the site). This header area
459 should also be employed to note any and all criteria or conventions used throughout the study. For example, the use of any
460 convention, such as right-hand rule for strike and dip measurements, should be noted in the header. The criteria employed to select
461 clasts or outcrops (e.g., their size, composition, etc.) and the nature of the observation areas (ex: only the north face of all clasts;
462 or entire exposed clast surface for all outcrops) should also be noted.

463 5.2 The use of semi-quantitative indices

464 We recommend employing indices for many observations following similar existing semi-quantitative methods commonly
465 employed in both soil sciences (e.g., Soil Survey Staff, 1999) and sedimentology (e.g., rounding and sorting). The use of indices,
466 rather than precise measurements, is especially appropriate for fractures and fracture characteristics, given the natural variation
467 between different rocks, and the daunting number of measurements that would be required to accurately quantify, for example,
468 something like total number of very small cracks.

469

470 Here, we define two particularly useful generic ‘abundance’ indices that are similar to those employed for quantifying the
471 abundance of roots and pores in soils (Schoeneberger et al., 2012), whereby the quantity or coverage of specific elements or features
472 is estimated within a specified area. For both, a ‘frame’ is employed whose size is dependent on the size of the feature being
473 observed (Fig. 5). Features that are ≤ 0.5 cm are observed in 1 cm² frames; features > 0.5 to < 2 cm are observed in a 10 cm² frame;
474 and features ≥ 2 cm are observed in a m² frame. Cut-out cardboard stencils of these sizes may be constructed and employed. The
475 observer imagines randomly placing the ‘frame’ several times on any given portion of the observation area, noting the abundance
476 of the feature of interest within the frame. The indices are based on the average value of abundance observed in any given such
477 ‘frame’ across the entire area of observation (e.g., the entire clast, the entire outcrop, or the outcrop window).

478
479 The first index scales from 0 to 4 and is applicable for ‘countable’ features of interest in the research like small cracks, fossils, or
480 large phenocrysts. The index is: none – 0 (no visible features in ANY frame), few -- 1 (< 1 feature on average), common -- 2 (≥ 1
481 and < 5 features on average), very common -- 3 (≥ 5 and < 10 features on average), and many -- 4 (≥ 10 features on average).

482
483 The second index scales from 0 to 5 and is employed for features that are not readily counted nor consistent in size (like lichen,
484 varnish, fine grained mafic, or felsic minerals). In these cases, the index is based on the percentage of the rock surface covered by
485 the feature: none – 0; very little – 1 ($< 10\%$); little – 2 (≥ 10 and $< 30\%$); common – 3 (≥ 30 and $< 60\%$); very common – (≥ 60 and
486 $< 90\%$); and dominant – 5 ($\geq 90\%$). A percentage estimator (Fig. 6) should always be employed to assign the index categories –
487 even experienced field workers are subject to ‘quantity bias’.

488 5.3 Measuring rock characteristics

489 The following rock characteristics should be measured for each observation area – each clast, outcrop, and/or window – that is
490 employed in a study. Some cracking characteristics not captured in individual crack measurements are also included.

491 5.3.1 Clast, outcrop, or window dimensions

492 Rock – or outcrop – size, aspect, and slope can impact stress-loading through, for example, thermal stress distribution (e.g. Molaro
493 et al., 2017; Shi, 2011). Or, for example, outcrop height has been linked to its exposure age and/or erosion rates (e.g., Hancock and
494 Kirwan, 2007). The dimensions of the clast, outcrop, or window employed for fracture observations are also required for
495 calculations of fracture density and intensity (i.e., the number/length of crack per unit area; see section 6.1).

496
497 The length and width of planar ‘windows’ are measured directly. If a window ‘bends’ across multiple faces of the rock surface,
498 then separate length and width measurements should be made for each face with a distinct aspect. These areas are then added
499 together for crack density and intensity calculations. The vast majority of rock clasts and outcrops found in nature have ‘prismatic’
500 forms (Domokos et al., 2020). Thus, length, width, and height of individual clasts or outcrops may be reasonably employed to
501 calculate the exposed surface area (see section 6.1 for calculations).

502
503 For all dimension measurements regardless of rock shape, metrics are measured as point-to-point orthogonal measurements. Length
504 is measured parallel to the longest axis. Width is measured on the widest extent that is perpendicular to length, and height is
505 measured vertically from the uppermost surface of the rock down to the ground surface. If a through-going crack splits the rock
506 into two pieces that remain *in situ*, it should still be considered one rock and measured accordingly. If a clast or outcrop is spheroidal
507 in shape, that should be noted for future surface area calculations.

508

509 For site preservation, and to minimize geoheritage and environmental impacts, rocks should not be moved from their natural state;
510 therefore, the height measurement of a highly embedded rock will only represent the height of the exposed rock surface above the
511 ground. We have derived a metric to estimate the degree to which clasts are exposed vs. embedded (see section 5.3.8).

512 5.3.2 Sphericity and roundness

513 Sphericity and roundness from standard sedimentology practices (e.g., Krumbein and Sloss, 1951) provide metrics for rock shape.
514 Shape can influence stress distribution in a mass and, therefore, cracking. For example, in general, corners tend to concentrate
515 stresses, and ‘corner cracks’ are a recognized phenomenon in fracture mechanics (e.g., Kobayashi and Enetanya, 1976). Thus, we
516 include this metric as one to be measured both for outcrops and for clasts.

517

518 Sphericity refers to the length by width ratio, or elongation, of the clast or outcrop, whereas roundness is a measure of angularity
519 (Fig. 7). The roundness and sphericity designation for the square on the chart in Fig. 7 most closely matching the dominant shape
520 of the entire clast or outcrop should be noted (ex. r-SR; s-SE). If a more precise rock shape analysis is needed, a modified Kirkbride
521 device can be used to quantitatively measure rock roundness (see Cox et al., 2018 for device modifications and methodology).

522 5.3.3 Grain Size

523 Mean grain size can impact numerous fracture and stress characteristics including the proclivity for granular disintegration
524 (Gomez-Heras et al., 2006), fracture toughness (Zhang et al., 2018), initial crack length, thermal stress disequilibrium (Janio De
525 Castro Lima and Paraguassú, 2004), and bulk elastic properties (Vázquez et al., 2015). The mean grain size should be visually
526 estimated by comparing the size of the dominant size of individual grains or mineral crystals to a standard grain size card. This
527 size can be reported as one average value for all minerals, or different values for different suites of minerals (e.g., felsic vs. mafic),
528 depending on the lithological assemblage(s) of the observation area(s).

529 5.3.4 Fabric

530 We employ the term ‘fabric’ to refer to any preexisting (prior to weathering) primary or diagenetic planar, linear, or randomly
531 oriented anisotropies within the rock comprising the outcrop or clast of interest. Fabric is most commonly observed as fossils,
532 lithological bedding planes, and/or diagenetic veins in sedimentary rocks, and as crystal horizons, foliation structures, and dikes in
533 igneous or metamorphic rocks. Rock fabric can impart anisotropy that could influence cracking rates and orientations (e.g., Nara
534 and Kaneko, 2006; Zhou et al., 2022). Any visible fabric type, as well as the strike(s) and dip(s) (or trend(s) and plunge(s)) of each
535 parallel or subparallel set should be noted in the crack sheet for each observation area.

536 5.3.5 Cracks <2 cm in length

537 Cracks <2 cm in length can comprise a significant portion of all cracks on a given rock exposure, particularly in coarse crystalline
538 rock types (e.g., Alneasan and Behnia, 2021). Thus, we recommend recording an index, using an observation ‘frame’ (see section
539 5.2), that quantifies the abundance of cracks less than 2 cm in length (hereafter ‘small cracks’).

540

541 Observe the approximate number of small cracks visible each time the ‘frame’ is moved. Take a rough average of all theoretical
542 frames and use the categories in Fig. 5 to assign an abundance. For example, if generally there are either zero or one small crack
543 in any given 10 x 10 cm frame, the abundance would be “1” – i.e., few, <1 per unit area.

544 5.3.6 Granular disintegration

545 Granular disintegration refers to evidence of *active* loss of individual crystals or grains due to cracking along grain boundaries (i.e.,
546 sedimentary particles or igneous or metamorphic crystals). This feature is observed on the rock surface as individual grains or
547 small clusters of grains of the rock that can be brushed away with your hand. Granular disintegration is commonly observed in
548 coarse igneous, metamorphic, and sedimentary rocks, and over the long-term leads to the accumulation of grus – sediment
549 comprised of individual crystals – on the ground surface (Eppes and Griffing, 2010; Isherwood and Street, 1976; Gomez-Heras et
550 al., 2006).

551

552 This disintegration comprises the complete separation of intergranular cracking. Because the cracks that comprise granular
553 disintegration are typically too small to be readily measured in the field, however, its presence is assumed when loose grains are
554 present on the rock surface. The worker should mark yes (circle the ‘G’ on the Crack Sheet) if there is evidence of granular
555 disintegration on the rock surface of observation. If more detail is desired, an abundance index (e.g., Fig. 5) may be employed to
556 quantify what percentage of the surface of observation contains loose grains.

557 5.3.7 Pitting

558 Pitting is the occurrence of small holes or fissures that form on the rock surface due to granular disintegration or to preferential
559 chemical weathering of certain mineral types, typically feldspars and micas in silicate rocks. Pitting is distinct from granular
560 disintegration as it is not necessarily ‘actively’ occurring – i.e., pitting can exist without loose grains on the rock surface. We
561 include it as a rock property related to fracture because of its possible linkage to intergranular cracking. Furthermore, measuring
562 the extent and depth of pitting due to chemical weathering has long been employed as a relative age dating tool in Quaternary
563 geology applications (Burke and Birkeland, 1979).

564

565 Pitted surfaces form as individual grains become weathered and fall out or are dissolved; or, for soluble rocks like carbonates, as
566 entire rock regions are dissolved. Pitting can either be quantified as present/absent (circle P on the crack sheet) or as a quantity
567 index (Figs. 4 and 5).

568 5.3.8 Clast exposure

569 This metric is used to record to what degree individual clasts appear to be exposed above the ground surface. Individual clasts are
570 known to weather and erode from the upper rock surface down until they become ‘flat’ rocks at the ground surface (e.g., Ollier,
571 1984). Surface exposure can be estimated as the amount and shape of a boulder’s exposed surface that is currently not covered by
572 loose sediment, vegetation, or other material. We grouped this exposure into four categories: 0 -- the clast is sitting above the
573 ground, and its sides curve downward toward the ground surface almost meeting; 1 -- the clast is partially covered, with sides
574 curving downward toward the ground surface but not meeting; 2 – the clast is “half” covered, with sides projecting roughly
575 vertically into the ground surface; 3 -- the clast has only one upward facing side visible at the ground surface. In a field study, a
576 correlation test on data from 300 boulders revealed a positive correlation of 0.66 between the indices and the fraction of boulder
577 embeddedness (in vertical length) (Shaanan et al., 2022).

578 5.3.9 Lichen and varnish

579 Lichens and other plant life can act to push rocks apart during growth (Scarciglia et al., 2012), but have also been shown to
580 strengthen rocks through infilling of voids or shielding from stress-inducing sunlight (Coombes et al., 2018). We note that lichen

581 are living organisms that would be killed by removal. In order to determine if a lichen-coated lineation is in fact a measurable
582 fracture (see section 4.1), a needle or straight pin may be employed to poke through the lichen into the possible void of the crack.

583

584 Rock varnish (oxide staining that can appear as a dark gray/black or orange coating on rock and typically contains Fe or Mn oxides)
585 is well-documented to evolve over time. The extent of varnish cover has been employed frequently as a relative-age indicator,
586 particularly in arid environments (e.g., McFadden et al., 1985; Macholdt et al., 2018). Thus, variations in varnish across the rock
587 face can provide evidence of loss of surface material through *in situ* cracking.

588

589 Lichen and varnish can come in many forms and be difficult to distinguish from each other and from primary rock minerals, hiding
590 in cracks, pitting holes, and atop mafic crystals. So, careful consideration of the types of lichen and varnish that may be found in
591 field site and close inspection with a hand lens is recommended. A fresher exposure of the rock surface can help in the identification
592 of lichen and varnish relative to the natural rock composition and color. Due to the geodiversity impact, however, do not make
593 such exposures with force.

594

595 The quantity of lichen and varnish (secondary chemical precipitates deposited on the subaerial rock surface) visible on the rock
596 observation surface are separately estimated using a visual percentage estimator (Fig. 6) and a quantity index is assigned (Fig. 5;
597 Section 5.2).

598 5.4 Crack characteristics

599 The following properties are measured for each crack found within the observation area that meets all the crack selection criteria
600 listed in Table 1.

601 5.4.1 Length

602 Crack length is measured for the entire surface exposure length of the crack; i.e., around corners and up and down rock topography
603 (Fig. 2a). Measurements can be made with flexible seamstress tape to follow the curve of a crack's exposure on the rock surface.
604 Length is only measured where there is an open void (Fig. 2b; Section 4.1). If a seemingly continuous crack (Fig. 2b, left) is in
605 fact separated by bridges of solid rock (Fig. 2b, right inset), then these should be measured as two different cracks and their lengths
606 should terminate at the rock bridges. The inset in Fig. 2b reveals four cracks possibly meeting all Table 1 criteria. Photographs do
607 not allow the 3D visualization required to determine if there is open void along the entire length. The precise length of the smaller
608 cracks would be needed to determine if they meet the 2 cm/10 grain cutoff.

609

610 Importantly, when using a 'window' approach to rock observation area, both the total length of the crack extending beyond the
611 window, as well as the total length within the window, should both be recorded. The latter is employed in crack intensity
612 calculations (section 6.1); the former provides representative information about all crack lengths on the rock being measured.

613 5.4.2 Width

614 Crack aperture widths (hereafter, 'widths') can impact both the strength and permeability of rock. Generally, they scale with crack
615 length and thus can possibly reflect the innate subcritical cracking parameters of the rock (Olson, 2004). Crack widths typically
616 vary along their exposure and pinch out at crack tips. Determining an average or representative width can thus be somewhat
617 arbitrary and subject to bias. Locating the widest aperture is less subject to bias and can also provide information about cracking

618 processes. Thus, we recommend consistently recording crack width at the midpoint of the measured length of the exposed crack
619 and also recording its maximum width along its exposure.

620

621 Both measurements should only be made in regions of the crack where crack walls are parallel or sub-parallel (e.g., green arrows
622 in Fig. 8), avoiding locations where crack edges have been obviously rounded by erosion or chemical weathering, or where large
623 pieces have been chipped off or are missing (e.g., red arrows in Fig. 8). If it is unclear if a portion of the crack has chipped off
624 (e.g., orange arrow in Fig. 8), a notation can be made and employed later to eliminate potential outliers in the dataset. Cracks
625 greater than about 3 mm in width can be easily measured by inserting the back-blades of digital calipers into the widest opening
626 of the crack. For narrower cracks, a ‘crack comparator’ (Fig. 7) is recommended, whereby the line on the comparator most closely
627 matching the crack aperture is chosen.

628 5.4.3 Strike and dip

629 Crack orientation (i.e., strike and dip) is a function of the orientation of existing anisotropy within the rock and the orientation of
630 the principle stresses that drove its propagation. There is a common misperception that preferred crack orientations are solely
631 related to tectonic forces; however, both gravitational and environmental stresses can also be directional (e.g., St. Clair et al., 2015;
632 McFadden et al., 2005). When cracks are growing at subcritical rates, they can lengthen through a series of ‘jumps’ that link parallel
633 or subparallel smaller fractures. The following suggestions are for research aimed not at characterizing these small heterogeneities,
634 but rather identifying major stresses and heterogeneity in the entire rock body.

635

636 Crack orientation is measured with a geological compass or similar tool that has both azimuthal direction and inclinometer
637 functionality. When measuring strike and dip of cracks, it is important to visualize how the crack plane intersects the rock surface,
638 as if you were to slip a sheet of paper into the ‘file folder’ of the fracture. For larger cracks, there may be different dips on either
639 side of the crack due to weathering of the crack opening, so it is imperative to measure the angle at the interior of the crack where
640 its walls are parallel (Fig. 8).

641

642 Cracks grow until they intersect other cracks. If cracks appear to intersect or branch (i.e., two connected planar voids with
643 noticeably different orientations), their total length should be measured as one crack, but their orientations should be measured
644 separately (e.g., two strikes and dips for the single crack). For cracks that meander around small heterogeneities like phenocrysts
645 or fossils, the overall trend is measured. For curvilinear cracks, the average orientation can be measured, as the orientation of the
646 non-curved plane whose ends are defined by the ends of the crack. Alternatively, the crack curvilinear plane may be subdivided
647 into roughly linear planes and each orientation measured. It is important to note which method was employed and to remain
648 consistent for all measurements.

649

650 There are numerous commonly-employed conventions for measurements of strike and dip. If the worker is consistent and clear in
651 their use of their preferred convention and in the presentation of their data, any are acceptable. If the worker has no such prior
652 habits, we recommend recording strikes as an azimuthal orientation from 0-359 degrees, and dip angle as an angle deviation from
653 horizontal of 0-90 degrees. For dip direction, we also recommend employing a convention such as the “right-hand rule,” whereby
654 the dip direction is always known from the orientation of the strike alone. For example, the right-hand rule states that the down-
655 dip direction is always to the “right” of the measured and recorded strike when the observer is facing the same direction of the

656 strike. Therefore, the strike that is recorded is the one whereby the dip direction is always +90 degrees clockwise (to the right)
657 from the strike direction.

658 5.4.4 Fracture parallelism

659 Noting the parallelism of the cracks can help to better understand the origins of the population of fractures at a site. Parallelism is
660 common because cracks often follow rock heterogeneities or anisotropies such as bedding, foliation, veins, or even the rock surface.
661 Fractures in a single bedrock outcrop or clast are also commonly parallel because they have formed due to external stress-loading
662 with a consistent orientation (e.g., those related to tectonics or directional insolation). Thus, noting parallelism may help to
663 distinguish the origins of fractures, though not always. For example, ‘surface parallel cracks’ (e.g., Fig. 2a) - commonly referred
664 to as exfoliation, sheeting joints (e.g., Martel, 2017), or spalling – vary dramatically in scale and can have origins related to several
665 different factors including tectonic-topographic interactions (Martel, 2006), chemical weathering and volumetric expansion (Røyne
666 et al., 2008), and thermal stresses related to insolation (e.g. Lamp et al., 2017; Collins and Stock, 2016) and fire (e.g. Buckman et
667 al., 2021).

668

669 In the crack sheet, note to which features the crack is parallel. A visual inspection will suffice for most applications, but for
670 occasions where more precision is needed, the crack may be considered parallel if the strike and dip of a crack is within +/-10° of
671 the orientation of the feature (the rock’s long axis, its fabric, or its outer surface). A crack may be parallel to more than one feature
672 in the rock. Add categories as necessary for rocks with other repeating features unique to the field site (fossils; veins, etc.).

673 5.4.5 Sheet height

674 Surface parallel fractures naturally detach ‘sheets’ of rock between the fracture and the rock surface (‘h’ in Fig. 2a). The thickness
675 of these sheets may be of interest for understanding the size of sediment produced from the fracture or for understanding the
676 stresses that produced the fracture. Sheet height is measured using calipers at the location of the maximum height of the sheet and
677 is only used for surface parallel cracks. To limit these measurements to those that have likely formed in situ as related to the current
678 morphology of the rock, a rule of thumb is to only measure those ‘sheets’ that would result in removal of <10% from the outer
679 surface of the rock downward into the dimension(s) of the rock face(s) to which they are perpendicular.

680 5.4.6 Weathering index

681 Rock fracture is ultimately a molecular scale bond-breaking process; so, when cracks propagate, they initially form a razor-sharp
682 lip or edge. Over time, these edges naturally round through subsequent chemical and physical weathering, erosion, and abrasion
683 (e.g., regions of the red arrows in Fig. 8).

684

685 We have established an index of relative degree of such rounding along a crack edge to be noted in the crack sheet:

686

687 1: fresh with evidence of recent rupture (flakes/pieces still present, but not attached)

688 2: sharp, no rounded edges anywhere

689 3: mostly sharp with occasional rounded edges

690 4: mostly rounded edges with occasional sharp edges

691 5: all rounded edges

692

693

694 6 Suggestions for Data analyses

695 For initial data exploration, normal cross-plots or quantile-quantile plots (as well as standard correlation analysis) may be applied
696 to rock and crack data. For categorical data, normal analytical techniques (histograms, discrete correlation analysis, etc.) can be
697 applied. As with all heavy-tailed data, the median is preferred over the mean value to understand a characteristic value—though
698 power distributed data generally does not have a characteristic dimension. Standard statistics such as mean, variance, skewness,
699 and kurtosis all remain valid to explore and evaluate the datasets.

700 To understand crack length and crack width data, it is key to first recognize that, with the exception of studies such as in rocks
701 with cracks with uniform spacing and bedding-controlled widths (Ortega et al., 2006), the data will have a heavy-tailed distribution,
702 such as lognormal, gamma, or power law. As we mention above, of these, strong observational and theoretical evidence suggests
703 that fracture size is most commonly power law distributed (Bonnet et al., 2001; Davy et al., 2010; Hooker et al., 2014; Ortega et
704 al., 2006; and Zeeb et al., 2013), i.e.,

$$705 \quad n(b) = Ab^{-\alpha} \quad (1)$$

706 where b is the crack dimension (length or width) of interest, n is the number of cracks with dimension d , and A and α are constants.
707 When log-transformed, Eq. (1) becomes

$$708 \quad \log(n(b)) = \log(A) - \alpha \log(b) \quad (2)$$

709 which has led many practitioners to fit Eq. (2) by linearly binning the data in n , then log-transforming the data and fitting the
710 resulting data with a linear regression. This has proven to lead to significant bias in estimates, $\hat{\alpha}$, of the power law exponent
711 (Bonnet et al., 2001; Clauset et al., 2009; Hooker et al., 2014) and is not recommended despite its common usage.

712 Two straight-forward approaches have been shown not to have biases, or misestimates of the exponent α . 1) The following is based
713 on Clauset et al., (2009). First, the exponent can be found from the cumulative distribution of the dimensions, $C(b)$, or number of
714 fractures with dimension greater than b , i.e.,

$$715 \quad C(b) = \int_b^{b_{\max}} n(b) db \quad (3)$$

716 Where b_{\max} is the maximum size of the crack dimension (e.g., maximum length or width). The cumulative power law distribution
717 has the form

$$718 \quad C(b) \propto b^{1-\alpha} \quad (4)$$

719 It is common to denote $1-\alpha$ as c . To find α (or c), the dimension data is logarithmically binned. In other words, the dimension data
720 is binned on a logarithmic (1, 10, 100, ...) frequency scale, and then log-transformed. At this point, linear regression techniques
721 can be applied to estimate α and assess uncertainty. However, in all cases, uncertainty estimates such as R^2 will overestimate the
722 certainty for such log-transformed data; but at least the estimate of α is unbiased.

723 2) Another method to find α from a data set of crack dimensions is to use the maximum likelihood estimator (MLE) given by

$$724 \quad \hat{\alpha} = 1 + N \left[\sum_{i=1}^N \ln \left(\frac{b_i}{b_{\min}} \right) \right]^{-1} \quad (5)$$

725 where $\hat{\alpha}$ is the estimate of the exponent in (1), b_i is the dimension of the i th crack, b_{min} is the minimum valid crack dimension
726 (see below) and N is the total number of samples (Clauset et al., 2009; Hooker et al., 2014). The MLE estimate has the advantage
727 of an accurate estimate of standard error, σ , given by

728
$$\sigma = \frac{\hat{\alpha}-1}{N} + O\left(\frac{1}{N}\right). \quad (6)$$

729 Clauset et al., (2009) showed that both the logarithmically-binned cumulative distribution and the MLE estimator produce unbiased
730 estimates of the exponent. For all empirical power law distributions, there is a scale, in our case b_{min} , below which power law
731 behavior is not valid. This can be visually assessed by plotting Eq. 2 with logarithmically binned n . The interval between b_{min} and
732 b_{max} where the slope is linear is where the power law is valid (Clauset et al., 2009; Ortega et al., 2006); Clauset et al. (2009)
733 presents a formal method to find b_{min} and b_{max} . Hooker et al. (2014) use a χ^2 test to evaluate the goodness of fit, which is
734 simpler than the p-tests of the Kolmogorov-Smirnov statistic proposed by Clauset et al. (2009).

735

736 6.1 Crack density and intensity

737 In fracture mechanics literature, crack density commonly refers to the number of cracks per unit area (e.g., # cracks/m²), and crack
738 intensity refers to the sum length of all cracks per unit area (e.g., cm/m²). However, these terms are interchanged in some literature.
739 It is therefore important to define them in each usage; and for clarity, the term ‘number density’ might be employed.

740

741 In either calculation, the ‘area’ refers to the surface area of observation area. For cracks measured in ‘windows’ (section 3.4), use
742 the length of cracks only *within* the window and the area of the window (e.g., 10 cm x 10 cm) for the calculations. For loose clasts
743 and outcrops, the appropriate calculation of surface area will depend on the shape and angularity of the rock. For most rocks,
744 calculations for the surface area of the exposed sides of a rectangular cuboid ($L*W + 2*(L*H) + 2*(W*H)$) are appropriate.

745 6.2 Circular Data

746 Standard ‘linear’ statistics cannot be employed for circular data. We suggest the use of circular statistical and plotting software for
747 the visualization and analysis of strike and dip data. The statistics employed by such software is typically based on established
748 circular statistical research methods (e.g., Mardia and Jupp, 1972; Fisher, 1993). The following statistics are useful in reporting
749 strike and dip data.

750

751 The Mean Resultant Direction (a.k.a. vector mean, mean vector) is analogous to the slope in a linear regression. Circular variance
752 can be quantified using either a Rayleigh Uniformity Test (for single mode datasets) or a Rao Spacing Test (for datasets with
753 multiple modes), whereby p-values <0.05 indicate non-random orientations. If p-values for these tests are below a threshold (e.g.,
754 <0.05), then data are considered non-uniform or non-random.

755

756 The Rayleigh statistic is based on a von Mises distribution (i.e., a normal distribution for circular data) of data about a single mean
757 (i.e., unimodal data). Therefore, for multi-modal data, the variance might be high, but nevertheless, the data might be non-uniform.

758 The Rayleigh Uniformity Test calculates the probability of the null hypothesis that the data are distributed in a uniform manner.
759 Again, this test is based on statistical parameters that assume that the data are clustered about a single mean.

760

761 Rao's Spacing Test is also a test for the null hypothesis that the data are uniformly distributed; however, the Rao statistic examines
762 the spacing between adjacent points to see if they are roughly equal (random with a spacing of $360/n$) around the circle. Thus,
763 Rao's Spacing Test is appropriate for multi-modal data and may find statistical significance where other tests do not.

764 8 Case Example

765 To demonstrate the consistency of results that might be achieved across users, we provided minimal training (one demonstration
766 with some minor oversight of initial work) to four groups of two students each. The fifth pair of workers included a scientist who
767 had logged over 500+ hours of experience using the standardized methods. Each of the five groups followed the methods to
768 measure the length and abundance of cracks on boulders (15-50 cm max diameter) on the same geomorphic surface (a 6000-year-
769 old alluvial fan in Owens Valley California, comprised of primarily granitic rock types). Each group followed the methods
770 described herein for rock and crack selection and measurements. As such, the results from each group (Fig. 9; Data Supplement)
771 could be compared not only for crack selection and measurements, but also for observation area selection – a key component of
772 collecting data that is representative of a particular site.

773

774 We find that the data collected by each of the groups for crack length, number of cracks per rock and rock size are statistically
775 indistinguishable by student t-test (all pairs of p-values > 0.1 ; Fig. 9; Data Supplement). Also, there is no consistent difference
776 between measurements made by the novice groups and that of the trained group. The mean crack lengths from the four novice
777 groups novice group (37 ± 23 mm to 59 ± 51 mm) span across that of the mean collected by the well-trained group (42 ± 22 mm;
778 Supplement), as do the number of cracks per rock (2 ± 2 to 6 ± 8 for novice groups compared to 3 ± 3 for trained group). With only
779 one exception (crack length for group 1) variance between groups does not range by more than a factor of 3 in any of the data – a
780 common rule of thumb for the threshold of 'similar' variance between small datasets. Overall, especially given the relatively small
781 size of the datasets (~ 10 -20 rocks and ~ 40 -60 cracks each), this comparison suggests that the results using the standardized methods
782 are reproducible, even with novice workers with minimal training.

783 9 Conclusions

784 The methods proposed herein comprise a standardization of field data collected in rock fracture research surrounding surface
785 processes and weathering-based geologic problems. These methods comprise best practices extracted from existing research and
786 methods that have been developed in the context of structural geology and fracture mechanics research, while also providing
787 general guidance and nuances developed from experiences (and mistakes) over the last two decades of fracture-focused field
788 research applied to geomorphology and soil science. It is our hope that providing these detailed, accessible, standardized procedures
789 for gathering and reporting field-based crack data will open the door to rapidly building a rigorous galaxy of new datasets as these
790 guidelines and methods become more widely adopted. In turn, they may enable future workers to better compare and merge
791 fracture data across a wide range of studies, permitting future refinements of our understanding of rock fracture and in the methods
792 themselves. Compiling such a standardized global dataset is the best hope for fully characterizing the role and nature of fractures
793 in Earth surface systems and processes.

794 10 Author Contributions

795 MCE spearheaded evolution of the development of the guiding principles and methods described herein as well as writing of the
796 manuscript. JA, SB, MD, SE, FM, SP, MR, and US all participated extensively in field campaigns during which the methods were
797 developed and refined, and they contributed to editing of manuscript and editing and development of figures. MM, AR and RK

798 contributed to the development of theoretical statistical analyses practices that are outlined in the document and the editing of the
799 manuscript.

800 **11 Competing interests**

801 The authors declare that they have no conflict of interest.

802

803 **12 Data Availability**

804

805 All data presented in the manuscript are available in the Supplement.

806 **13 Acknowledgements**

807 The body of knowledge presented herein was derived in large part over the course of research funded by the National Science
808 Foundation Grant Nos. EAR#0844335 (with supplements #844401, #0705277), #1744864, and #1839148 and NASA ROSES
809 Mars Data Analysis Program award #NNX09AI43G. Several photographs in figures were cropped and employed with permission
810 from Marek Ranis, Artist-in-Residence for NSF #1744864. In addition, the authors wish to acknowledge the contributions from
811 countless undergraduate and graduate students who contributed to the application and development of these methods in classes
812 taught by MCE at the University of North Carolina at Charlotte.

818 Fig. 1. Images illustrating the selection of observation areas for clasts and outcrops. A. Photograph of a transect established for
819 clast selection. Black dot: predefined transect interval location on the tape. Red dot: clast that does not fit the predefined clast
820 selection criteria (e.g., it is too big). Green dot with red circle: clast that fits criteria but is further away from the interval point
821 that the clast with the green dot. Green dot: closest clast to the transect interval that meets the selection criteria. B. Annotated
822 photograph showing an idealized placement of ‘windows’ (dashed black squares) on a bedrock outcrop. Outcrop dimensions are
823 measured and the windows are placed using predetermined selection criteria. In this example, the windows are equally spaced
824 along the centerline of the long-dimension of the upward-facing side of the outcrop.

825

826 Fig. 2. A. Example of the measurement of a surface exposure length (L ; yellow line) of a crack meeting the criteria in Table 1.
827 The ‘h’ refers to the location where sheet height would be measured for this surface parallel crack. B. Example of fractures that
828 may appear to be a single fracture (left), but upon close examination are in fact multiple fractures intersecting and/or separated
829 by rock (right inset). Arrow points to the location of the inset image on the main image. Compass in the foreground for scale.

830

831 Fig. 3. Example histograms and statistics of crack length data measured on the exposed surfaces of clasts 15-50 cm max diameter.
832 Upper row are data for clasts found on a modern ephemeral stream boulder bar. Clasts overall have very low crack density. Lower
833 row are data for clasts on an ~6.2 ka surface where crack density is much higher. Note that it takes about 100 clasts to arrive at a
834 statistically significant power law distribution for the Modern Wash clasts, but only 5 rocks for the rocks with higher crack
835 densities. Producing histograms interactively as data is collected can help establish how many observation areas are necessary for
836 a given site.

837

838 Fig. 4. Reduced size image of an 8.5” x 11” ‘crack sheet’ to be employed in the field to increase efficiency and to reduce ‘missing’
839 data. Sheet templates for both clasts and outcrops that can be modified are provided in Data Supplement as well as a data-entry
840 template.

841

842 Fig. 5. Visual aide for estimating the abundance of “countable” rock features – including cracks. An index of 0-4 is assigned
843 depending on the abundance of features within an average of any given observation area (ex: 10 x 10 cm) on the clast or window
844 being examined. The area of observation is defined by the size of the features being measured. A 10 cm x 10 cm square is used
845 for estimating the abundance of ‘cracks < 2 cm’ defined as cracks with lengths of ~0.5 cm but < 2 cm (see section 5.2 for details
846 of how to use the index). For features ≤ 0.5 cm, a 1 cm x 1 cm area would be employed and for features ≥ 20 mm, a 1 x 1 m area.

847

848 Fig. 6. A visual percent estimator (modified from Terry and Chilingar, 1955). Estimator should be employed in every estimate of
849 percentages. See section 5.2 for using the estimator to assign a percent coverage index to features that are not countable or vary
850 in size (e.g., lichen coverage, fine mafic minerals, etc.).

851

852 Fig. 7. **Inset:** Roundness and sphericity chart – modified from Krumbein and Sloss (1951). **Roundness:** A = angular; SA =
853 subangular; SR = subrounded; R = rounded; WR = well-rounded. **Sphericity:** S = spherical; SS = subspherical; SE = sub-elongate;
854 E = elongate. **Edges:** crack comparator whereby the width most closely matching the crack aperture is noted. Note: a to-scale pdf
855 is available in the Data Supplement, however, owing to printing and publication scaling, it is highly recommended to calibrate
856 the comparator prior to using it in the field.

857

858 Fig. 8. Examples of aperture transects that are appropriate for measurement of crack aperture widths (green) and transects where
859 there is evidence that the crack walls have been eroded or chipped and therefore should not be employed for a width measurement
860 (red). In cases where it is not clear if erosion or chipping has occurred (orange), a note can be made for the crack width to possibly
861 eliminate outliers during data analysis.

867

868 **Table 1. List of proposed rule-based criteria for defining measurable cracks**

The answer to the following questions must be ‘yes’ for all measured cracks. Measure <u>all cracks meeting these criteria</u> within the observation area.	NOTES
<ul style="list-style-type: none"> • Is the feature a lineament longer than it is wide? • Does the lineament contain open space bounded by walls? • If the lineament is not open, can the infilling material (ex: dust and lichens) be readily scraped out? • If the lineament is open or after the material has been scraped out, is the opening deeper than it is wide <u>and</u> bounded by ~parallel walls? • Is the open portion of the lineament ≥ 2 cm (>10 grains) in length (without interrupting bridges of cemented infilling material)? 	Do not measure: <ul style="list-style-type: none"> • Spherical pores/vesicles. • Lineaments, or portions of lineaments, with solid mineral infilling/cement. • Ledge edges or linear etchings.

869

870 **Table 2. List of proposed data to collect for the rock observation area and for all cracks ≥ 2 cm in length**

871

Rock Observations	Crack Observations
<ul style="list-style-type: none"> • Dimensions of the observation area (e.g. clast, outcrop, and/or window length, width, height) • Rock Type • Grain Size • Mineralogy % (minimally felsic vs. mafic) • Sphericity of Exposure • Roundness of Exposure • Fabric Description: strike, dip, type (i.e. vein, foliation, bedding) • Evidence of Granular Disintegration: define an index • Evidence of Pitting: define an index • Lichen or Varnish: % 	<ul style="list-style-type: none"> • Length: surface exposure length measured with a flexible tape • Aperture Width: center and maximum widths as measured with crack comparator or calipers • Strike: right hand rule preferred • Dip: 0-90 degrees • Parallelism: Note features parallel to crack (fabric, rock faces) • Weathering characteristics: an index of rounded edges where 1 = entirely sharp, fresh edges; 2=mostly sharp edges, some rounding; 3 = mostly rounded edges, some sharp; 4= entirely rounded edges • Sheet Height: the thickness of what would be the detached spall or sheet of rock (only if crack is surface parallel and it were to detach the rock surface)

872

873

874 **Table 3. List of field equipment**

Required	Recommended
<ul style="list-style-type: none"> • Hand lens (large, 10x) • Grain size card • Crack comparator (for crack widths) • Flexible seamstress tape measure (with mm) • Calipers (mm 0.0 to 150) • Brunton or similar compass • Roundness and sphericity chart • Visual percentage estimator • Crack sheets 	<ul style="list-style-type: none"> • Camera with macro lens • Chalk for marking measured cracks and windows • Safety pin or needle for crack exploration • Cardboard cutout frames for windows • Small white board or chalk board for including observation area ID in photos
