

Response to Editor's Review – Esurf Manuscript

Effects of seasonal variations in vegetation and precipitation on catchment erosion rates along a climate and ecological gradient: Insights from numerical modelling

By: Sharma and Ehlers

Response to Associate Editor: Simon Mudd

Dear Prof. Simon Mudd,

We would like to thank you for suggesting the minor edits in our manuscript. We performed minor revisions in our manuscript as per your comments and suggestions. We addressed each comment and believe that the quality of our manuscript is substantially improved and made it more useful to prospective readers. We hope the revised manuscript also meets your expectations and high standard of Esurf. The most important changes are summarized below.

We have modified the Methods section to include the description of processes in the model simulations which include the equations of the Landlab components and their modifications based on vegetation cover fraction. The Appendix section is also modified accordingly to remove the description of governing equations in the model simulations. In addition, we modified the section 5.3 to include the influence of catchment topology on time lags in sediment dynamics in the basins. We have provided the details of manuscript revision in the point-by-point response to the your comments. We deeply appreciate your efforts to help us improve our manuscript.

The submission file consists of our cover letter, followed by point-by-point response to your comments, and the revised manuscript (with tracked-changes) specifying all the modifications made in accordance with the your comments.

Please contact us if further clarifications are required.

Sincerely,

Hemanti Sharma and Todd Ehlers (corresponding author).

Response to editor's review

The editor's comments are mentioned in black and authors' responses are in blue.

My comments are available in the attached pdf, but my main request is to make the setup of the simulation clearer. First, the erosion components of the model are reported primarily in the appendix, and there are not enough references in the text to this section. I don't believe all this material should be placed there since the appendix contains important details about how the model works that should be placed in the methods: the paper is about how erosion rates are modulated by vegetation and precipitation so the model governing equations dictating this behaviour should be in the methods section.

We thank the editor for raising an important issue here. To address this issue, we have added the description of Landlab components with governing equations and their modification based on the vegetation cover in the Methods section 3.3 (Lines 246-331) and removed the same from the Appendix.

It is also not clearly stated how the regional area are used in the simulations. One must infer that each region has the original topography as the initial condition, so in addition to vegetation and precipitation components, each site has its own starting morphology. This needs to be stated clearly.

We thank the editor for raising an important issue here. To address this issue, we have modified Lines 334-337 in the Methods section 3.4 to include the initial conditions explicitly related to topography of the four study areas.

On the other hand, the erosion parameters (e.g., K_s) do not vary between simulations.

We thank the editor for raising this issue. The (initial-) erosion parameters mentioned in the input parameters are uniform for the study areas. However, these are modified in the model driver scripts based on the vegetation cover fraction, as mentioned in Section 3.3.2 and equations 12-13 (lines 302-303) in the revised manuscript.

Because the initial topography appears different between sites, the transient response should be different, and there needs to be a comment about how the time lags depend on the topology of the basin. I think the effect is probably small, because it is not base level that is the main driver of changes to the erosion rate, but rather a "top down" forcing by the changes to vegetation. But I think this point should be mentioned in the text.

We thank the editor for raising this issue. To address this issue, we have modified lines 539-543 and 552-558 section 5.3 in the revised manuscript to include the text on the importance of catchment topology in the time lags in sediment dynamics.

Line specific comments:

Line 29: This needs an "e.g." since there are numerous papers that say this.

Added e.g. in Line 28 in the revised manuscript.

Line 117: This is a bit abrupt: in the previous sentence you say erosion rates vary over two orders of magnitude. So where does the 0.05 mm/yr come from? It is not clear, at this point, if you are trying to model these specific catchments to reproduce their erosion rates or if you are using them as inspiration for a study that is primarily numerical. It should be made clear which one of these you are doing in this paper.

The rock uplift rate of 0.05 mm yr⁻¹ is adapted from our previous modeling study in the same study areas (Sharma et al., 2021). Which is in coherence with the tectonic setting of the study areas. Also, in order to remove the influence of tectonics in our modeling study, which is primarily numerical, we prefer to use uniform uplift rates for all the catchments modeled. To address the above issue, we have added text in Lines 115-117 in the revised manuscript to state that this study focuses on evaluating the sensitivity of the topography to seasonal variations in precipitation and vegetation change. Hence, the tectonic parameter (rock uplift rate) for each study area is held constant.

Line 129: I would have expected a sentence here alluding to some mitigation of the saturation problem. I suggest adding a sentence before the previous one.

Unfortunately, the model does not mitigate the saturation problem. So, we have added the implications of the saturation problem regarding its impact on (modified-) erodibilities in lines 129-131 in the revised manuscript.

Line 137: I think "study areas" sounds better.

The part of this paragraph is now readjusted to the Section 3.4 and modified in Line 334 in the revised manuscript.

Line 138: So four different initial conditions? For four sites?

The part of this paragraph is now readjusted to the Section 3.4 and modified in Line 336-337 in the revised manuscript to mention that we use four initial conditions for topography, climate, vegetation, etc. for four different study areas.

Line 144: Add citation, or say "our preliminary modelling suggests that"

Added "our preliminary modeling results suggest that" in line 140 in the revised manuscript.

Line 157: This whole sentence quite awkward. Consider rewriting.

Modified line 153-155 as suggested by the editor.

Line 157: based

The line is modified already and does not include the above word anymore.

Line 161: I suggest "used"

Modified in line 158 in the revised manuscript.

Line 163: Seems like you are missing a noun here.

We prefer it to stay as it is in line 160 in the revised manuscript.

Line 177-179: So the model does not mitigate for this? If it does, say something about it. If it doesn't, explain the implications.

Unfortunately, the model does not mitigate the saturation problem. We have added the possible implications in line 176-178 in the revised manuscript.

Line 190-192: There is quite a bit of text here for the soil properties, and how they relate to runoff. But the paper is mostly interested in erosion rates. The methods section doesn't have information on how erosion is calculated, and how the erosion is parameterised in the model. It needs to have such a section.

We thank the editor for the comment. To address this issue, we have added a sub-section 3.3 in the Methods section to include the description (including driving equations) on how the erosion is calculated and how erosion parameters are modified in the driver scripts in lines 246-331 in the revised manuscript.

Line 204-206: So for the different climate zones in simulations (arid, semi-arid, etc), are these for the different sites with all the other variables between the sites? Topography, soil texture, etc? That should be made clear.

Yes, the climate zones depicted in Figure 2 correspond to different study areas with all other variables. To address this issue, lines 204-206 are modified to make the description clearer in the revised manuscript.

Line 223: Not sure if I missed this, but what data did you use to determine if there is soil or not? If not mentioned, it should be since it plays a role in the simulations.

The sediment thickness in each grid cell is updated at each time-step (as mentioned in eq. 6 in revised manuscript, line 278). Hence, the model first identifies if there is sediment present in the grid cell to facilitate soil water infiltration. If soil is not present, infiltration would be zero. This clarification is added in lines 327-329 in the revised manuscript.

Line 230-232: So do I have this right that if the model thinks soil is present, it assumes effectively an unlimited soil thickness? Or are you updating the soil thickness? This component of the model needs a few sentences before you start on Green-Ampt.

Please see response to the previous comment. The soil thickness is updated at each time-step. To minimize the confusion for the reader, we have added the governing equations for soil thickness in the model, in the Methods section 3.3 in lines 276-281 in the revised manuscript. We have readjusted the description Green-Ampt in the consecutive sub-section in lines 308-321 in the revised manuscript.

Line 244.245: This needs to be explained here.

We have added lines 225-226 to mention that the vegetation modifications to erosion modeling and constitutive equations for the model components are presented in sub-section 3.3 in the Methods section.

Line 246: Using what constitutive equations? Refer to appendix.

Please refer to previous comment.

Line 271: It is very difficult to tell if this is important since the erosion component is not explained in the methods (there needs to be a few important details in the method, and then refer to the appendix). Does the topography adjust at all to this uplift rate? Is the erosion driven by soil parameters? Is there a different channel erodibility? All these important topics are buried in the equations in the appendix, I think the most important details need to be here. I think in a 1000 year simulation any base level effects would not propagate very far into the model domain, so my intuition is that the uplift rate isn't really important. I think this discussion could be had if there were more detail about the erosion modelling.

We thank the editor for pointing this out. In the estimation of fluvial bedrock erosion, rock uplift rate is needed to be defined (see eq. 5 in revised manuscript in line 270). However, the role of uplift rates is not very significant in this study because of short timescale (i.e. 1000 years) and the simulation results suggest minor changes in the topography (and bedrock elevation differences). We have added the argument suggested by the editor in lines 341-342 in the revised manuscript.

Line 275-276: "step-wide increase in model complexity" is clunky. Why not just say "the following three scenarios"?

Modified lines 344-346 in the revised manuscript, as suggested by the editor.

Line 287: It is not clear from this sentence whether topography was updated during the simulations.

We thank the editor for pointing this out. To address this issue, we have modified the lines 356-359 in the revised manuscript to mention that the topography was updated at each time-step based on erosion and rock uplift rates.

Line 288-290: This implies that diffusivity, erodibility are set by something (plants? soil texture?) rather than calibrated. So there needs to be a section explaining how the erosion works and how the parameters are set. Please refer to the appendix and explain the selection of parameters.

We thank the editor for pointing this out. The erosional parameters are based on the vegetation cover fraction in the grid cell. To address this issue, we have added model description in section 3.3 (lines 246-331 in the revised manuscript), where we have described the modification of erosional parameters (e.g. diffusivity and erodibility) based on vegetation cover fraction.

Line 317: This seems a strange thing to speculate upon when you are running a model and you can tell exactly whether or not they are dominated by fluvial processes. Was this not an output of the model? What stops you from saying definitively what drives the erosion? It would be useful to expand on this result.

We thank the editor for pointing this out. To address this issue, we have modified lines 386-389 in the revised manuscript to write the model results in assertive tone.

Line 357: needs "in our study areas" at the end of this sentence.

Added "in our study areas" in line 428 in the revised manuscript.

Line 404-408: We don't need a table of contents here, the section headers suffice.

Removed the lines (below line 474) in the revised manuscript.

Line 418: This is the first mention of SWAT. Why was it not mentioned in the methods?

We apologize for the confusion caused with this line. Here, we meant the study mentioned in the previous line i.e. Zhang et al. (2019) and not our current study. To address this issue, we have modified lines 482-484 in the revised manuscript.

Line 479-482: This is quite interesting, but time lags depend on the geometry of a catchment, and so how much of this signal is from different catchments and how much is from the climate parameters?

We thank the editor for raising this issue. We have modified the text to elaborate on the influence of topology of the catchments on the lag times in sediment dynamics in our results in lines 539-543 in the revised manuscript. However, the quantitative disentangling of the signal (from climate and topography) is beyond the scope of this study and is hence not included in the text.

Effects of seasonal variations in vegetation and precipitation on catchment erosion rates along a climate and ecological gradient: Insights from numerical modelling

Abstract. Precipitation in wet seasons influences catchment erosion and contributes to annual erosion rates. However, wet seasons are also associated with increased vegetation cover, which helps resist erosion. This study investigates the effect of present-day seasonal variations in rainfall and vegetation cover on erosion rates for four catchments along the extreme climate and ecological gradient (from arid to temperate) of the Chilean Coastal Cordillera (~26 °S – ~38 °S). We do this using the Landlab-SPACE landscape evolution model ~~using a set of runtime scripts and input files~~ to account for vegetation-dependent hillslope-fluvial processes and hillslope hydrology. Model inputs include present-day (90 m) topography, and a timeseries (from 2000-2019) of MODIS-derived NDVI for vegetation seasonality; weather station observations of precipitation; and evapotranspiration obtained from GLDAS NOAA. ~~Simulations were conducted with a step-wise increase in complexity to quantify the~~ The sensitivity of catchment scale erosion rates to seasonal average variations in precipitation and/or vegetation cover- was quantified using numerical model simulations. Simulations were conducted for 1,000 years (20 years of vegetation and precipitation observations repeated 50 times). After detrending the results for long-term transient changes, the last 20 years were analyzed. Results indicate that when vegetation cover is variable but precipitation is held constant, the amplitude of change in erosion rates relative to mean erosion rates ranges between 5% (arid) to 36% (Mediterranean setting). In contrast, in simulations with variable precipitation change and constant vegetation cover, the amplitude of change in erosion rates is higher and ranges between 13% (arid) to 91% (Mediterranean setting). Finally, simulations with coupled precipitation and vegetation cover variations demonstrate variations in catchment erosion of 13% (arid) to 97% (Mediterranean setting). Taken together, we find that precipitation variations more strongly influence seasonal variations in erosion rates. However, the effects of seasonal variations in vegetation cover on erosion are also significant (between 5-36%) and are most pronounced in semi-arid to Mediterranean settings and least prevalent in arid and humid-temperature settings.

Keywords: Landlab, vegetation, Chilean Coastal Cordillera, biogeomorphology, seasonality, precipitation, EarthShape.

1 Introduction

Catchment erosion rates vary spatially and temporally (e.g., Wang et al., 2021) and depend on topography (e.g., slope, Carretier et al., 2018), vegetation cover and type (e.g., Zhang et al., 2011; Starke et al., 2020; Schaller and Ehlers, 2022) and precipitation rates (e.g., Cerdà, 1998; Tucker and Bras, 2000). Over annual timescales, temporal variations in catchment erosion occur in response to seasonal variations in precipitation and vegetation cover. For example, previous work has found that a significant fraction of annual erosion occurs during wet seasons, with high runoff rates (Hancock and Lowry, 2021; Leyland et al., 2016; Gao et al., 2021; Wulf et al., 2010). However, this increase in precipitation during wet seasons also promotes vegetation growth, which in turn influences erosion rates (Langbein and Schumm, 1958; Zheng, 2006; Schmid et al., 2018). Seasonal and longer-term changes in both precipitation and vegetation cover play a crucial role in intra-annual changes in erosion rates (Istanbulluoglu and Bras, 2006; Yetemen et al., 2015; Schmid et al., 2018; Sharma et al., 2021). The intensity, frequency, and

38 seasonality of precipitation and vegetation cover change within a year depend upon the climate and ecological conditions of
39 the area of interest (Herrmann and Mohr, 2011). One means of investigating the effects of seasonality in precipitation and (or)
40 vegetation cover on erosion rates is through landscape evolution modeling (LEM), which can be parameterized for variations
41 in vegetation-dependent hillslope and fluvial processes over seasonal time scales.

42 Previous modeling and observational studies have investigated the effects of seasonality in precipitation and vegetation on
43 catchment erosion. Bookhagen et al., (2005), Wulf et al., (2010), and Deal et al., (2017) investigated the effects of stochastic
44 variations in precipitation on erosion and sediment transport in the Himalayas. They found that high variability in rainstorm
45 days (>80% of MAP) during the wet season (summer monsoon) caused high variability in the suspended sediment load. Similar
46 seasonality in sediment loads was reported in a field study in Iran, using sediment traps and erosion pins. These authors
47 concluded that wet seasons experienced maximum erosion rates (>70% of annual), which decreased in dry seasons (<10% of
48 annual) (Mosaffaie et al., 2015). Field observations in the heavily vegetated Columbian Andes concluded that soil erosion and
49 nutrient losses are significantly influenced by precipitation seasonality (Suescún et al., 2017). In contrast, work by Steegen et
50 al., (2000) in a loamy agricultural catchment in central Belgium found suspended sediment concentrations in streams were
51 lower during summer (wet) rather than winter (dry) months due to the development in vegetation cover in the wet season.
52 Other workers have found a dependence of seasonal erosion on ecosystem type. For example, Istanbuloglu et al., (2006)
53 found a reduction in the sensitivity of soil loss potential to storm frequency in humid ecosystems compared to arid and semi-
54 arid regions. Work by Wei et al., (2015) in the semi-arid setting of the Chinese Loess Plateau, reported that significant changes
55 in vegetation related land use/land cover may contribute to long-term soil loss dynamics. However, seasonal variations in
56 runoff and sediment yield are mainly influenced by intra-annual rainfall variations. Finally, previous work in a Mediterranean
57 environment by Gabarrón-Galeote et al., (2013), described rainfall intensity as the main factor in determining hydrological
58 erosive response, regardless of the rainfall depth of an event.

59 When looking at seasonal vegetation changes in more detail, several different studies suggest these changes are important for
60 catchment erosion. For example, Garatuza-Payán et al., (2005) emphasized that seasonal patterns in erosion are strongly
61 influenced by plant phenology as demonstrated by the changes in vegetation cover (measured by NDVI). A similar study on
62 the Loess Plateau, China, by Zheng (2006) documented decreasing soil erosion as vegetation cover increases during the wet
63 season. Work conducted in a forested setting (Zhang et al., 2014) documented the importance of tree cover as an effective
64 filter for decreasing the effects of rainfall intensity on soil structure, runoff, and sediment yield. Numerical modeling studies
65 have also found a significant impact of vegetation on erosion. For example, Zhang et al., (2019) found that when precipitation
66 was kept constant, the increase in vegetation cover resulted in a significant reduction in sediment yields (20-30% of the total
67 flux). Also, during early to mid-wet season, the species richness and evenness of plant cover both play an essential role in
68 reducing erosion rates during low rainfall events (Hou et al., 2020). However, in the case of high-intensity rainfall events at
69 the start of a wet season, when vegetation cover is low, the duration and intensity of rainfall were found to significantly affect
70 erosion rates (Hancock and Lowry, 2015). Other work conducted in a Mediterranean environment points to the coincidence of
71 peak rainfall erosivity in low vegetation cover settings, leading to an increased risk of soil erosion (Ferreira and Panagopoulos,
72 2014). Despite potentially conflicting results in the previous studies, what is clear is that seasonality in precipitation and
73 vegetation cover conspire to influence catchment erosion, although which factor (precipitation or vegetation) plays the
74 dominant role is unclear.

75 This study complements the previous work by applying a Landscape Evolution Model (LEM) to investigate seasonal transience
76 in catchment erosion due to variations in precipitation and vegetation. We do this for four locations spanning the extreme
77 climate and ecological gradient (i.e., arid, semi-arid, Mediterranean, and humid temperate) in the Chilean Coastal Cordillera.
78 Our efforts are focused on testing two hypotheses: (1) precipitation is the first-order driver of seasonal erosion rates, and (2)
79 catchment erosion in arid and semi-arid regions is more sensitive to seasonality in precipitation and vegetation than the

80 Mediterranean and humid temperate regions. To test the above hypotheses, we conduct a sensitivity analysis of fluvial and
81 hillslope erosion over four Chilean study areas to investigate the individual effects of seasonal changes in vegetation cover
82 and precipitation compared to simulations with coupled variations in precipitation and vegetation cover. We do this using a
83 two-dimensional LEM (the Landlab-SPACE software), which explicitly handles bedrock and sediment entrainment and
84 deposition. We build upon the approach of Sharma et al., (2021) with the additional consideration of soil-water infiltration.
85 Our model setup broadly representative of the present-day conditions in the Chilean Coastal Cordillera (Fig. 1) and uses
86 present-day inputs such as topography from SRTM DEMs (90 m) for four regions with different climate/ecological settings.
87 Simulations in these different ecosystems are driven by observed variations in vegetation cover from MODIS NDVI (between
88 2000 – 2019) and observed precipitation rates over the same time period from neighboring weather stations. We note that the
89 aim of this study is not to reproduce reality in these study areas. This is due to the uncertainties in the LEM initial conditions
90 and material properties, and rock uplift rates. Rather, our focus is a series of sensitivity analyses that are loosely ‘tuned’ to
91 natural conditions and observed vegetation and precipitation changes along an ecological gradient. As shown below, these
92 simplifications facilitate identifying the relative contributions of vegetation and precipitation changes on catchment erosion.

93 **2 Study Areas**

94 This section summarizes the geologic, climate, and vegetation settings of the four selected catchments (Fig. 1) investigated in
95 the Chilean Coastal Cordillera. These catchments (from north to south) are located in the Pan de Azúcar National Park (arid,
96 ~26°S), Santa Gracia Nature Reserve (semi-arid, ~30°S), and the La Campana (Mediterranean, ~33°S) and Nahuelbuta
97 (temperate-humid, ~38°S) national parks. Together, these study areas span ~1,300 km distance of the Coastal Cordillera. These
98 study areas are chosen for their steep climate and ecological gradient from north (arid environment with small to no shrubs) to
99 south (humid temperate environment with evergreen mixed forests) (Schaller et al., 2020). The study areas are part of the
100 German-Chilean priority research program EarthShape (www.earthshape.net) and ongoing research efforts within these
101 catchments.

Figure 1. Study areas in the Coastal Chilean Cordillera ranging from an arid environment in the north (Pan de Azúcar), semi-arid (Santa Gracia), Mediterranean (La Campana), and humid temperate environment in the south (Nahuelbuta). The above map is obtained from the Environmental System Research Institute (ESRI) map server (https://services.arcgisonline.com/ArcGIS/rest/services/World_Topo_Map/MapServer, last access: 25 April 2022).

The bedrock of the four study areas is composed of granitoid rocks, including granites, granodiorites, and tonalites in Pan de Azúcar, La Campana, and Nahuelbuta, respectively, and gabbro and diorites in Santa Gracia (Oeser et al., 2018). The soil types in each catchment were identified as a sandy loam in three northern catchments (with high bulk density: 1300 – 1500 kg m⁻³) and sandy clay loam in Nahuelbuta (with lower bulk density: 800 kg m⁻³) (Bernhard et al., 2018). The western margin of Chile along the latitudes of the different study areas is characterized by a similar tectonic setting whereby an oceanic plate (currently the Nazca Plate) has been subducting under the South American Plate since the Palaeozoic. Despite this common tectonic setting along, slight differences in modern rock uplift rates are documented in the regions surrounding the three northern catchments (i.e., < 0.1 mm yr⁻¹ for ~ 26 °S to ~33 °S) (Melnick, 2016) and the southern catchment (i.e., 0.04 to > 0.2 mm yr⁻¹ for ~38 °S over the last 4±1.2 Ma) (Glodny et al., 2008; Melnick et al., 2009). Over geologic (millennial) timescales, measured denudation rates in the region range between ~0.005 to ~0.6 mm yr⁻¹ (Schaller et al., 2018). ~~To facilitate a comparison between the study areas and focus~~ As this study focuses on erosion the sensitivity of topography to seasonal variations from seasonal changes in vegetation and precipitation and vegetation change, the tectonic parameters (rock uplift) specific to each study areas are held constant. Given this, we assume a uniform rock uplift rate of 0.05 mm yr⁻¹ for ~~this study~~ results presented here. This rate is broadly consistent with the range of previously reported values.

The climate gradient in the study areas ranges from an arid climate in Pan de Azúcar (north) with mean annual precipitation (MAP) of ~11 mm yr⁻¹ to semi-arid in Santa Gracia (MAP: ~ 88 mm yr⁻¹), a Mediterranean climate in La Campana (MAP: ~350 mm yr⁻¹), and a temperate-humid climate in Nahuelbuta (south) with a MAP of 1400 mm yr⁻¹ (Ziese et al., 2020)(Ziese et al., 2020). The observed mean annual temperatures (MAT) also vary with latitude ranging from ~20°C in the north to ~5°C in the south (Übernickel et al., 2020). The previous gradients in MAP and MAT and latitudinal variations in solar radiation result in a southward increase in vegetation density (Bernhard et al., 2018). The vegetation gradient is evident from mean

127 MODIS Normalized Difference Vegetation Index (NDVI) values range from ~0.1 in Pan de Azúcar (north) to ~0.8 in
128 Nahuelbuta (south) (Didan, Kamel, 2015). In this study, NDVI values are used as a proxy for vegetation cover density, similar
129 to the approach of Schmid et al. (2018). ~~However, one of the major limitations of using NDVI is that the values get saturated~~
130 ~~when the ground is covered by shrubs.~~ However, one of the major limitations of using NDVI is that the values are saturated
131 when the ground is covered by shrubs or larger broad-leaved forests in regions with high biomass (Van Der Meer et al., 2001)
132 (e.g., the catchment in humid-temperate setting). This may have implications on the shear stress partitioning ratio used to
133 estimate the sediment and bedrock erodibilities (see eq. 10-13), as the NDVI values for shrub covered land and a mature forest
134 could be similar in such cases (Huang et al., 2021).
135 This gradient in climate and vegetation cover from north to south in the Chilean Coastal Cordillera provides an opportunity to
136 study the effects of seasonal variations in vegetation cover and precipitation on catchment-scale erosion rates in different
137 environments/climate settings.

138 3 Methods

139 ~~This section comprises a description of model inputs (section 3.1), estimation of runoff rates (section 3.2), model setup (section~~
140 ~~3.3), and initial and boundary conditions (section 3.4). This is followed by an overview of simulations conducted (section 3.5),~~
141 ~~and a brief description of how detrending the model results was conducted to remove long term transients (section 3.6).~~

142 3.1 Data used for model inputs

143 ~~In contrast to previous modeling studies (Schmid et al., 2018; Sharma et al., 2021) in the same regions, we used present-day~~
144 ~~topography as the initial condition for simulations instead of a synthetic topography produced during a model spin-up phase~~
145 ~~in Landlab.~~ This study focuses on predicting and comparing the average responses in catchment erosion that occur over
146 seasonal timescales with variable precipitation and vegetation cover. However, erosion in arid and semi-arid regions can vary
147 on sub-seasonal time scales due to high-intensity storms occurring over timescales of a couple of hours or days. Hence, the
148 model does not capture the role of extreme precipitation events. ~~The effect of vegetation on erosion during extreme events is~~
149 ~~the focus of ongoing work by the authors.~~ Also, at seasonal time steps, our preliminary modeling results suggest that the
150 relationship between vegetation cover and erosion rates may be affected by inherited simulated slope values from the previous
151 season, which may lead to the blended signal in the output.

152 Initial topography for the four selected catchments was obtained by cropping the SRTM digital elevation model (DEM) in
153 rectangular shapes encapsulating the catchment of interest (Fig. 1). These catchments are the same as those investigated with
154 previous soil, denudation, and geophysical studies within the EarthShape project (e.g., Bernhard et al., 2018; Oeser et al., 2018;
155 Schaller et al., 2018; Dal Bo et al., 2019). The DEM has a spatial resolution of 90 m and is the same as the cell size used in
156 the model (dx and dy) (SRTM data set of Earth Resources Observation And Science (EROS) Center, 2017). The present-day
157 total relief in the catchments are ~1852 m in La Campana (~33 °S), followed by ~1063 m in Santa Gracia (~30 °S), ~809 m in
158 Nahuelbuta (~38 °S) and ~623 m Pan de Azúcar (~26 °S). Investigated catchment sizes considered here vary between ~64 km²
159 in Pan de Azúcar, ~142.5 km² in Santa Gracia, ~106.8 km² in La Campana, and ~68.7 km² in Nahuelbuta. We note that present-
160 day topography as the initial condition in simulations can introduce an initial transience in erosion rates due to assumed model
161 erosional parameters (e.g., erodibility, hillslope diffusivity) differing from actual parameters within the catchment. We address
162 this issue through a detrending of model results described later (see Section 3.6). Also, Furthermore, the inherent timescales
163 at which the topography and surface processes represented by LEMs have inherent timescales that they respond to
164 base (depicted by LEMs) are dependent on the physical properties used/incorporated and the model forcings (e.g., such as rock
165 uplift), which are unknown/all of which have uncertainties associated with them. Hence, it is unlikely that the SRTM DEM

166 used for the initial condition, is in equilibrium. Given this, the detrending of our time series of results to remove long-term
 167 transience aids in identifying seasonal transients in precipitation and vegetation cover.
 168 Precipitation data applied used over each study area (Fig. 3b) was acquired from the Global Precipitation Climatology Centre
 169 (GPCC) for the period 01/03/2000 to 31/12/2019 (DD/MM/YEAR). The data has a spatial resolution of 1° and a 1-day temporal
 170 resolution and comprises daily land-surface precipitation from rain gauges built on the Global Telecommunication System-
 171 based and historic data (~~Ziese et al., 2020~~)(Ziese et al., 2020). The previous data was augmented with daily precipitation
 172 weather station data from 01/02/2020 to 28/02/2020 obtained from Übernickel et al., (2020). We do this to include all the
 173 seasons between 2000 to 2019, i.e., from the austral autumn of 2000 to the austral summer of 2019. The periods (months of a
 174 year) of specific seasons in the Chilean Coastal Cordillera are given in Table 1. Seasonal precipitation rates were calculated
 175 by summing daily precipitation rates at three-month intervals. The seasonality and intensity of precipitation in the wet season
 176 (winter) increases from the arid (Pan de Azúcar) to humid temperate (Nahuelbuta) region.

177 **Table 1. Months of a year corresponding to specific seasons in the Chilean Coastal Cordillera**

Seasons	Months
Summer ^{d*}	December - February
Autumn ^{w*}	March - May
Winter ^{w*}	June - August
Spring ^{d*}	September - November

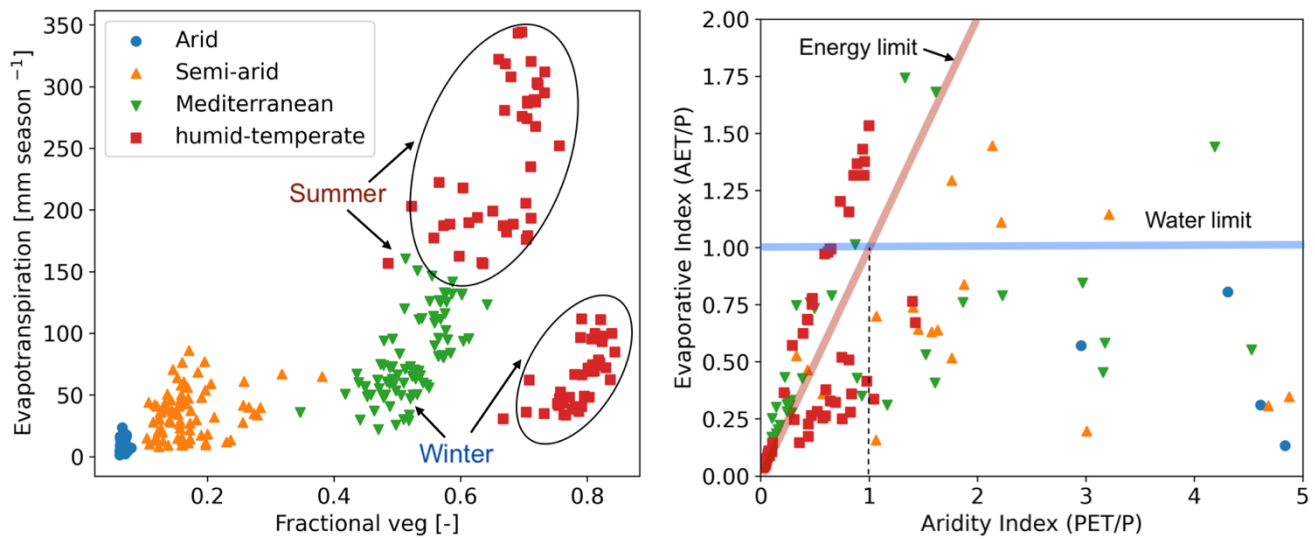

178 *d: dry season, w: wet season
 179

180 NDVI derived from remote sensing imagery has been proven as an effective tool to estimate seasonal changes in vegetation
 181 cover density (Garatuza-Payán et al., 2005). Normalized difference vegetation index (NDVI) values were obtained from
 182 MODIS (Didan, Kamel, 2015) satellite data and were used as a proxy for changes in vegetation cover in the catchments.
 183 However, the major limitation of the conversion of NDVI to vegetation cover includes a saturation problem in NDVI values
 184 that occurs in high biomass regions such as our humid-temperate setting (Huete et al., 2002). This saturation can occur if the
 185 ground is covered by shrubs, at which point the information on different plant communities for associated erosion-relevant
 186 properties is lost (e.g., rooting depth, etc.). The effect of a saturation in NDVI values could lead to uncertainties in calculating
 187 the shear stress partitioning ratio (see eq. 10-11), consequently affecting estimates of erodibility (see eq. 12-13). This is
 188 potentially important for humid-temperate climate setting characterized by high NDVI values (i.e. >0.8). The NDVI data were
 189 acquired for 20 years (01/03/2000 – 28/02/2020), with a spatial resolution of 250 m and temporal resolution of 16 days. For
 190 application within the model simulations, the vegetation cover dataset was resampled using the nearest neighbour method to
 191 match the spatial resolution (90 m) of SRTM DEM and temporal resolution of 3 months. To summarize, season variations in
 192 precipitation rate and vegetation cover were applied to the simulations between 01/03/2000 and 28/02/2020 and encompass a
 193 20-year record of observation variations in these factors.

194 Additional aspects of the catchment hydrologic cycle were determined using the following approaches for the same time period
 195 previously mentioned. First, evapotranspiration (ET) data was obtained from Global Land Data Assimilation System (GLDAS)
 196 Noah version 2.1, with a monthly temporal resolution and spatial resolution of 0.25° (~28 km) (Beaudoin et al., 2020; Rodell
 197 et al., 2004). The data was obtained from March-2000 to February-2020. Due to the coarse resolution of the dataset, ET is
 198 assumed to be uniform over the entire catchment area. No higher resolution datasets were available over the 20-year time-
 199 period of interest.

200 Soil properties such as the grain size distribution (sand, silt, and clay fraction) and bulk density were adapted from Bernhard
 201 et al., (2018) to estimate soil water infiltration capacity in each study area. Based on these soil properties, the soils have been
 202 classified as a sandy loam (in Pan de Azúcar, Santa Gracia, and La Campana) and sandy clay loam (Nahuelbuta). Average

203 bulk density values of 1300 kg m^{-3} , 1500 kg m^{-3} , 1300 kg m^{-3} , and 800 kg m^{-3} were used for Pan de Azúcar, Santa Gracia, La
 204 Campana, and Nahuelbuta, respectively (Bernhard et al., (2018).

205
 206 **Figure 2. Parameter correlation for observations used as model input data (i.e., seasonal precipitation, vegetation cover and evapotranspiration) including: (a) fractional vegetation cover (derived from NDVI) and evapotranspiration (derived from GLDAS NOAH), (b) Budyko curve representing the relationship between precipitation (P), potential evapotranspiration (PET) and actual transpiration (AET). The points above the water limit (blue line) indicate the contribution of soil moisture to ET. The seasons (points) above the energy limit (red line) indicate the precipitation loss by infiltration. The plots represent observations corresponding to Autumn of 2000 to Summer of 2019. Each data point represents one season and are color coded by climate of the study areas. See section 3.1 for a description of the data sets used.**

214 Figure 2 shows correlations between the model input data, such as variable climatic or hydrologic cycle metrics (i.e., precipitation and evapotranspiration) and vegetation cover for the climate zone of each study area investigated, with other
 215 variables such as topography, soil texture etc. The relationships shown for each study area in different climate-ecological zones are based on the 20 years of data used (i.e., Autumn of 2000 – Summer of 2019). The relationship between fractional vegetation cover (V) and evapotranspiration (ET) indicates a slightly positive trend in the semi-arid setting (Fig. 2a). Whereas, the relationship in the Mediterranean setting is a steep positive gradient, with low vegetation cover (0.4– 0.55) and evapotranspiration (i.e., 50 – 100 mm season⁻¹) in the winter, which increases in summer (90 – 160 mm season⁻¹) in response to vegetation growth (i.e., V = 0.55 – 0.65). Similar trends in V and ET is indicated in the humid temperate setting during the summer with V in the range of 0.55 – 0.75 and ET ranging between 150 – 350 mm season⁻¹. However, during winters, even after high V in humid setting, lower values in ET are reported, with a positive trend. To help understand the datasets of precipitation (P) with ET, a Budyko curve is presented in figure 2b, where the actual ET (AET) and potential ET (PET) are normalized by P. In figure 2b most the data points from the humid temperate setting are above the energy limit and indicate high soil water infiltration during summer seasons. Also, data points above the water limit (blue line in Fig. 2b) indicate a carry-over in soil moisture from a wet season to few dry seasons in the humid, Mediterranean and semi-arid settings.

228 **3.2. Estimation of runoff rates**

229 The precipitation rates [m season⁻¹] are subjected to soil water infiltration [m season⁻¹] and evapotranspiration [m season⁻¹] to
 230 estimate the seasonal runoff rates [mm season⁻¹]. The runoff rates (R) at every time step (t) are calculated using the actual soil-
 231 water infiltration (I_a) and the actual evapotranspiration (ET) as follows;

$$R(t) = P(t) - I_a(t) - ET(t), \quad (1)$$

where, P is the precipitation amount in a season. This relationship was applied in the model grid cells with non-zero sediment thickness. As ET is the input parameter, there may be instances of higher ET than P in the summer seasons in the humid, Mediterranean and semi-arid settings. This is evident in figure 2b where the minimum of both values is used as ET in the given time step.

The soil water infiltration rate was estimated by applying the Green-Ampt equation (Green and Ampt, 1911; Julien et al., 1995):

$$f(t) = K_e \left(1 + \frac{\psi \cdot \Delta\theta}{F} \right), \quad (2)$$

where $f(t)$ is the infiltration rate [m s^{-1}] at time t , K_e is the effective hydraulic conductivity [m s^{-1}], F is the cumulative infiltration [m], ψ is the suction at the wetting front [m], and $\Delta\theta$ is the difference between saturated and initial volumetric moisture content [$\text{m}^3 \text{m}^{-3}$]. Effective hydraulic conductivity is highly variable and anisotropic; hence, it was considered to be uniform with a value of $1 \times 10^{-6} \text{ m s}^{-1}$ for each catchment.

Following the approach of Istanbuluoglu and Bras, (2006) for loamy soils, the soil water infiltration was modified to account for variable vegetation cover in each grid cell, as follows:

$$I_c(t) = f(t)(1 - V(t)) + 4f(t)(V(t)), \quad (3)$$

$$I_a(t) = \text{Min}[P(t), I_c(t)], \quad (4)$$

where I_c is the infiltration capacity and V is the vegetation cover (between 0 and 1) in a model grid cell at time step t . Values used in the simulations for the parameters in equations 2-4 are provided in appendix Table A1.

3.3.2 Model setup

We applied the Landlab landscape evolution model, a python-based modeling toolkit (Hobley et al., 2017), combined with the SPACE 1.0 model (Shobe et al., 2017). The SPACE model allows coupled detachment-transport limited fluvial processes with simultaneous bedrock erosion and sediment entrainment/deposition. The Landlab-SPACE programs were applied using a set of runtime scripts and input files (Sharma and Ehlers, 2023) to account for vegetation and climate change effects on catchment erosion (i.e., fluvial erosion and hillslope diffusion), using the approach described in Schmid et al. (2018) and Sharma et al. (2021). ~~In addition, the geomorphic processes considered involve weathering and regolith production (Barnhart et al., 2019) and~~ In addition, the geomorphic processes considered involve infiltration of surface water into soil (Rengers et al., 2016) (Rengers et al., 2016) based on the Green-Ampt method (Green and Ampt, 1911), and runoff modeling. The constitutive equations for the processes involved in the model simulations are presented in section 3.3.

The model parameters (Table. A1 in Appendix) are selected for the distinct climate and ecological settings in the Chilean Coastal Cordillera based on the observations presented ~~in~~ by Schaller et al., (2018); Bernhard et al. (2018), and Übernickel et al. (2020). The model state parameters (i.e., erodibility, diffusivity, rock uplift rate, etc.) in the simulations are adapted from Sharma et al., (2021). The parameters pertaining to the effect of vegetation cover on erosion rates (e.g., Manning's number for bare soil and reference vegetation cover, etc.) are adapted from Schmid et al. (2018). The model was simulated at a seasonal scale (time step of three months) from the autumn of 2000 (01/03/2000) to the summer of 2019 (28/02/2020). Simulations were conducted for a total time of 1000 years with a time-step of 1 season (3 months) with 20 years (2000 – 2019) of observations in vegetation and precipitation. These 20-years of observations were repeated (looped) 50 times, to identify, and detrend, long-term transient trends in catchment erosion rates due to potential differences in actual and assumed erosional parameters such as the hillslope diffusivity or fluvial erodibility. The combined effects of temporally variable (at seasonal

270 scale) precipitation and vegetation cover (also spatially variable) on catchment-scale erosion rates are therefore the primary
 271 factors influencing predicted erosion rates.

272

279 3.3 Implementation of vegetation dependent hillslope and Fluvial processes in Landlab components

280 This section includes the description of vegetation dependent hillslope and fluvial erosion routines defined in the Landlab
 281 components used in this study. Our approach is based on previous work by Istanbuluoglu (2005), Schmid et al., (2018), and
 282 Sharma et al., (2021).

283 3.3.1 Vegetation dependent hillslope processes

284 The rate of change in topography due to hillslope diffusion (Fernandes and Dietrich, 1997) is defined as follows:

$$285 \frac{\partial z}{\partial t}(\text{hillslope}) = \nabla q_s \tag{1}$$

286 where q_s is sediment flux along the slope S at a time step (where, dt is 1 season) in a grid cell. We applied slope and depth-
 287 dependent linear diffusion rule following the approach of Johnstone and Hilley (2014) such that:

$$288 q_s = K_d S d_* (1 - e^{-H/d_*}) \tag{2}$$

where K_d is diffusion coefficient [$\text{m}^2 \text{ season}^{-1}$], d_* is sediment transport decay depth [m], and H denotes sediment thickness in a grid cell at a particular time-step. In the model, the diffusion coefficient is dependent on vegetation cover present on hillslopes, which is estimated following the approach of Istanbuluoglu (2005), as follows:

$$K_d = K_b e^{-(\alpha V)} \quad (3)$$

where K_b is the diffusivity for bare soil [$\text{m}^2 \text{ season}^{-1}$] and α represents exponential decay coefficient (see Table A1 in Appendix). The vegetation cover fraction in a grid cell is denoted by V .

3.3.2 Vegetation dependent fluvial processes

The fluvial erosion is estimated for a two-layer topography (i.e., bedrock and sediment are treated explicitly) in the coupled detachment- / transport-limited model, SPACE 1.0 (Shobe et al., 2017). Bedrock erosion and sediment entrainment are calculated simultaneously in the model in each grid cell. The total fluvial erosion is defined as:

$$\frac{\partial z}{\partial t} (\text{fluvial}) = \frac{\partial R}{\partial t} + \frac{\partial H}{\partial t} \quad (4)$$

where, the left-hand side denotes the total fluvial erosion rate. The first and second terms on the right-hand side denote the bedrock erosion rate and sediment entrainment rate.

The rate of change of height of bedrock R per unit time [m season^{-1}] is defined as:

$$\frac{\partial R}{\partial t} = U - E_r \quad (5)$$

where E_r [m season^{-1}], is the volumetric erosion flux of bedrock per unit bed area. The previous equation implies that the topography adjusts to the rock uplift rates. As result, if model prescribed erosional parameters differ from those of the modern (actual) topography used for the initial condition, then a transience would occur until an equilibrium is reached between the prescribed parameters and the rock uplift rate. In practice, we found these the effect of this induced transience to be small, but we mitigated the effect through a linear detrending (see Section 3.6).

The sediment thickness is updated in each grid cell at a time-step such that the change in sediment thickness H [m] is defined as a fraction of net deposition rate and solid fraction sediments, which is expressed as:

$$\frac{\partial H}{\partial t} = \frac{D_s - E_s}{1 - \phi} \quad (6)$$

where, D_s [m season^{-1}] is the deposition flux of sediment, E_s [m season^{-1}] is volumetric sediment entrainment flux per unit bed area, and ϕ is the sediment porosity. The porosity in each study area are calculated from the bulk density estimations of Bernhard et al. (2018), which ranges from 0.43 in the semi-arid to 0.7 in the humid-temperate settings (see Table A1).

Following the approach of Shobe et al. (2017), E_s and E_r are expressed as follows:

$$E_s = (K_s q^m S^n - \omega_{cs}) \left(1 - e^{-\frac{H}{H_*}}\right), \quad (7)$$

$$E_r = (K_r q^m S^n - \omega_{cr}) e^{-H/H_*}, \quad (8)$$

where, K_s [m^{-1}] and K_r [m^{-1}] are the sediment erodibility and bedrock erodibility parameters, respectively. The threshold stream power for sediment entrainment and bedrock erosion are denoted as ω_{cs} [m season^{-1}] and ω_{cr} [m season^{-1}] in above equations.

Bedrock roughness is denoted as H_* [m] and the term e^{-H/H_*} corresponds to the soil production from bedrock. With higher bedrock roughness magnitudes, more sediment would be produced.

K_s and K_r were modified in each time step in the model simulations by introducing the effect of Manning's roughness to quantify the effect of vegetation cover on bed shear stress in each model grid cell:

$$\tau_v = \rho_w g (n_s + n_v)^{6/10} q^m S^n F_t \quad (9)$$

where, ρ_w [kg m⁻³] and g [m s⁻²] are the density of water and acceleration due to gravity respectively. Manning's numbers for bare soil and vegetated surface are denoted as n_s and n_v . F_t represents shear stress partitioning ratio. Manning's number for vegetation cover and F_t are calculated as follows:

$$n_v = n_{vr} \left(\frac{V}{V_r} \right)^w \quad (10)$$

$$F_t = \left(\frac{n_s}{n_s + n_v} \right)^{\frac{3}{2}} \quad (11)$$

where, n_{vr} is Manning's number for the reference vegetation. Here, V_r is reference vegetation cover (i.e. $V = 100\%$), V is local vegetation cover in a model grid cell, and w is the empirical scaling factor.

By combining the stream power equation (Tucker et al., 1999; Howard, 1994; Whipple and Tucker, 1999) and above concept of the effect of vegetation on shear stress, we define modified sediment and bedrock erodibility parameters, following the approach of Schmid et al. (2018) and Sharma et al. (2021), which are as follows:

$$K_{vs} = K_s \rho_w g (n_s + n_v)^{6/10} F_t \quad (12)$$

$$K_{vr} = K_r \rho_w g (n_s + n_v)^{6/10} F_t \quad (13)$$

where, K_{vs} [m⁻¹] and K_{vr} [m⁻¹] are modified sediment and bedrock erodibilities respectively. These are influenced by fraction of vegetation cover V in each grid cell at time-step. Hence, K_s and K_r in Eq. (7) and Eq. (8) are replaced by K_{vs} and K_{vr} in the model, to account for vegetation-dependent fluvial erosion. The trends of K_d , K_{vs} and K_{vr} are illustrated in Fig. 3 in Sharma et al., (2021).

3.3.3 Vegetation dependent soil-water infiltration

The soil-water infiltration rate is estimated by applying the Green-Ampt equation (Green and Ampt, 1911; Julien et al., 1995), which is as follows:

$$f(t) = K_e \left(1 + \frac{\psi \Delta \theta}{F} \right) \quad (14)$$

where $f(t)$ is the infiltration rate [m s⁻¹] at time t , K_e is the effective hydraulic conductivity [m s⁻¹], F is the cumulative infiltration [m], Ψ is the suction at the wetting front [m], and $\Delta \theta$ is the difference between saturated and initial volumetric moisture content [m³ m⁻³]. Effective hydraulic conductivity is highly variable and anisotropic; hence, it was considered to be uniform with a value of 1×10^{-6} m s⁻¹ for each catchment.

Following the approach of Istanbuluoglu and Bras, (2006) for loamy soils, the soil-water infiltration was modified to account for variable vegetation cover in each grid cell, as follows:

$$I_c(t) = f(t)(1 - V(t)) + 4f(t)(V(t)) \quad (15)$$

$$I_a(t) = \text{Min}[P(t), I_c(t)] \quad (16)$$

where I_c is the infiltration capacity and V is the vegetation cover (between 0 and 1) in a model grid cell at time-step t . Values used in the simulations for the parameters in equations 14-16 are provided in appendix Table A1.

3.3.4 Estimation of runoff rates

The precipitation rates [m season⁻¹] are subjected to soil-water infiltration [m season⁻¹] and evapotranspiration [m season⁻¹] to estimate the seasonal runoff rates [mm season⁻¹]. The runoff rates (R) at every time step (t) are calculated using the actual soil-water infiltration (I_a) and the actual evapotranspiration (ET) as follows,

$$R(t) = P(t) - I_a(t) - ET(t), \quad (17)$$

where, *P* is the precipitation amount in a season. This relationship was applied in the model grid cells with non-zero sediment thickness, which is updated at each time-step (see eq. 6) in order to facilitate infiltration. If the sediment is not present in the grid cell, there is no soil-water infiltration. As ET is the input parameter, there may be instances of higher ET than P in the summer seasons in the humid, Mediterranean and semi-arid settings. This is evident in figure 2b where the minimum of both values is used as ET in the given time-step.

3.4 Boundary and initial conditions

The boundaries are closed (no flow) on all sides, with a single stream outlet at the point of minimum elevation at boundary nodes (Fig. 3). In contrast to previous modeling studies (Schmid et al., 2018; Sharma et al., 2021) in the same study areas, we used present-day topography as the initial condition in each study area for simulations instead of a synthetic topography produced during a model spin-up phase in Landlab. This implies four different initial conditions for four study areas, such as topography, climate, vegetation, sediment thickness and porosity etc. Initial sediment cover thickness is considered uniform across the model domain, and was approximated based on observations by Schaller et al., (2018) and Dal Bo et al., (2019). The sediment thicknesses used are 0.2 m in the arid (AZ), 0.45 m in semi-arid (SG), 0.6 m in the Mediterranean (LC), and 0.7 m in humid temperate (NA) catchments. The rock uplift rate is kept constant throughout the entire model run as 0.05 mm yr⁻¹, adapted from a similar study (Sharma et al., 2021). However, in a 1000-year simulation, differences in base level (rock uplift) effects have limited impact on the variations in results interpreted here.

3.5 Overview of simulations conducted

The simulations were designed to identify the sensitivity of erosion rates to seasonal variations in either precipitation rates or vegetation cover, as well as the more realistic scenario of coupled seasonal variations in both vegetation cover and precipitation. We evaluated this sensitivity with a step-wise increase in model complexity. Three sets of simulations were designed for the four selected study areas, which are as follows, the following three scenarios:

1. Scenario 1: Influence of constant (mean seasonal) precipitation with seasonal variations in vegetation cover on catchment-scale erosion rates.
2. Scenario 2: Influence of seasonal variation in precipitation and constant (mean seasonal) vegetation cover on catchment-scale erosion rates.
3. Scenario 3: Influence of coupled seasonal variations in both precipitation and vegetation cover on catchment-scale erosion rates.

The results for scenarios 1 – 3 are illustrated in sections 4.1, 4.2, and 4.3, respectively.

3.6 Detrending of results for long term transients

Model simulations were conducted for 1,000 years using 20 years [March-2000 – Feb-2020] of observations in vegetation cover, and precipitation and were repeated 50 times for a total simulation duration of 1000 years. Simulations presented here were conducted on the present-day topography, which was updated at each time-step in the LEM (based on rock uplift rates and erosion) to allow for the application of observed time series of precipitation and vegetation change in different ecosystems and study areas. This choice of setting comes with the compromise that the erosional parameters (e.g., diffusivity, erodibility,

394 etc.) used in the model (see Table A1 in Appendix) are likely not the same as those that led to the present-day catchment
395 topography. As a result, a long-term transient in erosion rates is expected as the model tries to reach an equilibrium with
396 assumed erosional parameters. To correct for any long-term transients in erosion influencing our interpretations, we conducted
397 a linear detrending of the results to remove any long-term variations. The detrending was conducted through a linear regression
398 over entire time series of 1000 years and the values were corrected using the slope of the regression line. Hence, the detrended
399 model results for the last 20 years were analyzed and discussed in sections 4 and 5. In practice, the detrending of time series
400 did not impart a significant change to the results presented.

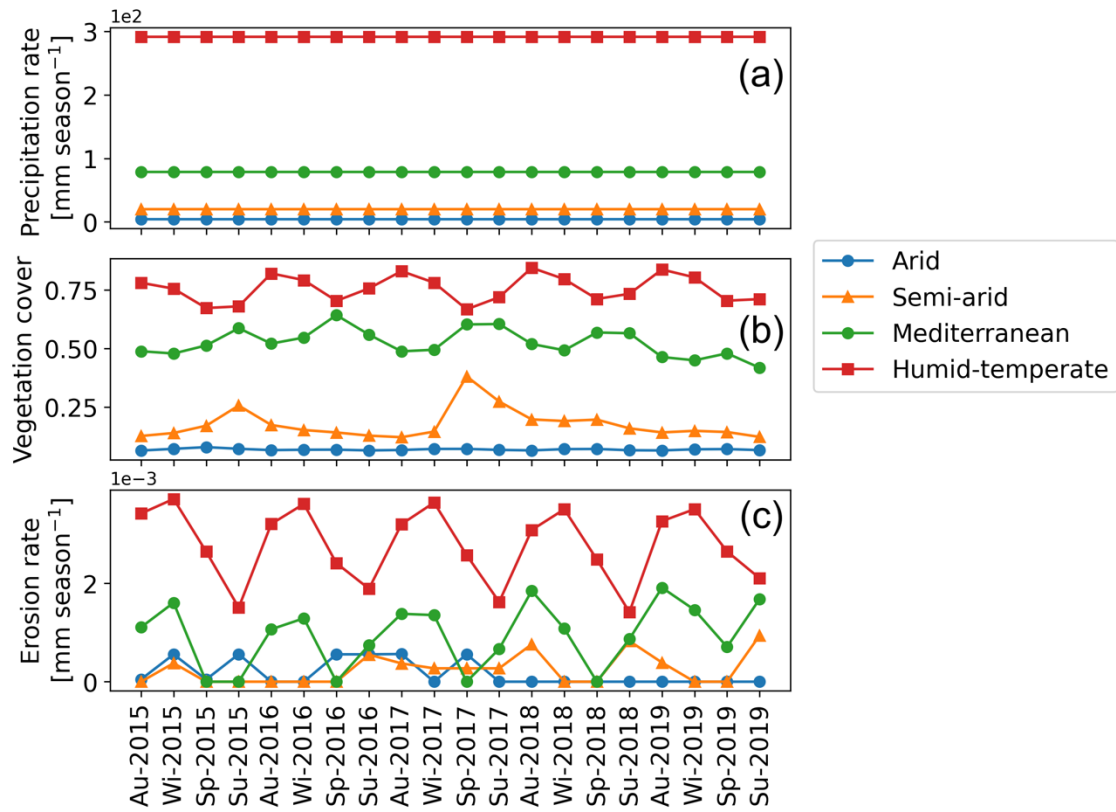

401 **4 Results**

402 In the following sections, we focus our analysis on the mean catchment erosion rates over seasonal (3 months) time scales (see
403 Table. 1). In all scenarios, the rock uplift rate was kept constant at 0.05 mm yr⁻¹ following the approach of Sharma et al. (2021).
404 For simple representation, the results of the last five years of the last cycle of transient simulations starting from Autumn-2015
405 to Summer-2019 are displayed in Fig. 4, 6, and 8 (after detrending, see section 3.6). The results for the entire time series
406 (Autumn-2000 – Summer-2019) are available in the supplement (Fig. 1 – 3). The precipitation and erosion rates are shown
407 with the units [mm season⁻¹].

408 **4.1 Scenario 1: Influence of constant precipitation and seasonal variations in vegetation cover on erosion rates**

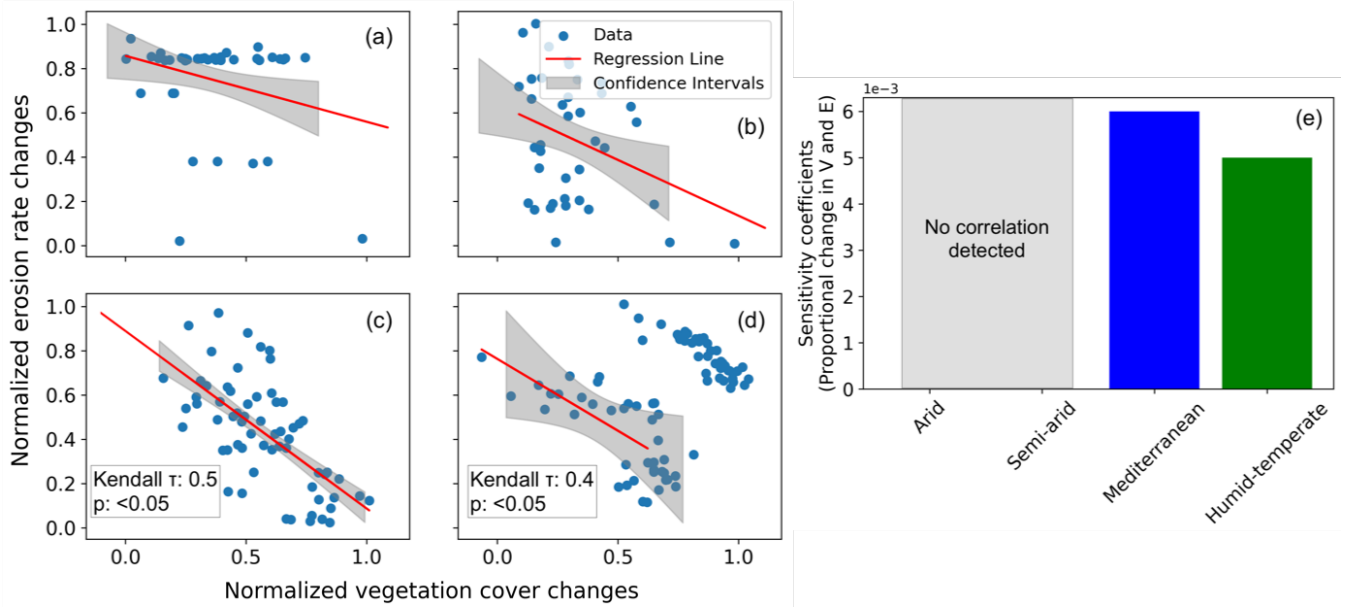

409 In scenario 1, vegetation cover (MODIS NDVI from March 2000 to February 2020) fluctuates seasonally (Fig. 4b), and
410 precipitation rates are kept constant at the seasonal mean (i.e., MAP divided by the number of seasons in a year) during the
411 entire time-series (Fig. 4a) (Ziese et al., 2020). The range of seasonal vegetation cover variations (and mean seasonal
412 precipitation rates) are observed as 0.06 – 0.08 (3.92 mm season⁻¹), 0.1 – 0.4 (20.16 mm season⁻¹), 0.35 – 0.65 (79 mm season⁻¹),
413 and 0.5 – 0.85 (292 mm season⁻¹) for the arid, semi-arid, Mediterranean and, humid temperate settings, respectively (Figs.
414 4a-b). The predicted mean catchment seasonal erosion rates range between 0 – 6 × 10⁻⁴ mm season⁻¹, 0 – 9.4 × 10⁻⁴ mm
415 season⁻¹, 0 – 2.3 × 10⁻³ mm season⁻¹, and 1.2 × 10⁻³ – 4 × 10⁻³ mm season⁻¹ for the arid, semi-arid, Mediterranean and
416 humid temperate settings, respectively (Fig. 4c).

417 To analyze the relationships between the relative changes in forcings and responses, seasonal changes in vegetation cover and
418 erosion rates were normalized between 0 and 1 and plotted in Figs. 5a-d. An inverse relationship and negative correlation
419 (Kendall-tau correlation coefficient: 0.4 – 0.5) is visible between the normalized catchment erosion rates and vegetation cover
420 for the dry season and wet season separately in the humid temperate (Fig. 5d) and Mediterranean settings (Fig. 5c). The
421 observed inversely linear relationship inbetween vegetation and erosion changechanges in the-Mediterranean and humid-
422 temperate settings indicates that these catchments are dominated by demonstrates the prevalence of fluvial (water-driven) and
423 overland flow processes, and the role of within these catchments, with hillslope diffusion is minimal playing a negligible role.
424 In contrast, no correlation was found for the arid and semi-arid settings.

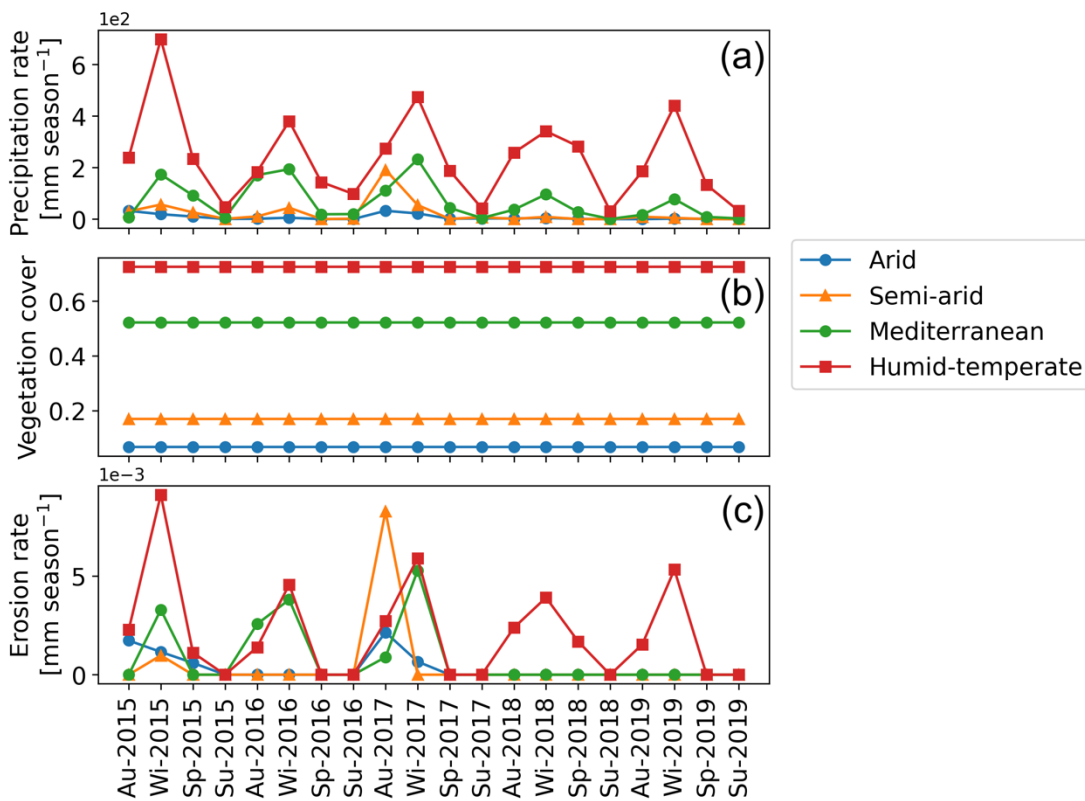

Figure 5. Seasonal changes (normalized) in vegetation cover and erosion rates for the scenario with constant precipitation and seasonal changes in vegetation cover in (a) arid, (b) semi-arid, (c) Mediterranean, and (d) humid-temperate settings, with the information on confidence interval (grey shading) and Kendall-tau correlation coefficients. (e) Sensitivity coefficients for proportional changes in vegetation cover and erosion rates based on the slope and intercept of the regression lines for the above environmental settings. The sensitivity coefficient is defined as the slope of the regression line presented in sub-sections a-d.

437 The sensitivity coefficients based on slope and intercept of the regression lines (Figs. 5a-d) are plotted in Fig. 5e. The results
 438 indicate a higher sensitivity of erosion rates to seasonal vegetation changes in the Mediterranean setting relative to humid-
 439 temperate setting. However, in the arid and semi-arid settings, the lack of a significant correlation in the change in vegetation
 440 cover and erosion rates leads to a low sensitivity. This is owed to very low mean precipitation rates ($<20 \text{ mm season}^{-1}$) in the
 441 arid and semi-arid settings. The predicted erosion rates are relatively low (e.g., $<0.004 \text{ mm season}^{-1}$) in this scenario, due to
 442 low mean precipitation rates, which are primarily subjected to infiltration and evapotranspiration in these drier settings.

443 4.2 Scenario 2: Influence of seasonal variations in precipitation and constant vegetation cover on erosion rates

444 In scenario 2, vegetation cover (MODIS NDVI from Mar-2000 – Feb-2020) is kept constant at the mean seasonal vegetation
 445 cover (Fig. 6b) and precipitation rates vary seasonally (Mar-2000 – Feb-2020) (Fig. 6a). The range of seasonal precipitation
 446 rate variations are observed in the range of $0 - 32.42 \text{ mm season}^{-1}$, $0 - 191.66 \text{ mm season}^{-1}$, $0.03 - 417 \text{ mm season}^{-1}$, and $26 -$
 447 $987 \text{ mm season}^{-1}$ in the arid, semi-arid, Mediterranean and, humid temperate settings, respectively.

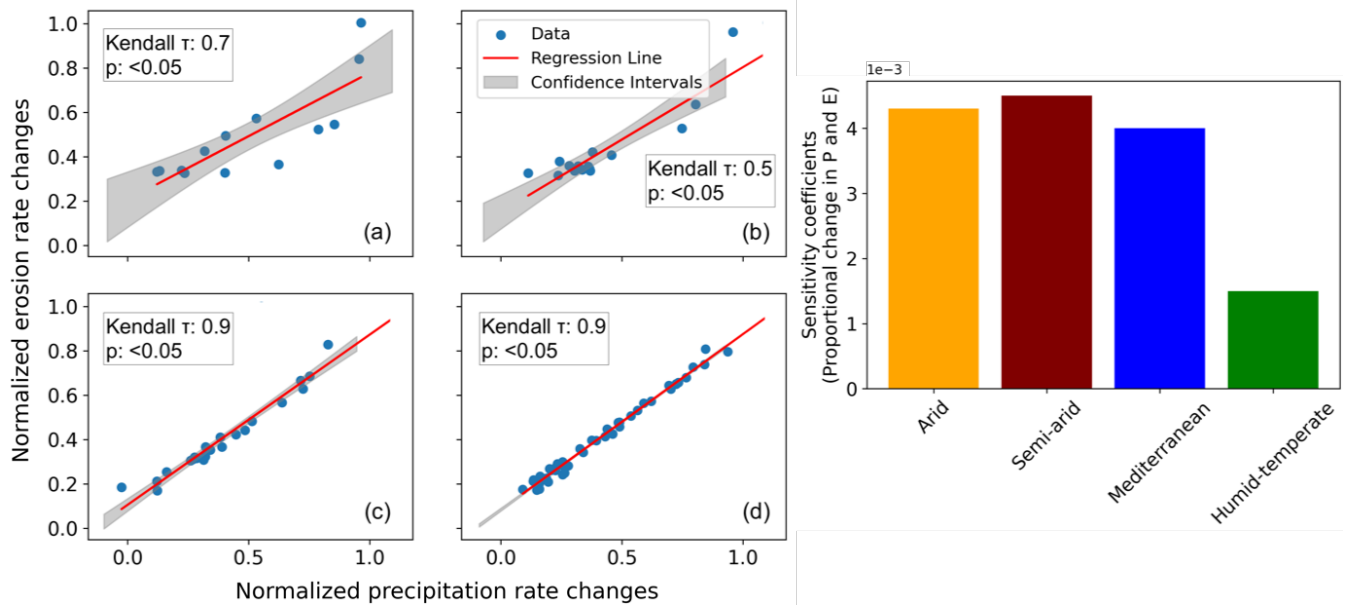

448 The simulated mean catchment seasonal erosion rates are observed in the range of $0 - 2 \times 10^{-3} \text{ mm season}^{-1}$, $0 - 8.3 \times 10^{-3}$
 449 mm season^{-1} , $0 - 1.37 \times 10^{-2} \text{ mm season}^{-1}$, and $0 - 1.3 \times 10^{-2} \text{ mm season}^{-1}$ in the arid, semi-arid, Mediterranean and, humid
 450 temperate settings, respectively (Fig. 6c).

451
 452 **Figure 6. Results of simulations with variable seasonal precipitation and constant vegetation over the last 5 years**
 453 **(Autumn-2015 – Summer-2019) of last cycle of transient-state model run representing: (a) mean catchment seasonal**
 454 **precipitation rates [mm season^{-1}], (b) mean catchment seasonal vegetation cover [-], and (c) mean catchment seasonal**
 455 **erosion rates [mm season^{-1}].**

456 Similar to scenario 1, the changes in seasonal precipitation and erosion rates were normalized between 0 and 1 and plotted in
 457 Figs. 7a-d. A strong positive correlation (Kendall-tau correlation coefficient ranging from 0.5 in semi-arid to 0.9 in
 458 Mediterranean and humid-temperate settings) in the normalized precipitation and erosion rates changes is predicted with the
 459 majority of the data points within the 95% confidence interval in all the settings. The sensitivity coefficients based on the
 460 proportional changes in precipitation and erosion rates, indicate the highest sensitivity in semi-arid settings) with $\sim 5\%$, $\sim 11\%$

461 and ~67% lower sensitivities in the arid, Mediterranean, and humid-temperate settings, respectively (Fig. 7e). This may be
 462 owed to the occasional El Niño events with extremely high precipitation occurring in the arid and semi-arid settings (with
 463 sparse vegetation cover-) in our study areas.

464
 465 **Figure 7. Seasonal changes (normalized) in precipitation and erosion rates for the scenario with seasonal changes in**
 466 **precipitation rates and constant vegetation cover in (a) arid, (b) semi-arid, (c) Mediterranean, and (d) humid-temperate**
 467 **settings, with the information on confidence interval (grey shading) and Kendall-tau correlation coefficients. (e)**
 468 **Sensitivity coefficients for proportional changes in precipitation and erosion rates based on the slope and intercept of**
 469 **the regression lines for the above environmental settings. The sensitivity coefficient is defined as the slope of the**
 470 **regression line presented in sub-sections a-d.**

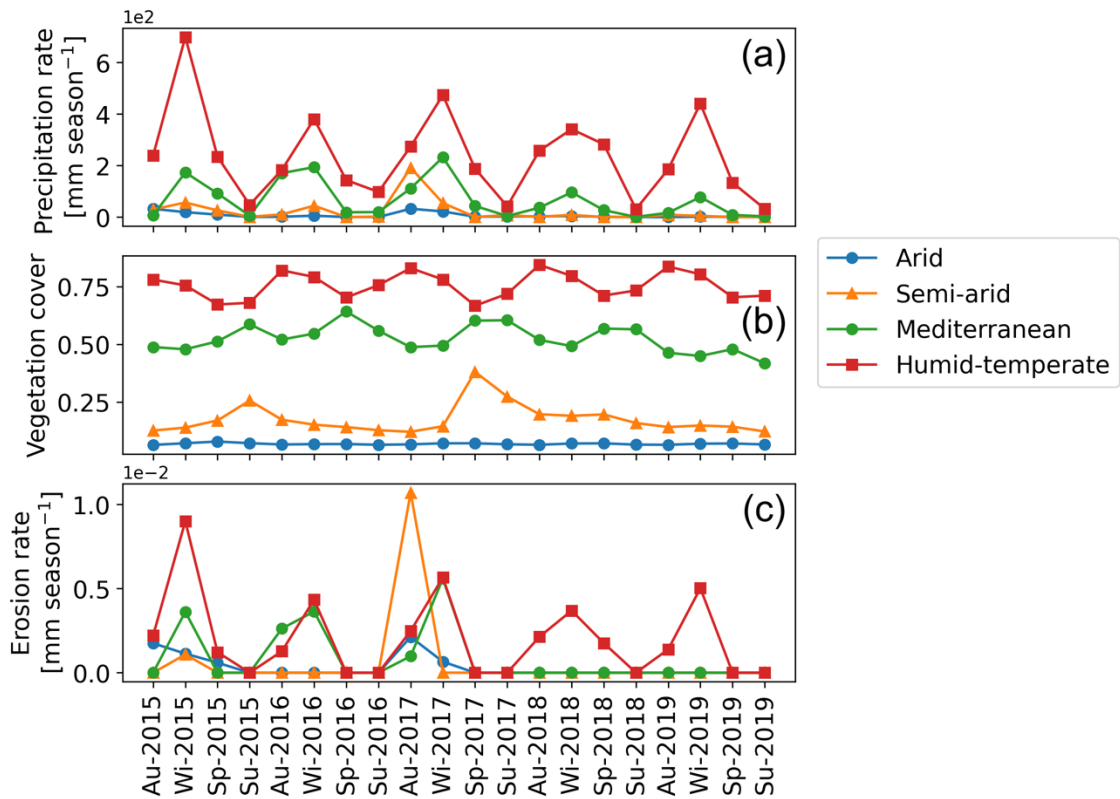

471 **4.3 Scenario 3: Influence of coupled seasonal variations in both precipitation and vegetation cover on erosion rates**

472 In this scenario, coupled variations in seasonal vegetation cover (MODIS NDVI from Mar-2000 – Feb-2020) (Fig. 8b) and
 473 precipitation rates are presented for the years 2000 - 2019 (Fig. 8a). The range of seasonal precipitation rates (and seasonal
 474 vegetation cover, V) variations are 0 – 32.42 mm season⁻¹ (V= 0.06 – 0.08), 0 – 191.66 mm season⁻¹ (0.1 – 0.38), 0.03 – 417
 475 mm season⁻¹ (0.35 – 0.65), and 26 – 987 mm season⁻¹ (0.5 – 0.85) in the arid, semi-arid, Mediterranean and, humid temperate
 476 settings, respectively (Figs. 8a-b). The mean catchment seasonal erosion rates range between 0 – 2×10^{-3} mm season⁻¹, 0 –
 477 1×10^{-2} mm season⁻¹, 0 – 1.4×10^{-2} mm season⁻¹, and 0 – 1.4×10^{-2} mm season⁻¹ in the arid, semi-arid, Mediterranean
 478 and, humid temperate settings, respectively (Fig. 8c).

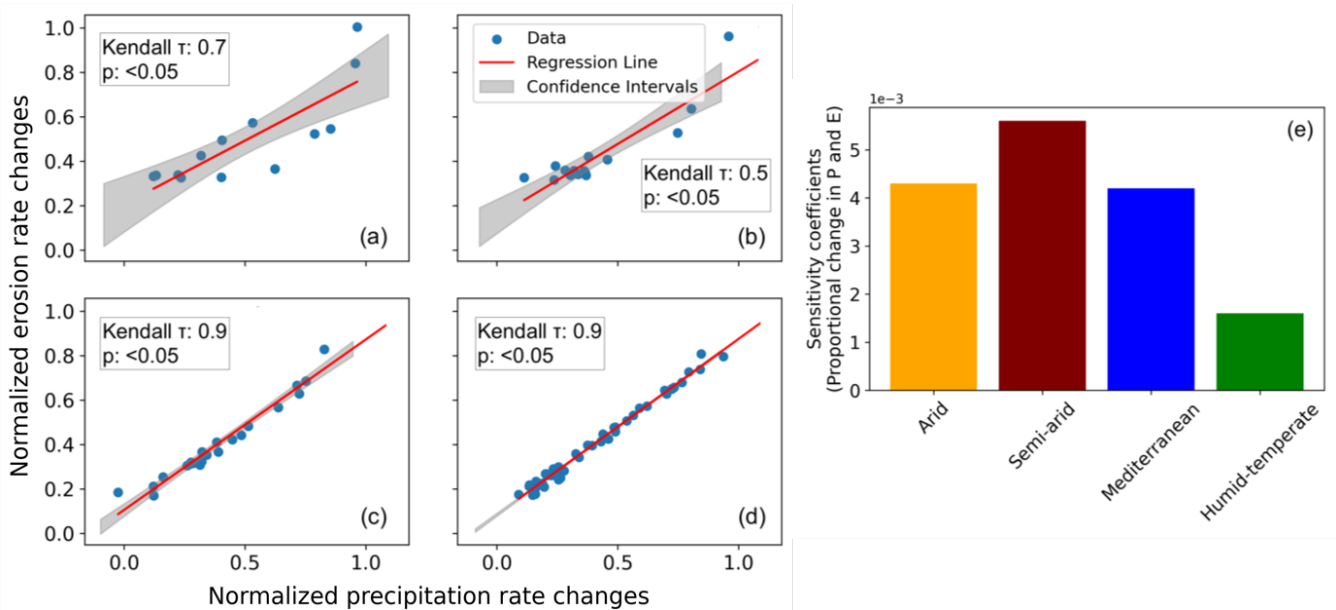

479 Changes in precipitation on erosion rates were normalized between 0 and 1 and plotted in figures. 9a-d. Similar to the results
 480 from scenario 2, a strong positive correlation was predicted in all the environmental settings. The sensitivity coefficients based
 481 on the proportional changes in precipitation and erosion rates, indicate the highest sensitivity in the semi-arid settings with
 482 ~25% and ~71% lower sensitivities in arid and Mediterranean, and humid-temperate settings, respectively (Fig. 9e). Similarly,
 483 the isolated effect of changes the in the vegetation cover on erosion rates (Fig. 10) does not yield a significant correlation in
 484 arid, semi-arid and Mediterranean settings. However, we observe a strong negative correlation in the humid-temperate setting
 485 (Fig. 10d) during the wet season (Kendall tau correlation coefficient: -0.6, with >95% significance level). Hence, the sensitivity
 486 coefficients in this case are not plotted.

487 The similarity in results obtained from scenarios 2 and 3 suggest a first-order control of seasonal precipitation changes on
 488 erosion rates (~70% higher sensitivity to changes in precipitation), with less significance to vegetation cover changes. For

489 example, the sensitivity of erosion to precipitation rate changes in semi-arid setting is predicted as ~70% higher to that of
 490 humid-temperate setting in both the scenarios.
 491

492

509 **5 Discussion**

510 ~~This section discusses the relationship between variations in seasonal precipitation and vegetation cover with erosion rates in~~
 511 ~~the form of the amplitude of change for each model scenario (section 5.1). This is followed by the synthesis of catchment scale~~
 512 ~~erosion rates variability over wet and dry seasons (section 5.2). In section 5.3, we discuss the impact transient dynamics of~~
 513 ~~sediment transport in our modelling approach. Finally, we compare our results with previously published studies (section 5.4)~~
 514 ~~and discuss model limitations (section 5.5).~~

515 **5.1 Synthesis of the amplitude of change in erosion rates for model scenarios 1-3**

516 The amplitude of change of mean catchment erosion rates [in percentage] varies at a seasonal scale (Fig. 11) between the study
 517 areas. The amplitude of change in erosion rates to their respective mean values was estimated (Fig. 11) using the coefficient
 518 of variation in percent (standard deviation divided by the mean of a dataset). The coefficient of variation is a statistical tool to
 519 compare multiple variables free from scale effects. It is a dimensionless quantity (Brown, 1998). This comparison represents
 520 the sensitivity of each catchment to changing seasonal weather for all three model scenarios (sections 4.1 – 4.3).

521 In scenario 1, with seasonal variations in vegetation cover and constant seasonal precipitation (Fig. 11), the amplitude of
 522 change in erosion rates ranges between 5% in the arid and 36% in Mediterranean setting. The above results support the findings
 523 of Zhang et al. (2019), which used the soil and water assessment tool (SWAT) based on NDVI and climate parameters. They
 524 observed 20-30% of the total change in sediment yield with constant precipitation and variable vegetation cover. ~~The above~~
 525 ~~study used the soil and water assessment tool (SWAT) based on NDVI and climate parameters.~~

526

527 **Figure 11. Stacked bar plot depicting the amplitude of change in seasonal erosion rates (relative to their respective**
 528 **means). Scenario 1 is shown in blue and had variable vegetation cover and constant precipitation rates. Scenario 2 is**
 529 **shown in orange and had constant vegetation cover and variable precipitation rates, and scenario 3 is shown in green**
 530 **and represents the simulation with coupled variations in vegetation cover and precipitation rates.**

531 In scenario 2, with constant vegetation cover and variable precipitation rates (Fig. 11), the amplitude of change in erosion rates
 532 ranges from 13% in the arid setting (AZ) to 52%, 65%, and 91% in humid-temperate (NA), semi-arid (SG) and Mediterranean
 533 (LC) settings, respectively. A similar trend is observed in scenario 3 with coupled variations in vegetation cover and
 534 precipitation rates (Fig. 11), with the amplitude of change in erosion rates between 13% in the arid setting up to 50%, 86%,
 535 and 97% in the humid-temperate, semi-arid and Mediterranean settings, respectively. The magnitude of erosion rate changes
 536 is amplified in scenario 3, especially in the semi-arid setting (e.g., ~21% increase in the amplitude of change from scenario 2
 537 to scenario 3). This amplification could be owed to the 35% change in vegetation cover in the semi-arid setting (Fig. 8).
 538 Overall, these observations indicate a high sensitivity of erosion in semi-arid and Mediterranean environments compared to
 539 arid and humid-temperate settings.

540 The pattern of erosion rate changes in scenarios 1-3 implies a dominant control of precipitation variations (rather than
 541 vegetation cover change) on catchment erosion rates at a seasonal scale. This interpretation is consistent with previous
 542 observational studies. For example, a field study by Suescún et al. (2017) in the Columbian Andes highlighted the significant
 543 influence of precipitation seasonality (over vegetation cover seasonality) on runoff and erosion rates. An observational
 544 catchment-scale study in the semi-arid Chinese Loess Plateau by Wei et al. (2015) indicated that intra-annual precipitation
 545 variations were a significant contributor to monthly runoff and sediment yield variations.

546 **5.2 Synthesis of catchment erosion rates over wet and dry seasons**

547 In this section, we discuss the ratio of seasonal precipitation and erosion rates with the mean annual precipitation (MAP) (Fig.
 548 12a) and mean annual erosion (MAE) (Fig. 12b) during different seasons (i.e., autumn – summer) in a year, averaged over the
 549 last cycle of the transient simulations (i.e., depicting the erosion rate predictions for 2000 – 2019). These are defined as the
 550 ratio of the mean erosion (and precipitation) rates in a season (e.g., winter) to the mean annual erosion rates (and MAP) during
 551 the last 20 years of the transient simulations. This was done to identify the impact of precipitation during wet seasons (in this
 552 case, winter) in influencing the annual erosion rates. This analysis was performed for the simulation results of scenario 3 for

553 different climate and ecological settings (i.e., arid to humid-temperate). We do this specifically with scenario 3 results to
 554 capture the trends in erosion rates with coupled variations in model input (i.e., precipitation and vegetation cover).

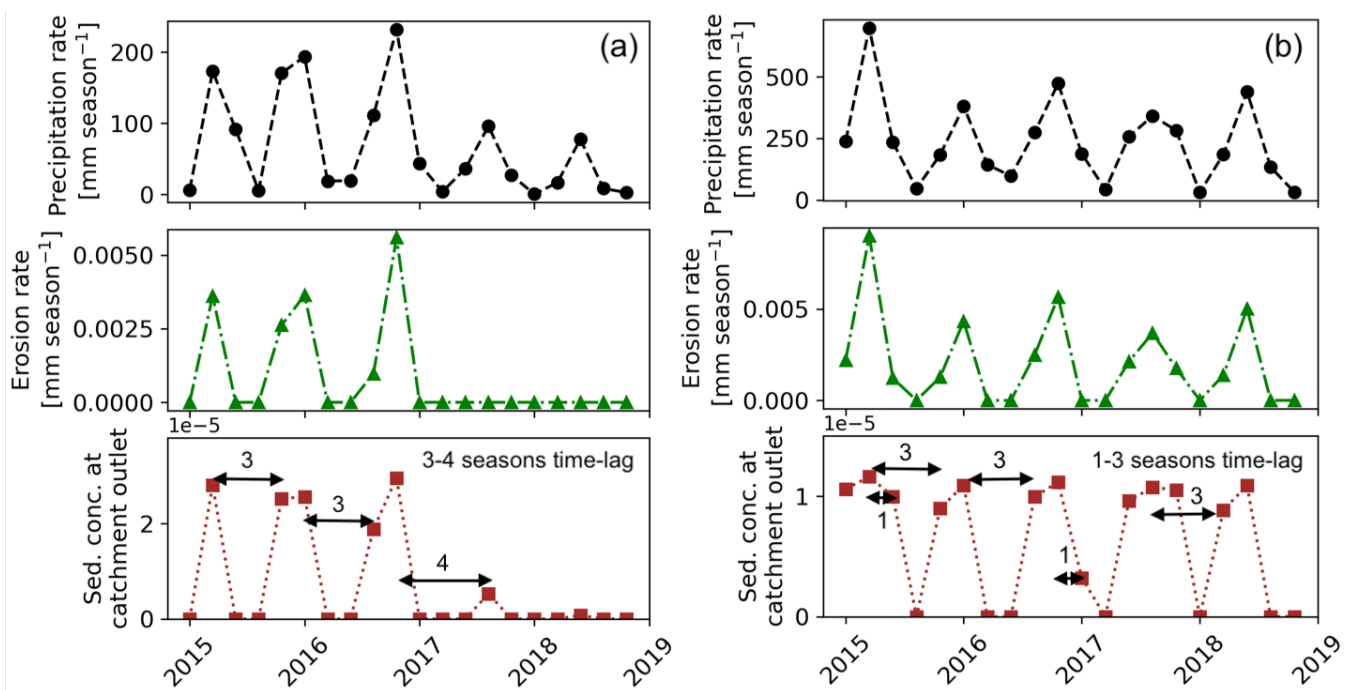

555
 556 **Figure 12. The ratio of seasonal precipitation and erosion rates to mean annual precipitation (MAP) and mean annual**
 557 **erosion (MAE) during the last cycle of transient simulations results from scenario 3 (coupled seasonal variations in**
 558 **precipitation and vegetation cover). The plots correspond to (a) the ratio of MAP per season [%] and (b) ratio of MAE**
 559 **per season [%]. Each color and point style represent the ratio for a distinct climate setting i.e., arid, semi-arid,**
 560 **Mediterranean, and humid-temperate settings.**

561 The values for the ratio of MAP during different seasons (Fig. 12a) depicts winter (June-August) and summer (December-
 562 February) as the wettest and driest seasons of the year, respectively. For example, all study areas receive >50% and <6% of
 563 MAP during winters and summers. The same is reflected in Fig. 12b with 45%, 55%, 78%, and 71% of MAE in the arid, semi-
 564 arid, Mediterranean, and humid-temperate settings, respectively, during winters. On the contrary, during summers the share of
 565 MAE decreases from 14% in the arid setting to 1% in the humid-temperate setting. The Autumn (March-May) receives lower
 566 precipitation amounts that range from 20–30% of MAP in the study areas. Arid and semi-arid settings experience a relatively
 567 higher share of MAE (e.g., ~30%) than the Mediterranean and humid temperate settings (e.g., ~15-20%). The Spring season
 568 experiences relatively higher erosion rates despite a smaller share of MAP in arid and semi-arid settings. For example, the arid
 569 and semi-arid settings experience 10-14% of the MAE for ~7% of MAP. At the same time, the Mediterranean and humid-
 570 temperate settings experience 5-7% of MAE for ~12-18% of MAP during Spring. Overall, we find that arid and semi-arid
 571 settings experience <15% and ~50% of MAE during the wet (winter) and dry (summer) seasons. The above relationship is
 572 amplified for the Mediterranean and humid-temperate settings with <5% and >70% of MAE occurring during wet and dry
 573 seasons, respectively. The latter is in agreement with an observational study by Mosaffaie et al., (2015) in a Mediterranean
 574 catchment in Iran. More specifically, Mosaffaie et al., (2015) used field observations from 2012-2013 to conclude that
 575 maximum erosion rates (>70%) are observed during the wet season, which decreases in the dry season (<10%).

576 **5.3 Consideration of transient sediment dynamics in model results**

577 This section discusses the impact of lag times from when sediment is eroded ~~in from~~ a source area until it leaves the catchment
 578 outlet. This analysis was conducted because in natural systems, when sediment is eroded from its source, it takes time to leave
 579 the catchment (in this case the model domain) and recorded as eroded in our analysis. According to field studies and modeling
 580 experiments, this time lag is usually more than a season (*i.e.* 3 months) (e.g., Buendia et al., (2016)). ~~To capture~~ Also, these
 581 ~~time lags in precipitation, erosion and concentration of sediment leaving the catchment outlet, the model output for the~~
 582 ~~Mediterranean and humid temperate settings are compared (Fig. 13). We perform this analysis lags are dependent~~ on the
 583 ~~morphology of the catchment in addition to the geology, climate and vegetation cover of the area. Hence, the simulation results~~
 584 ~~(of scenario 3 with coupled variations in seasonal precipitation and vegetation cover) for the catchments in the Mediterranean~~
 585 ~~(Fig. 13a) and humid-temperate settings (Fig. 13b) are compared. We do this to capture the topological influence on lag times,~~
 586 ~~as both the catchments have different topographies and surface area. The time-lags in precipitation, erosion and concentration~~
 587 ~~of sediment leaving the catchment outlet are analyzed and presented in Fig. 13. The concentration of sediment is defined as a~~
 588 ~~dimensionless quantity (Q_s/Q) estimated from sediment flux (Q_s) and discharge rates (Q) at catchment outlet at a particular~~
 589 ~~time-step in the model simulation.~~

590
 591 **Figure 13. Simulation results (scenario 3: coupled variations in precipitation in vegetation cover) to capture the time-**
 592 **lags in precipitation, erosion rates and sediment concentration at catchment outlet) over the last five years (Autumn-**
 593 **2015 – Summer-2019) of the last cycle of transient-state model run for the catchments in: (a) Mediterranean and (b)**
 594 **humid-temperate setting.**

595 In the Mediterranean settings, these time lags range from 3 to 4 seasons, and are relatively large (e.g., from wet season 2016
 596 to wet season of 2017, see Fig. 13a-), ~~despite high channel relief of 1800 m. This signal is also blended due to the relatively~~
 597 ~~large surface area of the catchment (i.e., 106 km²). However, in humid-temperate setting, these time lags range from 1 to 3~~
 598 ~~seasons, mostly owed to the relatively higher (Fig. 13b) with relatively lower channel relief (i.e., 800 m) and smaller catchment~~
 599 ~~area (i.e., 69 km²). Hence, the time lags in the study areas are dominated by the changes in vegetation cover and precipitation~~
 600 ~~magnitude and frequency in this the region (Fig. 13b) with minimal influence of topology of the catchment. This is owed to the~~
 601 ~~primary influence of vegetation and precipitation modulations rather than the base level changes in the catchment topology on~~
 602 ~~the lag times in sediment dynamics.~~ In the catchments in both these climate settings, the pulse of sediment leaving the

603 catchment is fairly distributed with the maximum concentration of sediment leaving the catchment in the same wet season
604 when it is eroded from its source. These time-lags would result in enhanced sensitivity of the proportional changes in erosion
605 rates to the changes in seasonal precipitation and (or) vegetation cover, as the sediment is transported even in the seasons when
606 the sediment is not eroded from its source (e.g., wet season in 2017 in both the above climate settings). This poses a limitation
607 to the current study and is again revisited in the model limitations (section 5.5).

608 **5.4 Comparison to previous studies**

609 In this section, we relate the broad findings of this study to the previously published observational studies. In an observational
610 study in an agrarian drainage basin in the Belgian Loam Belt, Steegen et al., (2000) evaluated sediment transport over various
611 time scales (including seasonal). They observed lower sediment fluxes during the seasons with high vegetation cover. In
612 addition, an observational study by Zheng (2006) investigated the effect of vegetation changes on soil erosion in the Loess
613 Plateau, China, and concluded that soil erosion was significantly reduced (up to ~50%) after vegetation restoration. Another
614 observational study in semi-arid grasslands in the Loess Plateau, China, by Hou et al., (2020) highlighted a considerable
615 reduction in erosion rates due to the development of richness and evenness of the plant community in the early to the mid wet
616 season. Our results from scenario 1 (seasonal variations in vegetation cover with constant precipitation rates) support the
617 findings of the above studies whereby a negative correlation (Kendal τ : -0.4 – -0.5) was found between vegetation cover and
618 erosion rates in humid-temperate and Mediterranean settings (see Fig. 5).

619 A catchment-scale observational study in Baspa Valley, NW Himalayas (Wulf et al., 2010), analyzed seasonal precipitation
620 gradients and their impact on fluvial erosion using weather station observations (1998 – 2007). The study observed a positive
621 correlation between precipitation and sediment yield variability, demonstrating the summer monsoon's first-order control on
622 erosion processes. An observational study by Wei et al., (2015) in Loess Plateau, China, evaluated erosion and sediment
623 transport under various vegetation types and precipitation variations. They found that significant changes in landscape pattern
624 and vegetation coverage (i.e., land use land cover) might contribute to long-term dynamics of soil loss. However, seasonal
625 variations in runoff and sediment yield were mainly influenced by rainfall seasonality. In comparison to the results of this
626 study, we find the similarity in the patterns of erosion rates in scenario 2 (variable precipitation and constant vegetation cover)
627 and scenario 3 (coupled variations in precipitation and vegetation) are consistent with the findings of Wei et al., (2015). For
628 example, the amplitude of change in erosion rates (Fig. 10) in scenarios 2 and 3 differ by 0%, 6%, and -2% in the arid,
629 Mediterranean, and humid-temperate settings, respectively. However, this difference is enhanced in the semi-arid region (i.e.,
630 ~23%) due to a relatively high degree of variation (~25%) in seasonal vegetation cover change.

631 Finally, an observational study in the Columbian Andes by Suescún et al., (2017) assessed the impact of seasonality on
632 vegetation cover and precipitation and found higher erosion rates in regions with steeper slopes. Another study by Chakrapani
633 (2005) emphasized the direct impact of local relief and channel slope on sediment yield in natural rivers. The broad findings
634 of the above studies agree with our results from scenarios 1-3, as we find higher erosion rates in the Mediterranean and humid-
635 temperate regions with steeper topography (mean slope ~20 deg), which encounter high seasonality (and intensity) in
636 precipitation.

637 **5.5. Model Limitations**

638 The model setup used in this study was designed to quantify the sensitivity of erosion rates in different climate and ecological
639 settings with variations in precipitation rates and vegetation cover at seasonal scales. We represent the degree of variations in
640 erosion rates in terms of changes in the amplitude (with respect to the mean) for different model scenarios (see sections 4.1 –
641 4.3).

642 Our modeling approach used several simplifying assumptions that warrant discussion and are avenues for investigation in
643 future studies. For example, model results presented here successfully capture the major surface processes, including
644 vegetation-dependent erosion and infiltration, sediment transport, and surface runoff. However, groundwater flow is not
645 considered in the current study, and how the reentry of groundwater into streams over seasonal scales would influence
646 downstream erosion. The reason is that groundwater flow modeling includes a high amount of heterogeneity and anisotropy
647 and requires much finer grid sizes (<1m) and smaller time steps (in seconds to hours). Thus, due to the large grid-cell size (90
648 m), timescales (monthly), and high uncertainty in subsurface hydrologic parameters we were unable to evaluate the effects of
649 groundwater flow on our results. Furthermore, this study assumed uniform lithologic and hydrologic parameters (e.g., vertical
650 hydraulic conductivity, initial soil moisture, evapotranspiration, erodibility, etc.) over the entire catchment. As said earlier,
651 these properties are subject to a high level of uncertainty and heterogeneity, the best fitting parameters, based on previously
652 published literature (e.g., Schaller et al., 2018; Bernhard et al., 2018; Schmid et al., 2018; Sharma et al., 2021) are used for the
653 model simulations. However, the heterogeneity in vegetation cover and related soil-water infiltration per grid cell is used in
654 this study. For the heterogeneity in vegetation cover, we use MODIS-derived NDVI as a proxy of vegetation cover. According
655 to Garatuza-Payán et al. (2005), NDVI is assumed as an effective tool for estimating seasonal changes in vegetation cover
656 density. However, the spatial resolution (250 m) of the NDVI dataset is lower than that of the SRTM DEM (90 m) used in the
657 study. Nevertheless, the difference in spatial resolution of vegetation cover and topography might introduce ambiguity in the
658 model results. Furthermore, transient dynamics associated with sediment storage in the model is not incorporated in the study
659 to capture the time lag required for the eroded sediment to move out of the model domain. As the LEM (SPACE 1.0) used in
660 this study shuffles between detachment- and transport-limited fluvial erosion, we suspect that in such short timescales (3
661 months) and in small catchments, detachment-limited fluvial erosion is dominant. Hence, any sediment removed from its
662 source is transported out of the domain in a given time-step. However, it is recommended for future studies considering larger
663 or lower gradient catchments, where sediment storage may be more significant than documented here, an analysis of erosion
664 at a local scale (e.g., at individual model grid cells) is recommended.

665 A final limitation stems from several generalized model parameters (e.g., rock uplift rate, erodibility, diffusivity, etc.) applied
666 to the SRTM DEM (as initial topography). We did this to capture the effects of seasonality in precipitation and vegetation
667 cover in modern times (2000 - 2019). However, the current topography might not have evolved with the same tectonic and
668 lithological parameters. To address this limitation, we conducted simulations for 50 iterations and detrended the model results
669 to remove those transient effects (see section 3.6). This limitation can be handled in future studies by parameterizing the model
670 to the current topography using stochastic (e.g., Bayesian) techniques (e.g., Stephenson et al., 2006; Avdeev et al., 2011). As
671 this study was aimed to capture the control of seasonal precipitation and (or) vegetation changes on the relative variability of
672 erosion rates, the above limitation may not pose a problem in the model results.

673 **6 Summary and Conclusions**

674 In this study, we applied a landscape evolution model to quantify the impact of seasonal variations in precipitation and
675 vegetation on catchment averaged erosion rates. We performed this in regions with varied climate and ecology including: arid,
676 semi-arid, Mediterranean, and humid-temperate settings. Three sets of simulations were designed to model erosion rates for
677 (a) scenario 1: constant precipitation and variable vegetation cover, (b) scenario 2: variable precipitation and constant
678 vegetation cover, and (c) scenario 3: coupled variations in precipitation and vegetation cover. The main conclusions derived
679 from this study are as follows:

- 680 1. Scenario 1, with variable vegetation cover and constant precipitation (Fig. 4), resulted in small variations in seasonal
681 erosion rates (<0.02 mm yr⁻¹) in comparison to the other scenarios. The amplitude of change in seasonal erosion rates

682 (relative to the mean) is the smallest in humid-temperate setting and maximum in the Mediterranean setting (Fig.
683 10a). For example, it ranges from 5% in the arid setting (Pan de Azúcar) to 23% and 36% in the semi-arid (Santa
684 Gracia) and Mediterranean settings (La Campana), respectively.

- 685 2. Scenario 2, with constant vegetation cover and variable precipitation (Fig. 6), results in relatively higher seasonal
686 erosion rates ($<0.06 \text{ mm yr}^{-1}$) in comparison to scenario 1. The amplitude of change in seasonal erosion rates (relative
687 to the mean) is smallest in the arid setting and largest in the Mediterranean setting (Fig. 10b). For example, it ranges
688 from 13% in the arid setting (Pan de Azúcar) to 52%, 65%, and 91% in the humid-temperate (Nahuelbuta), semi-arid
689 (Santa Gracia), and Mediterranean settings (La Campana), respectively.
- 690 3. Scenario 3, with coupled variations in vegetation cover and precipitation (Fig. 8), results in similar seasonal erosion
691 rates ($<0.06 \text{ mm yr}^{-1}$) to scenario 2. Similarly, the amplitude of change in seasonal erosion rates (relative to the mean)
692 is the smallest in the arid setting and the largest in the Mediterranean setting (Fig. 10c). For example, it ranges from
693 13% in the arid setting (Pan de Azúcar) to 50%, 86%, and 97% in the humid-temperate (Nahuelbuta), semi-arid (Santa
694 Gracia), and Mediterranean settings (La Campana), respectively. A significant increase (from scenario 2) in the
695 variation in erosion rates ($\sim 21\%$) is owed to the $\sim 25\%$ variation in vegetation cover in semi-arid settings.
- 696 4. All study areas experience maximum and minimum erosion during wet and dry seasons, respectively (Fig. 11b).
697 However, the difference (in maximum and minimum) is amplified from the arid ($\sim 30\%$) to the Mediterranean and
698 humid-temperate settings ($\sim 70\text{-}75\%$). This is owed to the range of amplitude of precipitation rate change (Fig. 7)
699 increasing from the arid (e.g., $\sim 9 \text{ mm}$) to humid-temperate settings (e.g., $\sim 543 \text{ mm}$) in wet and dry seasons.

700 Finally, this study was motivated by testing the hypotheses that (1) if precipitation variations primarily influence seasonal
701 erosion, then the influence of seasonal vegetation cover changes would be less significant, and (2) catchment erosion in drier
702 settings is more sensitive to seasonality in precipitation and vegetation, than wetter settings. With respect to hypothesis 1, we
703 found that seasonal precipitation variations primarily drive catchment erosion and the effects of vegetation cover variations
704 are secondary. Results presented here (Fig. 10b) support this interpretation with a high amplitude of change in erosion rates
705 (with respect to means) ranging from 13 to 91% for the scenario with constant vegetation cover and seasonal precipitation
706 variations. However, the effect of seasonal vegetation cover changes is also significant (Fig. 10a), ranging between 5 – 36%.
707 Hence, the first hypothesis is partially confirmed, but the magnitude of response depends on the ecological zone investigated.
708 Concerning hypothesis 2, we found that seasonal changes in catchment erosion are more pronounced in the semi-arid and
709 Mediterranean settings and less pronounced in the arid and humid temperate settings. This interpretation is supported by Fig.
710 10c, with a significantly high amplitude of change in catchment erosion in semi-arid ($\sim 86\%$) and Mediterranean ($\sim 97\%$)
711 settings with relatively lower changes in humid temperate ($\sim 50\%$) and arid ($\sim 13\%$) settings, partially confirming the
712 hypothesis.

718 **Appendix A: Input parameters with corresponding units for the landscape evolution model**

719 **Table A1. Input parameters with corresponding units for the landscape evolution model**

Model Parameters	Values
Grid spacing (dx)	90 m
Model runtime (totalT)	1000 years (2000 - 2019 repeated over 50 times)
time-step (dt)	1 season (3 months)
Rock uplift rate (U) ¹	1.25 x 10 ⁻⁵ [m season ⁻¹] (or 0.05 [mm a ⁻¹])
Initial sediment thickness (H_initial) ²	20 (A*), 45 (SA*), 60 (M*), 70 (HT*) [cm]
Bedrock erodibility (Kr) ¹	2 x 10 ⁻⁹ [m ⁻¹]
Sediment erodibility (Ks) ¹	2 x 10 ⁻⁸ [m ⁻¹]
Reach scale bedrock roughness (H*) ¹	1 [m]
Porosity (Φ) ⁴	0.51 (A*), 0.43 (SA*), 0.51 (M*), 0.7 (HT*) [-]
Fraction of fine sediments (Ff) ¹	0.2 [-]
Effective terminal settling velocity (Vs) ¹	2.5 [mm season ⁻¹]
m, n ¹	0.6, 1 [-]
Bedrock erosion threshold stream power (ω_cr) ¹	1.25 x 10 ⁻⁵ [m season ⁻¹]
Sed. entr. threshold stream power (ω_cs) ¹	1.25 x 10 ⁻⁶ [m season ⁻¹]
Bare soil diffusivity (Kb) ¹	2.5 x 10 ⁻⁴ [m ² season ⁻¹]
Exponential decay coefficient (α) ¹	0.3 [-]
Critical channel formation area (A_crit) ³	1 x 10 ⁶ [m ²]
Reference vegetation cover <u>cover</u> (V_r) ³	1 (100%)
Manning's number for bare soil (n_s) ³	0.01 [-]
Manning's number for ref. vegetation (n_v) ³	0.6 [-]
Scaling factor for vegetation influence (w) ³	1 [-]
Soil bulk density (B) ⁴	1300 (A*), 1500 (SA*), 1300 (M*), 800 (HT*) [kg m ⁻³]
Soil type ⁴	sandy loam (A*, SA*, and M*); sandy clay loam (HT*)
Initial soil moisture (s) ⁵	0.058 (A*), 0.02 (SA*), 0.053 (M*), 0.15 (HT*) [m ³ m ⁻³]

721 *A: arid; SA: semi-arid; M: Mediterranean; HT: humid-temperate setting.

722 **Appendix B: Implementation of vegetation dependent hillslope and fluvial processes in Landlab components**

723 ~~This section includes the description of vegetation dependent hillslope and fluvial processes defined in the Landlab components~~
 724 ~~used in this study, based on the approaches by Istanbulluoglu (2005) Schmid et al., (2018), and Sharma et al., (2021).~~

725 ~~**B1 Vegetation dependent hillslope processes**~~

726 ~~The rate of change in topography due to hillslope diffusion (Fernandes and Dietrich, 1997) is defined as follows:~~

727
$$\frac{\partial z}{\partial t} (\text{hillslope}) = \nabla q_s \tag{A1}$$

728 ~~where q_s is sediment flux along the slope S . We applied slope and depth dependent linear diffusion rule following the approach~~
 729 ~~of Johnstone and Hilley (2014) such that:~~

730
$$q_s = K_d S d_* (1 - e^{-H/d_*}) \tag{A2}$$

731 where K_d is diffusion coefficient [$\text{m}^2 \text{yr}^{-1}$], d_x is sediment transport decay depth [m], and H denotes sediment thickness.

732 The diffusion coefficient is defined as a function of vegetation cover present on hillslopes, which is estimated following the
733 approach of Istanbulluoglu (2005), as follows:

$$734 \quad K_d = K_b e^{-(\alpha V)} \quad (\text{A3})$$

735 where K_d is defined as a function of vegetation cover V , an exponential decay coefficient α , and linear diffusivity K_b for bare
736 soil.

737 **B2 Vegetation dependent fluvial processes**

738 The fluvial erosion is estimated for a two-layer topography (i.e., bedrock and sediment are treated explicitly) in the coupled
739 detachment / transport limited model, SPACE 1.0 (Shobe et al., 2017). Bedrock erosion and sediment entrainment are
740 calculated simultaneously in the model. Total fluvial erosion is defined as:

$$741 \quad \frac{\partial z}{\partial t} (\text{fluvial}) = \frac{\partial R}{\partial t} + \frac{\partial H}{\partial t} \quad (\text{A4})$$

742 where, left hand side denotes the total fluvial erosion rate. The first and second terms on right hand side denote the bedrock
743 erosion rate and sediment entrainment rate.

744 The rate of change of height of bedrock R per unit time [m yr^{-1}] is defined as:

$$745 \quad \frac{\partial R}{\partial t} = U - E_r \quad (\text{A5})$$

746 where E_r [m yr^{-1}], is the volumetric erosion flux of bedrock per unit bed area.

747 The change in sediment thickness H [m] per unit time [yr] is defined as a fraction net deposition rate and solid fraction
748 sediments, as follows:

$$749 \quad \frac{\partial H}{\partial t} = \frac{D_s - E_s}{1 - \phi} \quad (\text{A6})$$

750 where, D_s [m yr^{-1}] is the deposition flux of sediment, E_s [m yr^{-1}] is volumetric sediment entrainment flux per unit bed area, and
751 ϕ is the sediment porosity.

752 Following the approach of Shobe et al. (2017), E_s and E_r given by:

$$753 \quad E_s = (K_s q^m S^n - \omega_{cs}) \left(1 - e^{-\frac{H}{H_*}}\right) \quad (\text{A7})$$

$$754 \quad E_r = (K_r q^m S^n - \omega_{cr}) e^{-H/H_*} \quad (\text{A8})$$

755 where, K_s [m^{-1}] and K_r [m^{-1}] are the sediment erodibility and bedrock erodibility parameters respectively. The threshold stream
756 power for sediment entrainment and bedrock erosion are denoted as ω_{cs} [m yr^{-1}] and ω_{cr} [m yr^{-1}] in above equations. Bedrock
757 roughness is denoted as H_* [m] and the term e^{-H/H_*} corresponds to the soil production from bedrock. With higher bedrock
758 roughness magnitudes, more sediment would be produced.

759 K_s and K_r were modified in the model runtime scripts by introducing the effect of Manning's roughness to quantify the effect
760 of vegetation cover on bed shear stress in each model cell:

$$761 \quad \tau_v = \rho_w g (n_s + n_v)^{6/10} q^m S^n F_t \quad (\text{A9})$$

762 where, ρ_w [kg m^{-3}] and g [m s^{-2}] are the density of water and acceleration due to gravity respectively. Manning's numbers for
763 bare soil and vegetated surface are denoted as n_s and n_v . F_t represents shear stress partitioning ratio. Manning's number for
764 vegetation cover and F_t are calculated as follows:

$$n_v = n_{vr} \left(\frac{V}{V_r} \right)^w, \quad (A10)$$

$$F_t = \left(\frac{n_s}{n_s + n_v} \right)^{\frac{3}{2}}, \quad (A11)$$

where, n_{vr} is Manning's number for the reference vegetation. Here, V_r is reference vegetation cover ($V = 100\%$) and V is local vegetation cover in a model cell, w is empirical scaling factor.

By combining stream power equation (Tucker et al., 1999; Howard, 1994; Whipple and Tucker, 1999) and above concept of the effect of vegetation on shear stress, we follow the approach of Schmid et al. (2018) and Sharma et al. (2021) to define new sediment and bedrock erodibility parameters influenced by the surface vegetation cover on fluvial erosion, as follows:

$$K_{vs} = K_s \rho_w g (n_s + n_v)^{6/10} F_t, \quad (A12)$$

$$K_{vr} = K_r \rho_w g (n_s + n_v)^{6/10} F_t, \quad (A13)$$

where, K_{vs} [m^+] and K_{vr} [m^+] are modified sediment erodibility and bedrock erodibility respectively. These are influenced by the effect of presence of fraction of vegetation cover V . Hence, K_s and K_r in Eq. (8) and Eq. (9) are replaced by K_{vs} and K_{vr} to include an effect of vegetation cover on fluvial processes in the model. The trends of K_{vs} , K_{vr} and K_{vr} are illustrated in Fig. 3 in Sharma et al., (2021).

Code and data availability

The code and data used in this study are freely available via Zenodo (<https://doi.org/10.5281/zenodo.8033782>, Sharma and Ehlers, 2023).

Author contributions

HS and TAE designed the initial model setup and simulation programs. HS and TAE conducted model modifications, simulation runs, and analysis. HS prepared the initial paper with contributions from TAE draft and both authors contributed to revisions.

Competing interests

The authors declare that they have no conflict of interest.
