12

13

14 **Abstract.** Substantial uncertainties in bedload transport predictions in steep streams have ~~triggered~~ encouraged intensive
15 efforts to develop surrogate monitoring technologies. One such system, the Swiss plate geophone (SPG), has been deployed
16 and calibrated in numerous steep water courses, mainly in the Alps. Calibration relationships linking the signal recorded by
17 the SPG system to the transported bedload can vary substantially between different monitoring stations, likely due to site-
18 specific factors such as ~~the~~ flow velocity and ~~the~~ bed roughness. Furthermore, recent controlled experiments on the SPG
19 system have shown that site-specific calibration relationships can be biased by elastic waves resulting from impacts
20 occurring outside the plate boundaries. Motivated by these findings, ~~here~~ we present here a hybrid calibration procedure
21 derived from flume experiments and an extensive dataset of 308 calibration measurements from four different SPG field
22 monitoring stations. Our main goal is to investigate the feasibility of a general, site-independent calibration procedure for
23 inferring fractional bedload transport from the SPG signal. First, we use flume experiments to show that sediment size
24 classes can be distinguished more accurately using a combination of vibrational frequency and amplitude information than
25 by using amplitude information alone. Second, we apply this amplitude-frequency method to field measurements to derive
26 general calibration coefficients for ten different grain-size fractions. The amplitude-frequency method results in more
27 homogeneous signal responses across all sites and significantly improves the accuracy of fractional sediment flux and grain-
28 size estimates. We attribute the remaining site-to-site discrepancies to large differences in flow velocity, and discuss further
29 factors that may influence the accuracy of these bedload estimates.

30 1 Introduction

31 Flood events across Europe in the summer of 2021 have illustrated the threat of flood-related hazards like bedload transport
32 to human life and infrastructure, especially in small and steep mountainous catchments (Badoux et al., 2014; Blöschl et al.,
33 2020). Understanding sediment transport processes is also essential for efforts to return rivers to their near-natural state by
34 restoring their continuity and re-establishing balanced sediment budgets (e.g. Brouwer and Sheremet, 2017; Pauli et al.,
35 2018; Logar et al., 2019; Rachelly et al., 2021). However, monitoring and predicting bedload transport still represents a
36 considerable challenge because of its large spatio-temporal variability (e.g. Mühlhofer, 1933; Einstein, 1937; Reid et al.,
37 1985; Rickenmann, 2018; Ancey, 2020). This is especially true for steep streams, because they are poorly described by
38 traditional bedload transport equations, which have mainly been developed for lower-gradient channels (e.g. Schneider et al.,

Formatiert: Englisch (USA)

39 2016). Predicting sediment transport in steep channels is challenging, notably due to the presence of macro-roughness
40 elements affecting both the flow resistance and the flow energy (e.g. Manga and Kirchner, 2000; Yager et al., 2007, 2012;
41 Bathurst, 2007; Nitsche et al., 2011; Rickenmann and Recking, 2011; Prancevic and Lamb, 2015). It is further complicated
42 by a sediment supply that varies in both space and time, due in part to cycles of building and breaking of an armoring layer
43 at the riverbed (e.g. Church et al., 1998; Dhont and Ancey, 2018; Rickenmann, 2020; Piantini et al., 2021).

44 Bedload transport equations established for lower-gradient streams typically result in ~~substantial multiple order-of-~~
45 ~~magnitude~~ errors when applied to steep streams, motivating the development of new indirect monitoring techniques for steep
46 mountain channels (e.g. Gray et al., 2010; Rickenmann, 2017). Indirect monitoring techniques provide large spatial coverage
47 of river transects at high temporal resolution, reduce personal risk related to in-stream sampling, and enable consistent data
48 collection at widely varying flow conditions, including ~~during~~ ~~flood~~ ~~ing~~ ~~events~~ ~~s~~ (e.g. Gray et al., 2010; Rickenmann, 2017;
49 Geay et al., 2020; Bakker et al., 2020; Choi et al., 2020; Le Guern et al., 2021). The drawback of these monitoring
50 technologies is that in order to provide quantitative measurements, they ~~often~~ require intensive calibration through direct
51 bedload sampling with retention basins (Rickenmann and McArdell, 2008), slot samplers (e.g. Habersack et al., 2017; Halfi
52 et al., 2020) or mobile bag samplers (e.g. Bunte et al., 2004; Dell'Agnese et al., 2014; Hilldale et al., 2015; Mao et al., 2016;
53 Kreisler et al., 2017; Nicollier et al., 2021^a).

54 Among indirect monitoring techniques, the Swiss plate geophone (SPG) system has been deployed and tested in more
55 than 20 steep gravel-bed streams and rivers, mostly in the European Alps (Rickenmann, 2017). Typically, linear or power-
56 law calibration relationships have been developed between measured signal properties and bedload transport characteristics
57 (Rickenmann et al., 2014; Wyss et al. 2016a; Kreisler et al., 2017; Kuhnle et al., 2017). Such calibration equations ~~facilitate~~
58 ~~permit absolute spatio-temporal estimates~~ ~~quantification~~ of bedload fluxes, ~~their variability in time and space (i.e. across a~~
59 ~~river section), estimates of absolute estimates of bedload fluxes and~~ bedload grain-size distributions, and the detection of the
60 start and end of bedload transport. However, these equations ~~have required~~ ~~require a~~ calibration ~~procedure~~ against
61 independent bedload transport measurements ~~from at~~ each individual field site, because until now we have lacked generally
62 applicable signal-to-bedload calibration equations that are valid ~~in multiple~~ ~~across~~ field settings. Although ~~the~~ similarities
63 between calibration relationships at various field sites are encouraging, it is not well understood why the linear calibration
64 coefficients for total mass flux can vary by about a factor of 20 among individual samples from different sites, or by about a
65 factor of six among the mean values from different sites (Rickenmann et al., 2014; Rickenmann and Fritschi, 2017). Given
66 the substantial field effort required for calibration campaigns, a generally applicable calibration equation would represent a
67 significant advance.

68 Numerous studies have reported successful calibration of impact plate systems in laboratory flumes (e.g. Bogen and
69 Møen, 2003; Krein et al., 2008; Tsakiris et al., 2014; Mao et al., 2016; Wyss et al., 2016b,c; Kuhnle et al., 2017; Chen et al.,
70 2022^d), although transferring these flume-based calibrations to the field remains challenging. Nonetheless, controlled flume
71 experiments are valuable because they allow ~~us~~ to systematically explore relationships between the recorded signal, the
72 transport rates of different sediment size fractions, and the hydraulic conditions. For example, the experiments of Wyss et al.
73 (2016b) showed that higher flow velocities induce a weaker SPG signal response per unit of transported sediment. More
74 recent controlled experiments have highlighted another important site-dependent factor influencing the SPG signal response,
75 namely the grain-size distribution (GSD) of the transported bedload (Nicollier et al., 2021^a), where coarser grain mixtures
76 were shown to yield a stronger signal response per unit bedload weight.

77 Subsequent impact tests and flume experiments showed that this grain-size dependence arises because the impacts
78 plates are insufficiently isolated from their surroundings (Antoniazza et al., 2020; Nicollier et al., 2021^b2022). The elastic
79 wave generated by an impact on or near a plate was found to propagate over several plate lengths, contaminating the signals
80 recorded by neighboring sensors within a multiple plate array. Nicollier et al. (2021^b2022) introduced the notion of

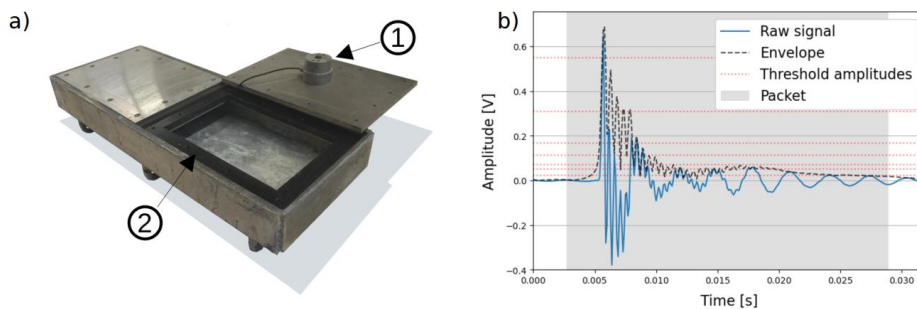

81 “apparent packets” ([in opposition to “real” packets](#)) to define the portions of the recorded signal that were generated by such
82 extraneous particle impacts.

83 The main goal of this contribution is to examine the feasibility of a general, site-independent signal conversion
84 procedure for fractional bedload flux estimates. We follow a comprehensive hybrid signal conversion approach that
85 encompasses a set of full-scale controlled flume experiments conducted at an outdoor flume facility, as well as 308 field
86 calibration measurements performed with direct sampling methods at four different bedload monitoring stations in
87 Switzerland between 2009 and 2020. We present the amplitude-frequency (AF) method, aiming to reduce the bias introduced
88 by apparent packets in the relationship between the signal characteristics and the particle size. Finally, we compare the
89 performance of this novel AF method against the [purely](#)-amplitude-histogram (AH) method developed by Wyss et al.
90 (2016a) for [both](#) fractional and total bedload flux estimates, [as well as for characteristic grain size estimates](#).

91 2 Methods

92 2.1 The SPG system

93 The Swiss plate geophone (SPG) consists of a geophone sensor fixed under a steel plate of standard dimensions 492 mm x
94 358 mm x 15 mm (Fig. 1a; Rickenmann, 2017). The geophone (GS-20DX by Geospace technologies; www.geospace.com)
95 uses a magnet moving inside an inertial coil (floating on springs) as an inductive element. The voltage induced by the
96 moving magnet is directly proportional to its vertical velocity resulting from particle impacts on the plate. [The SPG system](#)
97 [can detect bedload particles with a diameter down to 10 mm \(Rickenmann et al., 2014, 2020; Wyss et al., 2016a\)](#). Typically,
98 a SPG array includes several plates next to each other, acoustically isolated by elastomer elements and covering the river
99 cross-section. The array is either embedded in a concrete sill or fixed at the downstream face of a check dam. A detailed
100 description of the SPG system can be found in Rickenmann et al. (2014). [For all the calibration measurements and the](#)
101 [outdoor flume experiments analyzed in this study, ranging from a few seconds to one hour, the full raw signal 10 kHz](#)
102 [geophone signal was recorded \(Fig. 1b\). In the normal operational recording mode with continuous data storage, due to](#)
103 [data storage limitations, field stations usually do not continuously record the full raw 10 kHz geophone signal. Instead, it is](#)
104 [typically but only preprocessed, and summary values \(Rickenmann et al., 2014\), such as the maximum amplitude and the](#)
105 [number of impulses, are recorded at one minute intervals. However, for the relatively short duration of a single calibration](#)
106 [measurement, ranging from a few seconds to one hour, the full raw signal is recorded \(Fig. 1b\).](#)

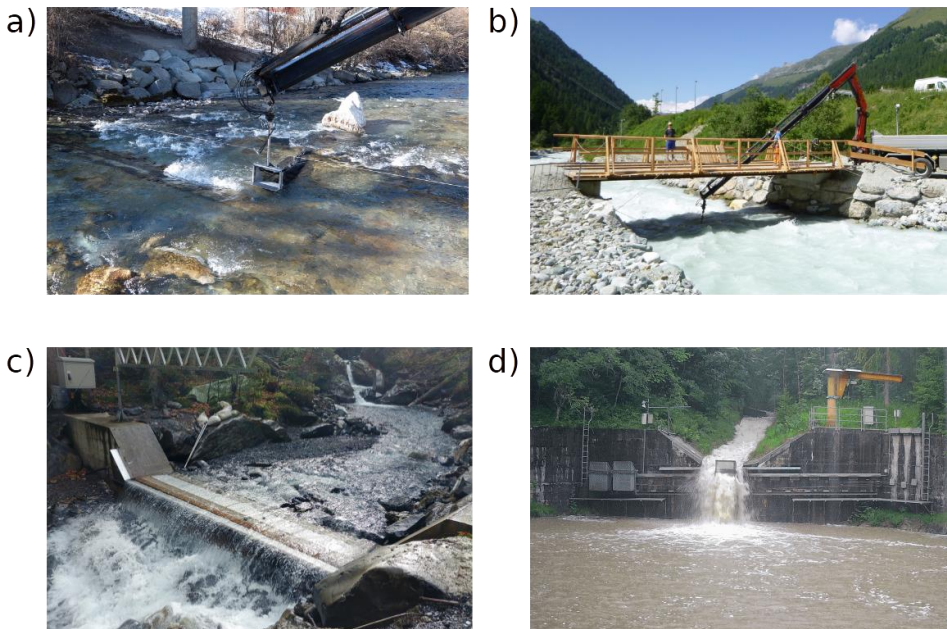

107
108 **Figure 1:** (a) Swiss plate geophone (SPG) system before installation (see Fig. 3). Each plate is equipped with a uniaxial geophone
109 sensor fixed in a watertight aluminum box (1) attached to the underside of the plate. The plates are acoustically isolated from each
110 other by elastomer elements (2). (b) Example of a packet (grey area) detected by the SPG system. A packet begins 20 time steps

111 (i.e., 2 ms) before the signal envelope crosses the lowest amplitude threshold of 0.0216 V and ends 20 time steps after the last
112 crossing of the lowest amplitude threshold (see Sect. 2.4).
113

114 2.2 Field calibration measurements

115 To test the AF and AH methods, this study uses 308 calibration measurements from four Swiss bedload monitoring stations
116 equipped with [the SPG systems](#) (Fig. 2; Table 1). Field calibration samples were collected at the Albula, Navisence and
117 Avançon de Nant stations, and extensive calibration efforts have been undertaken at the fourth field station, [the Erlenbach](#),
118 since 2009 (Rickenmann et al., 2012). The Erlenbach offers an interesting comparison with the other sites due to different
119 channel and flow characteristics upstream of the SPG plates. These are the only field sites equipped with an SPG system at
120 which the full raw geophone signal has been recorded during calibration measurements. Field calibrations carried out at each
121 of the four sites at the four sites consisted of the following steps: (i) direct bedload sampling downstream of an impact plate
122 using either crane-mounted net samplers adapted from Bunte traps (Bunte et al., 2004; Dell’Agnese et al., 2014; Nicollier et
123 al., 2019; Fig. 2a, b), automated basket samplers (Rickenmann et al., 2012; Fig. 2d) or manual basket samplers (Fig. 2c;
124 [Antoniazza et al., 2022](#)), (ii) synchronous recording of the raw geophone signal, (iii) sieving and weighing of bedload
125 samples using ten sieve classes ([see Sect. 2.4 Table 3](#)), and (iv) comparing the fractional bedload mass of each sample to the
126 ~~packet histogram data~~ geophone signal to derive the corresponding calibration coefficients. ~~$k_{b,t}$~~ . A more detailed
127 description of the sampling procedure is reported in Supporting Information S1, including the mesh sizes used for bedload
128 sampling. For the analysis, only particles larger than 9.5 mm were considered, being close to the SPG detection threshold.
129 Streamflow information was derived from various stage sensors (Table 1). Flow velocity V_w was introduced by Wyss et al.
130 (2016c) as a possible governing parameter affecting the number of particles detected by the SPG system. Unfortunately, due
131 to the lack of continuous flow velocity measurements at the Albula and Navisence sites, we were not able to account for the
132 effect of the flow velocity in the signal conversion procedure described in the present study.

133

151 2.3 Controlled flume experiments

152 The first part of the signal conversion procedure described in this study is based on controlled flume experiments conducted
 153 at the outdoor flume facility of the Oskar von Miller institute of TU Munich in Obernach, Germany. At this facility, we
 154 reconstructed the bed characteristics of the Albula, Navisence and Avançon de Nant field sites, one after another, in a flume
 155 test reach with dimensions of 24 m x 1 m equipped with two impact plates (Fig. 3). ~~For Each~~ site reconstruction ~~we tested~~
 156 ~~used~~ bedload material collected during field calibration measurements, and we adjusted the flow velocity, flow depth, and
 157 bed roughness to match the respective field observations. A detailed description of the original flume setup and the
 158 performed experiments can be found in Nicollier et al. (2020). In this paper, we primarily use the single-grain-size
 159 experiments conducted in 2018 with the flume configured to match conditions at the Albula field site (Table 2). Single-
 160 grain-size experiments consisted of feeding the flume with a fixed number of grains for each of the ten particle-size classes
 161 described in Sect. 2.2 above. While these particles were ~~being~~ transported over the SPG system, the full raw geophone signal
 162 was recorded. Up to 33 repetitions were conducted until a representative range of amplitude and frequency values for each
 163 grain-size class ~~were was~~ obtained (Nicollier et al., 2021^a). The same procedure was repeated for two different flow
 164 velocities ($V_f = 1.6 \text{ m s}^{-1}$ and 2.4 m s^{-1}). The obtained information was then used to derive empirical relationships between

165 the mean particle size $D_{m,j}$ and ~~the packet envelope's amplitude $MaxAmp_{env}$ and the ratio $MaxAmp_{env} / f_{centroid}$ properties~~
 166 ~~of the SPG signal~~, as described in Sect. 2.5.2 below.

167 To illustrate the AF and AH methods and their respective performance, we use flume experiments that mimic the
 168 Avançon de Nant field site, but with the addition of a 4 m wooden partition wall (Fig. 3) that shields one geophone plate
 169 from impacting particles (Nicollier et al., ~~2024b~~2022). With this modified setup, single-grain-size experiments were run
 170 using grains from each of the 10 particle-size classes ~~and originating from the Avançon de Nant channel~~, resulting in a total
 171 of 51 runs (Table 2). The flow velocity was set to 3 m s^{-1} to facilitate particle transport through the narrower flume section
 172 and is therefore not representative for the Avançon de Nant site, where typical flow velocities were roughly 1.3 m s^{-1} .

173

174
 175 **Figure 3:** Oblique view of the Obernach flume test reach with total length of 24 m and width of 1 m. The bed surface is paved with
 176 particles with diameters equaling the characteristic D_{67} and D_{84} sizes of the natural beds of the reconstructed sites. Grains were
 177 fed into the channel 8 m upstream from the SPG system location (G1 and G2) using either a vertical feed pipe or a tiltable basket
 178 (1). The sensor plate G1 (in red) was shielded from direct particle impacts by the 4 m long removable partition wall (2). The
 179 partition wall and the impact plates were decoupled from each other by a 2 mm vertical gap to prevent disturbances of the
 180 recorded signal. Plexiglas walls (3) on each side of the flume facilitated video recordings of the experiments.

181

182 **Table 2:** Flume and hydraulic characteristics for the reconstruction of the Albula and the Avançon de Nant field sites.

Parameter	Units	Reconstructed field site setup	
		Albula (without partition wall)	Avançon de Nant (with partition wall)
Flume width	m	1.02	1.02
Flume gradient of the natural bed	%	0.7	4.0
Bed surface D_{67}^a	mm	120	200
Bed surface D_{84}^a	mm	190	320
Number of D_{67} -particles/ m^2	m^{-2}	15.0	5.0
Number of D_{84} -particles/ m^2	m^{-2}	5.0	2.5
Min. water depth above SPG	m	0.79	0.35

Max. water depth above SPG	m	0.91	0.35
Min. flow velocity 10 cm above SPG ^b	m s ⁻¹	1.6	3.0
Max. flow velocity 10 cm above SPG ^b	m s ⁻¹	2.4	3.0
Min. unit discharge	m ² s ⁻¹	1.6	0.8
Max. unit discharge	m ² s ⁻¹	2.4	0.8
Number of different flow velocity settings	-	2	1
Total number of single-grain-size experiments	-	355	51
Total number of tested particles	-	10705	2485

^a On the basis of line-by-number pebble counts at the natural site and a photo-sieving based granulometric analysis with BASEGRAIN software (Detert and Weitbrecht, 2013).

^b Flow velocities measured with the OTT MF Pro magnetic-inductive flow meter.

2.4 The amplitude-histogram method

Wyss et al. (2016a) introduced the packet-based amplitude-histogram (AH) method to derive grain-size information from geophone signals. A packet is defined as a brief interval, typically lasting 5 to 30 milliseconds, reflecting a single [particle impact of a particle](#) on a plate (Fig. 1b); it begins and ends when the signal envelope crosses a threshold amplitude of 0.0216 V. The signal envelope is computed in Python with the Hilbert transform (Jones et al., 2002), yielding [the magnitude of the analytic signal](#) a continuous time series reflecting, i.e. the total energy in the signal. Each packet's maximum amplitude is then used to assign it to a predefined amplitude class j [delimited by amplitude-histogram thresholds \$th_{ah,j}\$](#) (Table 3), yielding a packet-based amplitude histogram (e.g. Fig. 4 in Wyss et al., 2016a). Each amplitude class j is related to a corresponding grain-size class through the following relationship between the mean amplitude $A_{m,j}$ [V] and the mean particle size $D_{m,j}$ [mm]:

$$A_{m,j} = 4.6 \cdot 10^{-4} \cdot D_{m,j}^{1.71}. \quad (1)$$

The coefficients in Eq. (1) were determined using 31 basket samples collected at the Erlenbach for which the maximum geophone amplitude was analyzed as a function of the B-axis of the largest particle found in the sample (Wyss et al., 2016a). The grain-size classes are delimited by the size of the meshes $D_{sieve,j}$ used to sieve the bedload samples from field calibration measurements. [For a given bedload sample, it](#) is assumed that the number of packets between two [amplitude-histogram thresholds \$th_{ah,j}\$](#) is [related to a good proxy for](#) the fractional bedload mass between the respective sieve sizes (Wyss et al., 2016a). In the present study, we have extended the seven size classes used by Wyss et al. (2016a) to ten classes, in order to assess the performance of the AH and AF methods for larger particles.

Table 3: Characteristics of the size classes j according to Wyss et al. (2016a) derived from with the sieve mesh sizes $D_{sieve,j}$ (for classes 1 to 7) according to Wyss et al. (2016a), and the mean particle diameter $D_{m,j}$, and the amplitude-histogram thresholds $th_{ah,j}$ derived from Eq. (1), and, Additionally the lower and upper amplitude-frequency thresholds $th_{af,low,j}$ and $th_{af,up,j}$ derived from Eq. (4) and (5), respectively (see Sect. 2.5.2). Particles in classes 8 to 10 were manually sorted on the basis of linearly extrapolated $D_{m,j}$ values. The value of $D_{m,j}$ for the largest class (10) in brackets is an estimate, because this size class is open-ended and thus the mean varied somewhat from site to site.

Class j	$D_{sieve,j}$	$D_{m,j}$	$th_{ah,j}$	$th_{af,low,j}$	$th_{af,up,j}$
[-]	[mm]	[mm]	[V]	[V]	[V Hz ⁻¹]
1	9.5	12.3	0.0216	0.0132	$1.55 \cdot 10^{-5}$
2	16.0	17.4	0.0527	0.0364	$2.33 \cdot 10^{-5}$
3	19.0	21.8	0.0707	0.0509	$4.45 \cdot 10^{-5}$
4	25.0	28.1	0.1130	0.0868	$7.67 \cdot 10^{-5}$

5	31.4	37.6	0.1670	0.1362	$1.78 \cdot 10^{-4}$
6	45.0	53.2	0.3088	0.2725	$3.93 \cdot 10^{-4}$
7	63.0	71.3	0.5489	0.5244	$7.05 \cdot 10^{-4}$
8	80.7	95.5	0.8378	0.8489	$1.56 \cdot 10^{-3}$
9	113.0	127.9	1.4919	1.6342	$2.79 \cdot 10^{-3}$
10	144.7	(171.5)	2.2760	2.6438	-

211

212 2.5 The amplitude-frequency method

213 In a recent study, Nicollier et al. (2021b2022) showed that the SPG system is sensitive to extraneous particle impacts despite
214 the isolating effect of the elastomer. Extraneous signals at individual geophone plates can arise from impacts occurring on
215 neighboring plates, or from impacts on the concrete sill surrounding the SPG array. While attenuated to some extent, the
216 elastic waves generated by such impacts can reach multiple geophone sensors with enough energy to be recorded as
217 “apparent” packets. Thus, packet histograms (i.e. counts of the number of packets per class j) are subject to a certain bias,
218 especially in the lower size classes. The degree of bias was found to depend mainly on two factors. First, coarser grain sizes
219 of transported bedload were shown to generate more apparent packets. Second, more apparent packets were recorded, for a
220 given bedload mass, at transects containing more SPG plates. Nicollier et al. (2021b2022) showed that packet characteristics
221 such as the start time, the amplitude and the frequency help in identifying apparent packets and filtering them out from the
222 final packet histograms. This filtering method was subsequently applied to all four field calibration datasets (Albula,
223 Navisence, Avançon de Nant and Erlenbach) and helped to reduce the differences between the site-specific mean calibration
224 relationships for the total bedload flux by about 30% (Nicollier et al., 2021b2022). Based on these observations, the present
225 study proposes an amplitude-frequency (AF) method as an adaptation of the amplitude-histogram (AH) method presented by
226 Wyss et al. (2016a). By introducing two-dimensional (amplitude and centroid frequency) size class thresholds, the new
227 method aims to reduce the effect of apparent packets and improve the accuracy of fractional bedload flux estimates. Note
228 that the procedure does not allow to make the difference between particles impacting one plate simultaneously, but the high
229 (10 kHz) recording frequency of the SPG system minimizes its probability of occurrence

230 2.5.1 Centroid frequency

231 According to the Hertz contact theory, the frequency at which a geophone plate vibrates is controlled by the size of the
232 colliding particle (Johnson, 1985; Thorne, 1986; Bogen and Møen, 2003; Barrière et al., 2015; Rickenmann, 2017). In the
233 present study, the frequency spectrum of a packet is characterized by the spectral centroid f_{centroid} . It represents the center of
234 mass of the spectrum and is computed as

$$235 \quad f_{\text{centroid}} = \frac{\sum f_n \cdot A_{\text{FFT},n}}{\sum A_{\text{FFT},n}} \quad (2)$$

236 where $A_{\text{FFT},n}$ [V·s] is the Fourier amplitude (computed with the Fast Fourier Transform FFT) corresponding to the frequency
237 f_n [Hz]. Following Wyss et al. (2016b), before applying the FFT, each packet is preprocessed in two steps. First, a cosine
238 taper is applied at the edges of a max. 8 ms time window around the peak amplitude of each packet. Second, the signal
239 contained in this time window is zero-padded on either side to reach an optimal number of sample points n_{FFT} . The taper is
240 used to smooth the transition between the packet and the concatenated zeros, and to suppress spectral leakage, which results
241 in a more accurate amplitude spectrum. The value of n_{FFT} was set to 2^7 in order to adequately resolve the amplitude
242 spectrum of the raw signal contained in the max. 8 ms time window. This time window focuses on the first arrival waveform
243 to obtain a more accurate evaluation of the high-frequency content of the packet (Nicollier et al., 2021b2022). The single-

244 sided Fourier transform of the processed packet is then computed in order to extract A_{FFT} and derive $f_{centroid}$ (Eq. 2). A
 245 decrease in $f_{centroid}$ with increasing particle size was observed for different bedload surrogate monitoring techniques
 246 (Belleudy et al., 2010; Uher and Benes, 2012; Barrière et al., 2015). Furthermore, $f_{centroid}$ has the advantage of showing
 247 weaker dependency on the flow velocity and transport mode than the maximum registered packet amplitude (Wyss et al.
 248 2016b; Chen et al., 2024). As shown by Nicollier et al. (2021b, 2022), $f_{centroid}$ also contains information about the impact
 249 location of a packet-triggering particle. Because high frequencies are more rapidly attenuated than low frequencies along the
 250 travel path of a seismic wave, (apparent) packets triggered by impacts on a given plate typically have higher $f_{centroid}$ values
 251 than packets triggered by impacts occurring beyond that plate's boundaries.

252 2.5.2 Flume-based amplitude-frequency thresholds

253 The ~~transported bedload particle~~ mass associated with an individual signal packet is strongly dependent on the size of the
 254 impacting particle. Inferring sediment transport rates from SPG signals thus requires assigning each packet to a
 255 corresponding sediment size class using threshold values of packet characteristics (Table 3). Wyss et al. (2016a) derived
 256 size class thresholds (or AH thresholds) of packet peak amplitude from field measurements (Eq. 1). In the present study, we
 257 ~~derive size class thresholds of packet amplitude and frequency take advantage~~ from the single-grain-size experiments
 258 conducted at the flume facility (without the partition wall) using the Albula setup (Nicollier et al., 2021a) to derive size class
 259 ~~thresholds combining packet amplitude and frequency (or AF thresholds). For each~~ Each packet is assigned to a given class j
 260 ~~delimited by the a~~ lower threshold $th_{af,low,j}$ is based on the maximum amplitude of the packet's envelope $MaxAmp_{env}$ [V],
 261 and ~~the an~~ upper threshold $th_{af,up,j}$ is based on the ratio $MaxAmp_{env}/f_{centroid}$ [V Hz⁻¹]. Compared to the raw signal, the
 262 envelope has the advantage of returning the magnitude of the analytical signal and thus better outlines the waveform by
 263 omitting the harmonic structure of the signal (Fig. 2b). Similar combinations of amplitude and frequency have been used to
 264 infer particle sizes and improve the detectability of bedload particles in previous studies involving impact plates (Tsakiris et
 265 al., 2014; Barrière et al., 2015; Wyss et al., 2016b; Koshiba and Sumi, 2018) and pipe hydrophones (Choi et al., 2020).

266 The lower and upper amplitude-frequency (AF)-thresholds are obtained as follows. First, all packets recorded during
 267 the single-grain-size experiments (without the partition wall) are filtered with respect to the following criterion adapted from
 268 Nicollier et al. (2021b, 2022):

$$269 \text{ Criterion: } f_{centroid} > a_c \cdot e^{(b_c \cdot MaxAmp_{env})}, \quad (3)$$

270 with $a_c = 1980$ Hz and $b_c = -1.58$ V⁻¹. ~~The values for the linear coefficient a_c and the exponent b_c were obtained through an~~
 271 ~~optimization process discussed below (Sect. 4.1), and were found to ideally set apparent packets apart from real ones.~~
 272 Packets that do not meet this criterion are considered as apparent packets and are ignored in the further analysis in order to
 273 obtain more accurate threshold values. Note that in the present study the criterion in Eq. 3 has not been applied to the data
 274 when implementing the AH method developed by Wyss et al. (2016a). ~~The values for the linear coefficient a_c and the~~
 275 ~~exponent b_c were obtained through an optimization process discussed below.~~

276 The next step consists in fitting a power-law least-squares regression line through the 75th percentile amplitude
 277 $MaxAmp_{env,75th,j}$ and amplitude-frequency $(MaxAmp_{env}/f_{centroid})_{75th,j}$ values of ~~the packets detected for a given grain-~~
 278 ~~size class j fed into the flume that met the filtering criterion each class j~~ (Fig. 4), resulting in the following two equations:

$$279 MaxAmp_{env,75th,j} = 1.66 \cdot 10^{-4} \cdot D_{m,j}^{1.95}, \quad \text{and} \quad (4)$$

$$280 \left(\frac{MaxAmp_{env}}{f_{centroid}} \right)_{75th,j} = 2.26 \cdot 10^{-8} \cdot D_{m,j}^{2.36}. \quad (5)$$

Kommentar [TN1]:

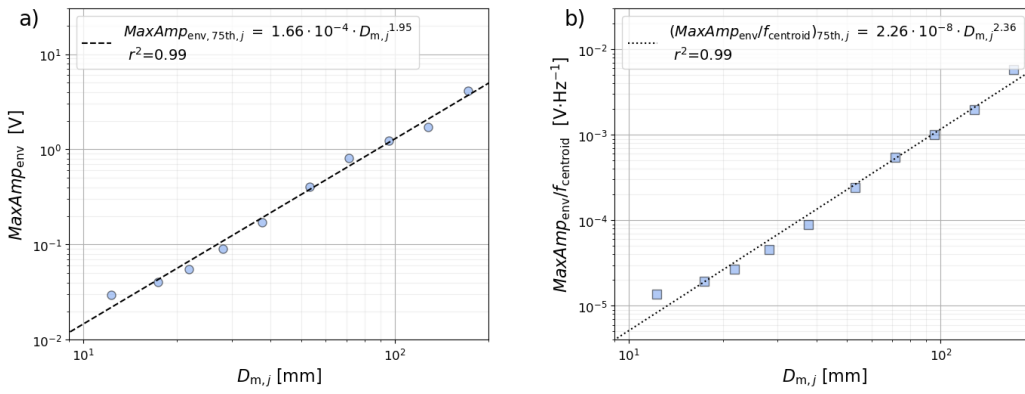

Formatiert: Italienisch (Italien)

Formatiert: Abstand Nach: 0 Pt.

Formatiert: Einzug: Erste Zeile: 0.75 cm, Abstand Nach: 0 Pt.

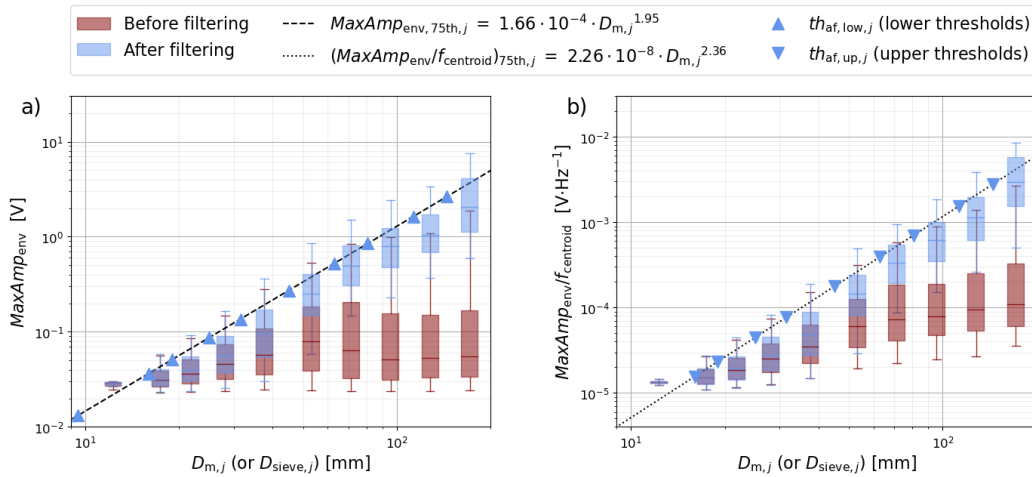

281 Finally, the lower ~~and upper~~ threshold values $th_{af,low,j}$ ~~and $th_{af,up,j}$~~ are obtained by replacing $D_{m,j}$ in Eq. (4) ~~and (5)~~
 282 with the lower (~~$D_{sieve,j}$~~) and upper (~~$D_{sieve,j+1}$~~) sieve sizes $D_{sieve,j}$, ~~while the upper threshold values $th_{af,up,j}$ are obtained by~~
 283 ~~replacing $D_{m,j}$ in Eq. (5) with the upper sieve sizes $D_{sieve,j+1}$, respectively~~ (Table 3 and triangles in Fig. 5). The advantage in
 284 fitting functions such as Eq. (4) and (5) is that they allow the computation of thresholds for any classification of particle
 285 (sieve) sizes.

286 Particularly for the largest particles, apparent packets can greatly outnumber real packets. Due to their relatively small
 287 amplitudes, these apparent packets can substantially dilute the average signal response associated with the largest grain sizes
 288 (see the red boxplots in Fig. 5). However, filtering out apparent packets reveals a clear relationship, which would otherwise
 289 be obscured, between the mean particle size $D_{m,j}$ and both the amplitude $MaxAmp_{env}$ and the ratio $MaxAmp_{env}/f_{centroid}$
 290 (see the blue boxplots in Fig. 5). Overall, the filtering with criterion (Eq. 3) at the Obernach flume site eliminated about 61%
 291 of all the packets.

304 2.5.3 Application to field calibration measurements

305 The lower and upper thresholds $th_{af, low,j}$ and $th_{af, up,j}$ obtained from the filtered flume experiments can ~~also be used for be~~
 306 ~~transferred to~~ the field calibration datasets, if the SPG apparatus and the geophone data recording and preprocessing routines
 307 are identical in both cases. The following steps will now lead us to the final general calibration coefficients $k_{b,j,gen}$ (Fig. 6).
 308 First, for each field measurement i , the thresholds $th_{af, low,j}$ and $th_{af, up,j}$ are used for counting the number of packets per
 309 class j from the recorded geophone signal. Second, a sample- and class-specific calibration coefficient $k_{b,i,j}$ with units $[kg^{-1}]$
 310 is obtained by dividing the number of recorded packets $PACK_{i,j}$ by the sampled fractional mass $M_{meas,i,j}$ as follows:

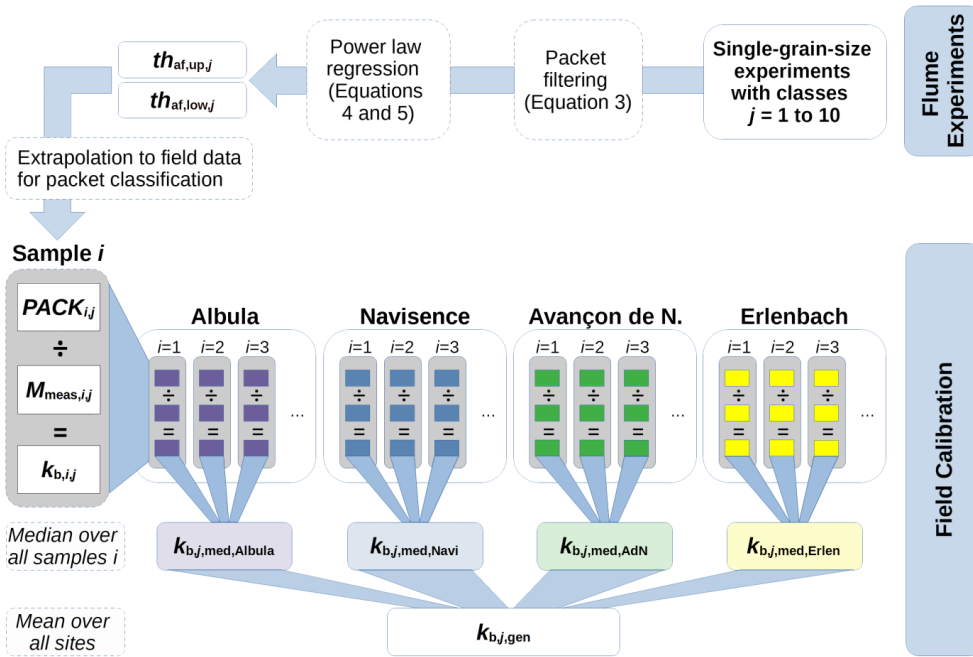

$$311 \quad k_{b,i,j} = \frac{PACK_{i,j}}{M_{meas,i,j}}. \quad (6)$$

312 Finally, the general calibration coefficient $k_{b,j,gen}$ is computed for each class j using

$$313 \quad k_{b,j,gen} = \frac{1}{N_{stations}} \sum_{stations} k_{b,j,med,station}, \quad (7)$$

314 where $k_{b,j,med,station}$ is the site-specific median calibration coefficient ~~computed over all samples j~~ , and $N_{stations}$ is the
 315 number of stations. Even though the number of calibration measurements differs from site to site, each coefficient
 316 $k_{b,j,med,station}$ in Eq. (7) is equally weighted in order to give the same importance to site-specific factors possibly affecting
 317 the signal response at each site.

318

319 **Figure 6: Workflow leading from the single-grain-size flume experiments with particles from ten size classes j (top right) to the**
 320 **final array of general calibration coefficients $k_{b,j,gen}$. Central elements are the lower and upper threshold values $th_{af,low,j}$ and**
 321 **$th_{af,up,j}$, the number of recorded packets $PACK_{i,j}$ per sample i and class j , the sampled fractional mass $M_{meas,i,j}$, the sample- and**
 322 **class- specific calibration coefficient $k_{b,i,j}$, and finally the site-specific median calibration coefficient $k_{b,j,med,station}$. To enable a**
 323 **comparison with the AH method developed by Wyss et al. (2016a), the “Field Calibration” part of the workflow was also carried**
 324 **out with the AH thresholds $th_{ah,j}$ (see Table 3).**

325 At this point, the single array of calibration coefficients $k_{b,j,gen}$ is applied as follows to each field calibration
 326 measurement i in order to obtain fractional bedload mass estimates $M_{est,i,j}$:

$$327 \quad M_{est,i,j} = k_{b,j,gen} \cdot PACK_{i,j} \quad (8)$$

328 Rickenmann and Fritschi (2017) showed that bedload mass estimates derived from SPG measurements are more accurate at
 329 higher transport rates. The estimated fractional bedload mass $M_{est,i,j}$ can be converted to a unit fractional transport rate
 330 $q_{b,est,i,j}$ [$\text{kg m}^{-1} \text{s}^{-1}$] using:

$$331 \quad q_{b,est,i,j} = \frac{1}{w_p \cdot n_p} \cdot \frac{M_{est,i,j}}{\Delta t_i} \quad (9)$$

332 where w_p is the standard width of an impact plate (0.5 m), n_p is the number of plates (which may include the whole transect,
 333 or a section of particular interest), and Δt_i is the sampling duration in seconds. Finally, the estimated unit total bedload flux
 334 $q_{b,tot,est,i}$ can be computed as follows:

$$335 \quad q_{b,tot,est,i} = \sum_{j=1}^{10} q_{b,est,i,j} \quad (10)$$

336 Note that the exact same procedure was followed using the AH thresholds $th_{ah,j}$ derived from Wyss et al. (2016a) (Eq. 1;
 337 Table 3) to compare the performance between the AH method and the new AF method.

338 3 Results

339 3.1 Flume experiments

340 The flume experiments performed in the modified Avançon de Nant setup with the partition wall help to illustrate the two
341 calibration methods. Fig. 7a and 7b show the amplitude and frequency characteristics of all packets detected by the SPG
342 system during these experiments. Packets detected by the shielded sensor G1 all originate from impacts that occurred either
343 on the concrete bed or on plate G2 (Nicollier et al., [2021b2022](#)). Packets detected by the unshielded sensor G2 are
344 considered as apparent if they are located in the area of the amplitude-frequency graph (Fig. 7a) where G1 and G2 packets
345 overlap. Such packets are presumed to have been triggered by impacts on the concrete bed too. This overlapping area arises
346 from the fact that a seismic wave generated by an impact on the concrete bed follows a similar path towards both sensors,
347 resulting in the recording of two apparent packets with comparable characteristics. The remaining packets, detected by G2
348 and located in the non-overlapping area of the amplitude-frequency graph, are considered as real, rather than apparent. The
349 difference in f_{centroid} between real and apparent packets (Fig. 7a) reflects the faster attenuation of higher frequencies during
350 wave propagation, as mentioned earlier. Size class boundaries derived by the AH method of Wyss et al. (2016a) encompass
351 all of the packets, both apparent and real (Fig. 7a). This is because the boundaries are defined solely by AH thresholds
352 ($th_{\text{ah},j}$). By contrast, in the AF method proposed here, the two-dimensional class boundaries given by $th_{\text{af,low},j}$ and $th_{\text{af,up},j}$
353 cover only a fraction of all detected packets (Fig. 7b). Applying the step-like AF thresholds leads to a strong reduction of the
354 number of packets $PACK_j$ within each size class j for plate G1 (shielded), particularly for the smaller classes. Meanwhile, the
355 AF thresholds had little effect on the number of detected packets for G2 (unshielded), except for a strong decrease for
356 classes $j = 1$ and 2, and a slight increase for classes $j = 6$ to 10 (Fig. 7c and 7d). The AH thresholds encompass in total 1945
357 packets for the shielded geophone G1, and 4823 packets for the unshielded geophone plate G2. In comparison, the AF
358 thresholds encompass in total 159 packets for the shielded geophone G1, and 2202 packets for the unshielded geophone plate
359 G2 (counting the packets in the overlapping class boundaries only once). Considering apparent packets as noise and real
360 packets as signal, applying the new AF method results in an increased signal to noise ratio, as shown by the larger vertical
361 separation between the blue (signal) and red (noise) lines in Fig. 7d compared to Fig. 7c.

Figure 7: Characteristics of the packets recorded during single-grain-size experiments conducted with the Avançon de Nant flume setup using the partition wall, with the maximum amplitude of the envelope $MaxAmp_{env}$ and the centroid frequency $f_{centroid}$. The red and blue dots correspond to packets recorded by the shielded plate G1 and the unshielded plate G2, respectively. The grey rectangles are the class boundaries delimited by the thresholds obtained for the AH method (a) and the AF method (b). The number of packets $PACK_j$ located within the class boundaries delimited by the AH thresholds and the AF thresholds are indicated in (c) and (d), respectively. In (a), $f_{centroid}$ is shown as function of $MaxAmp_{env}$ for information purposes only and is not incorporated in the thresholds. (c) and (d) represent the number of packets $PACK_j$ located within the class boundaries shown in (a) and (b), respectively. Missing markers signify that no packet was detected within the corresponding AH or AF thresholds.

384

385

As discussed in the previous section, the number of packets $PACK_{i,j}$ detected for a given class j varies together with the thresholds $th_{ah,j}$, $th_{af,low,j}$ and $th_{af,up,j}$. Because the measured fractional bedload mass $M_{meas,i,j}$ remains constant, the calibration coefficients $k_{b,i,j}$ will depend on the number of packets detected, and thus on the thresholds that are used to classify them. We can make the following observations regarding the calibration coefficients $k_{b,i,j}$ obtained using the AF method (Fig. 8b) compared to the AH method (Fig. 8a). First, the $k_{b,i,j}$ coefficients of the smaller size classes are substantially lower, meaning that fewer packets per unit mass are detected. Second, for the larger size classes, slightly more packets are detected per unit mass. Third, ~~considering all sites and all size classes j~~ , the overall scatter of the $k_{b,i,j}$ coefficients across all sites is smaller, in particular for the six smallest classes j . This is reflected in the decrease of the mean coefficient of variation (CV) across all classes j and all sites from CV = 1.17 (in the AH method) to CV = 0.93 (in the AF method). Fourth, the scatter of the site-specific $k_{b,i,j}$ coefficients is usually smaller. This is supported by the change of the mean CV across all classes from 0.89 to 0.54 for the Albul, from 0.83 to 0.75 for the Avançon de Nant and from 1.31 to 1.00 for the Erlenbach, between the AH and AF methods. The mean CV for the Navisence site however remains unchanged at 0.85. The general coefficients $k_{b,j,gen}$ obtained from the site-specific median coefficients $k_{b,j,med}$ using Eq. (7) are listed in Table 4.

394

395 3.3 Bedload flux estimates

396 We can now insert the general calibration coefficients $k_{b,j,gen}$ in Eq. (8) to compute fractional bedload mass estimates $M_{est,i,j}$
 397 and subsequently the unit fractional flux estimates $q_{b,est,i,j}$ (Eq. 9) for every sample collected at the four field sites. Fig. 9
 398 illustrates the accuracy of the bedload flux estimates obtained with the AF method for each sample across the grain-size
 399 classes and the field sites. The results obtained with the AH method can be found in Supplementary Information S3, and
 400 Table 5 provides further information on the performance of the two methods. The dashed colored power-law regression lines
 401 shown in Fig. 9, described by the corresponding linear coefficient a and exponent b (Table 5), indicate possible trends in
 402 over/under-estimation at each field site. The coefficient of determination R^2 describes the accuracy of the estimates relative
 403 to the 1:1 line. The root-mean-square error ($RMSE$) quantifies the expected error of the estimates and is expressed in [kg m^{-1}
 404 s^{-1}]. When applied to the field calibration data, the AF method generally yields more accurate flux estimates than the AH
 405 method does. This is most notably reflected by the R^2 values and the percentages p_{factor_2} and p_{factor_5} of all detected
 406 samples whose estimated bedload fluxes differ by less than a factor of 2 and 5, respectively, from the measured values
 407 (Table 5). The five smallest grain-size classes were most strongly affected by these improvements, whereas the estimates for
 408 the largest fractions ($j = 7$ to 10) were only slightly improved.

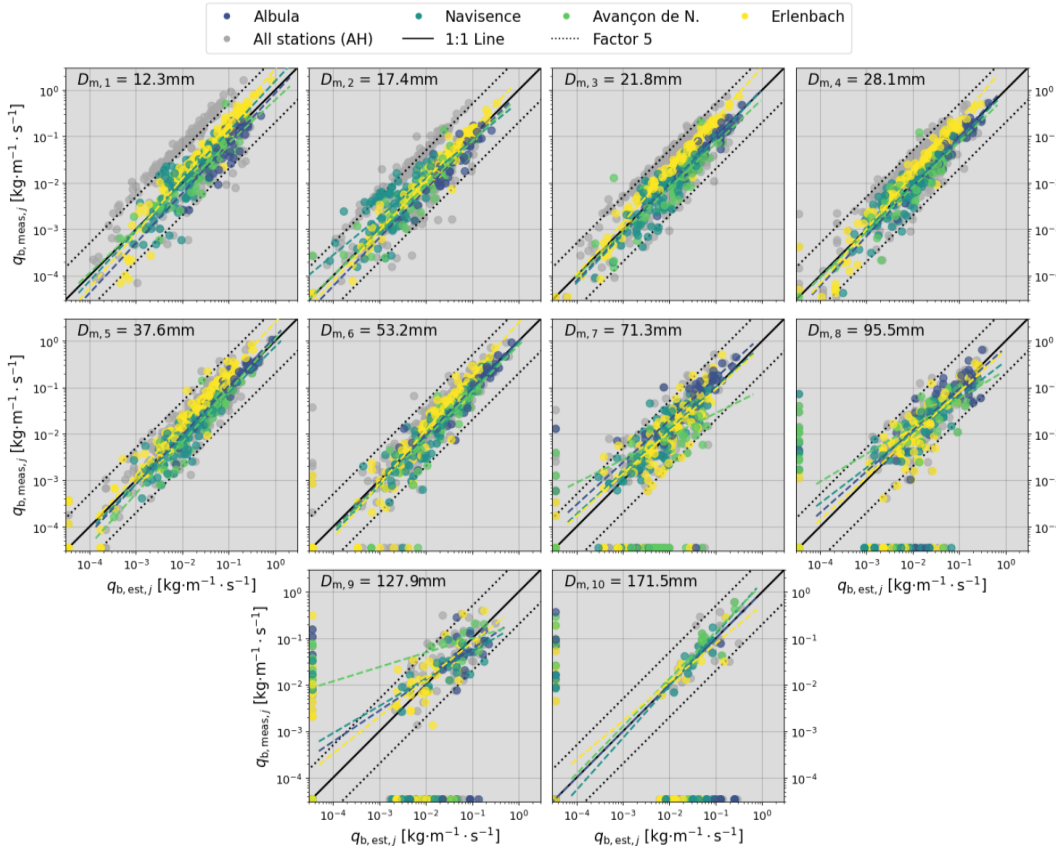

409 Aside from these comparative observations, it is also worth mentioning the following more general findings that are
 410 valid for both methods: (i) for most size fractions, the relative scatter of the estimates (on the log-log plots) decreases with
 411 increasing transport rates; (ii) at low transport rates, mass fluxes are generally overestimated, while at high transport rates
 412 they are generally underestimated; (iii) mass fluxes for the Erlenbach closely follow the 1:1 line but tend to be slightly
 413 underestimated; (iv) the number of measured ($N_{samples,meas}$) and estimated ($N_{samples,est}$) samples both decrease with

414 increasing particle size. Samples for which either the measured or the estimated flux equals 0 are indicated as dots along the
 415 axes in Fig. 9. If the measured flux is zero but the estimated flux is positive, the sample can be regarded as false positive
 416 (Fawcett, 2006). The difference between $N_{\text{samples,meas}}$ and $N_{\text{samples,est}}$ in Table 5 indicates that the occurrence of such false
 417 positive samples increases with increasing particle size. Further performance metrics derived from the confusion matrix can
 418 be found in the Supporting Information (Table S2).

 Times New Roman, 12 Pt.

419

420

421 **Figure 9:** Unit fractional transport rate estimates obtained with the AF method for each size class j and each station. The light grey
 422 dots in the background indicate the estimates obtained with the AH method and are represented in more detail in the Supporting
 423 Information (Fig. S1). Each frame is annotated with the mean particle size $D_{m,j}$ of the represented class. The solid black lines
 424 correspond to the reference 1:1 line while the dotted lines delimit factors of 5 above and below (from 0.2 to 5). The dashed colored
 425 lines are power-law regression lines; the mean coefficients over all four sites are listed in Table 5. The dots along the axes indicate
 426 samples for which either the measured or the estimated unit fractional flux equals 0. These samples are not considered for the
 427 computation of the trend lines.

428

429 **Table 5:** Performance of the AH method and the AF method regarding fractional flux estimates for each class j with following
 430 parameters: the linear coefficient a , the exponent b and the correlation coefficient r of the power-law regression lines visible in Fig.
 431 9; the coefficient of determination R^2 ; the root-mean-square error $RMSE$; and the percentage of all detected samples for which the
 432 estimated value differs from the measured value by less than a factor of 2 and 5 p_{factor_2} and p_{factor_5} , respectively. These values
 433 were first computed for each site separately and then averaged over all four sites. The number of measured $N_{\text{samples,meas}}$ and the
 434 number of estimated samples $N_{\text{samples,est}}$ showing a positive unit fractional rate were summed over all four sites.

442

443

As indicated by Eq. (10), the unit total flux estimates are computed as the sum of the unit fractional flux estimates over all 10 classes. Fig. 10 shows the ratio $r_{q_{b,\text{tot}}}$ between the estimated total flux $q_{b,\text{tot,est}}$ and the measured total flux $q_{b,\text{tot,meas}}$ for all 308 calibration samples, as a function of the sampled total mass $M_{\text{tot,meas}}$. Here, the estimates for the Albula, the Navisence and the Avançon de Nant sites are slightly more accurate with the AF method than with the AH method, whereas the estimates for the Erlenbach improve substantially, with the median $r_{q_{b,\text{tot}}}$ value increasing from 0.31 to 0.64. Note that the observations (i) to (iii) made earlier regarding the fractional flux estimates are also valid here. Fig. 10 also provides an interesting overview of the sampled masses at all four stations, reflecting the capacities of the different devices (automated and manual basket samplers and crane-mounted net sampler) used to collect the calibration samples.

444

445

446

Figure 10: Ratio $r_{q_{b,\text{tot}}}$ between the estimated and the measured unit total mass flux as a function of the total sampled mass $M_{\text{tot,meas}}$ for each collected sample i and each station, for the AH method (a) and the AF method (b). The boxplots on the right indicate the range of $r_{q_{b,\text{tot}}}$ values obtained for each station.

448

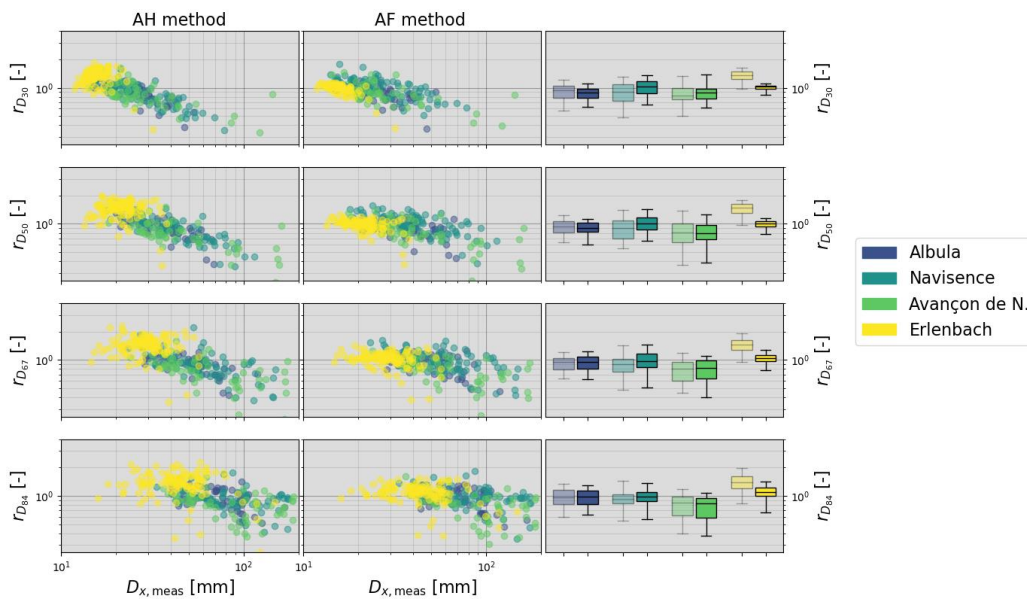

3.4 Grain-size estimates

449

450

We can combine the SPG bedload flux estimates for all grain-size fractions and thus derive grain-size distributions, which can then be compared to the measured size distributions of each calibration sample. Fig. 11 compares the performance of the

451 AH and the AF methods in estimating the characteristic grain sizes D_{30} , D_{50} , D_{67} and D_{84} (where D_x is the grain diameter for
 452 which x percent of the sampled bedload mass is finer). The accuracy of the estimates is indicated by the ratio r_{D_x} between the
 453 estimated and the measured characteristic grain size D_x . Compared to the AH method, the AF method mainly improves the
 454 estimates of the four characteristic grain sizes for the Navisence and the Erlenbach sites, but has little effect at the other two
 455 sites. The largest improvement is achieved for the Erlenbach site, with the median $r_{D_{30}}$ changing from 1.37 to 1.02, the
 456 median $r_{D_{50}}$ changing from 1.48 to 1.01, the median $r_{D_{67}}$ changing from 1.46 to 1.05 and the median $r_{D_{84}}$ changing from
 457 1.39 to 1.10. The overall accuracy of the estimates decreases with increasing characteristic size D_x for both methods, and for
 458 every characteristic size D_x , the D_x tends to be overestimated for finer grain mixtures and underestimated for coarser grain
 459 mixtures.

460
 461 **Figure 11:** Ratio r_{D_x} between the estimated and the measured characteristic grain sizes D_{30} , D_{50} , D_{67} and D_{84} as a function of the
 462 measured grain diameter $D_{x, meas}$ for each collected sample i and each station using the AH method (column 1) and the AF method
 463 (column 2). D_x is the grain diameter for which x percent of the sampled bedload is finer. The boxplots in column 3 indicate the
 464 range of r_{D_x} values obtained for each station. The boxes in faded colors show the results obtained with the AH method and the
 465 boxes in brighter colors show the results obtained with the AF method.

466 4 Discussion

467 4.1 The hybrid calibration procedure

468 Recent studies have pointed out the difficulty of transferring flume-based calibrations of the impact plate system to field
 469 applications (e.g. Mao et al., 2016; Wyss et al., 2016c; Kuhnle et al., 2017). In the hybrid calibration approach presented
 470 here, we took advantage of controlled flume experiments, ~~but only~~ to obtain amplitude and amplitude-frequency thresholds
 471 for each particle-size class, which were subsequently applied to field calibration datasets to derive the general calibration
 472 coefficients $k_{b,j,gen}$.

473 ~~Among the three sites reconstructed at the flume facility, only the experiments conducted in 2018 with the Albula setup~~
474 ~~were used for calibration purposes in the present study. Although the differences are small, the class thresholds derived from~~
475 ~~these experiments yielded slightly more accurate bedload flux estimates than the thresholds derived from the other site~~
476 ~~reconstructions. A possible explanation for this is the lower bed roughness used for the Albula site reconstruction as~~
477 ~~compared to the other two setups, which facilitated the transport of larger particles. The Albula setup was also less affected~~
478 ~~by lateral sorting of small particles (mainly classes $j = 1$ to 4) toward the flume walls, which resulted in a weaker signal~~
479 ~~response. Additionally, the flow velocities used in this setup ($V_f = 1.6$ and 2.4 m s^{-1}) lie between the velocities measured~~
480 ~~during the field calibration campaigns at the Navisence and Avançon de Nant sites.~~

481 The entire hybrid calibration procedure was run iteratively until the optimal linear coefficient and exponent of the
482 criterion (Eq. 3) used to filter out apparent packets were found (Fig. 6). As objective function we used an equally weighted
483 combination of parameters describing the accuracy of bedload flux and grain-size estimates, i.e. r , R^2 , p_{factor_2} , p_{factor_5} , and
484 $RMSE$ as shown in Table 5, r_{D_x} as shown in Fig. 11, and the accuracy derived from the confusion matrix (Fawcett, 2006) as
485 shown in Table S2 in Supporting Information. We looked for two types of optimal calibrations. The first type is a general
486 calibration, for which we have presented the results in Sect. 3. This calibration combines all four stations in order to
487 investigate the feasibility of a general signal conversion procedure applicable to multiple sites equipped with SPG systems.
488 The second type is a site-specific calibration aiming to improve the accuracy of bedload transport rate estimates at a single
489 monitoring station, to be used for a more detailed analysis of bedload-related processes at a given site (details of these site-
490 specific calibrations are available in Supporting Information Sect. S4 and S5).

491 The biases introduced by apparent packets can be removed by site-specific calibration of the coefficients $k_{b,i,j}$, so the
492 AF and AH methods perform about equally well when calibrated separately to each individual site (see Supporting
493 Information Sect. S4 and S5). This result supports the use of the AF method, considering the important number of packets
494 left out by the AF thresholds. However, the abundance of apparent packets varies considerably from site to site, owing to
495 differences in the channel geometry, the bedload grain-size distribution, and the construction details of the individual SPG
496 installations. Because the AF method filters out a substantial fraction of these apparent packets, it yields substantially better
497 general calibrations than the AH method does (see Table 5).

498 We also tested the performance of an adapted version of the AH method introduced by Rickenmann et al. (2018). This
499 method was originally developed for the Erlenbach site and aimed to correct for the relationship between the signal response
500 and the transport rate. In the present study, we applied this method to each field site. The only notable improvement
501 introduced by the adapted AH method is the increased number of detected samples at the Erlenbach station, leading to more
502 accurate estimates of the various characteristic grain sizes D_x at this site (Tables S8 and S9 in Supporting Information); the
503 results for the other sites were not substantially improved.

504 While the lack of accurate flow velocity measurements is certainly one of the critical points of the study, one could
505 argue that another lack is the low variability between the site-specific calibration relationships of the three natural sites
506 already before implementing the AF method (Fig. 8a). It would have been interesting to test the method on a larger number
507 (and variety) of sites. Unfortunately, these four chosen sites are the only ones at which a full geophone signal has been
508 recorded during calibration measurements.

509 4.2 Two-dimensional size class thresholds

510 To understand the performance of the new AF method it is worth taking a closer look at the role of the size class thresholds.
511 As shown in Fig. 7, replacing the upper amplitude thresholds with amplitude-frequency values results in the following two
512 important changes. First, a dimension is added, which facilitates focusing on the narrow range of signal responses
513 characteristic for real packets, and filtering out many of the apparent packets. Second, the areas of the amplitude-frequency

514 domain covered by two adjacent classes can now overlap. Packets located in overlapping areas are assigned once to each
515 class and therefore counted twice. This explains why both the number of detected packets $PACK_j$ (Fig. 7c and 7d) and
516 subsequently the $k_{b,j}$ values (Fig. 8) are slightly higher when the AF method (instead of the AH method) is applied to the
517 larger size classes. Counting such packets twice is not unreasonable, given that the ranges of signal responses recorded
518 during single-grain-size flume experiments for two contiguous grain-size classes significantly overlap, even after apparent
519 packets are filtered out (Fig. 5). Overlapping class boundaries therefore results in a less strict classification of the few
520 packets that are on the edges of the classes. In Fig. 7b, out of 2256 packets recorded by G2 (blue), 144 packets have been
521 counted twice. But interestingly, not a single of the 153 packets recorded by G1 (red) encompassed by the class boundaries
522 has been counted twice. A further result supports the use of the two-dimensional size class thresholds. When applying the
523 AF method, the $k_{b,j}$ coefficients obtained for the different sites (Fig. 8b) reach a maximum value at the third smallest size
524 class. A similar yet stronger decrease towards the two smallest classes was described by Wyss et al. (2016b) and was related
525 to the reduced detectability of the smallest particle sizes.

526 Through the reduced area covered by the new amplitude-frequency thresholds in Fig. 7b, a certain percentage of all the
527 packets recorded during the field calibration experiments is neglected for general calibration: 55% at the Albula site, 63% at
528 Navisence, 58% at Avançon de Nant and only 9% at Erlenbach. This suggests that the plates embedded at Erlenbach pick up
529 less noise from their surroundings. A similar trend was observed by Nicollier et al. (2021b,2022) when comparing the
530 maximum amplitude registered by two adjacent plates for a given impact at the same location. This difference in noise
531 detection levels is possibly accentuated by the number of impacted plates during bedload transport events. The SPG array
532 embedded in the artificial U-shaped channel of the Erlenbach has the particularity that only 2 out of its 12 plates are usually
533 impacted by bedload particles during floods (and only sediment crossing these two plates is caught by the automatic basket
534 sampler), while at the other stations all 10 to 30 embedded plates are submerged by the flow and thus can potentially be
535 impacted.

536 4.3 Sampling uncertainties

537 Even though the AF method improved the overall accuracy of flux estimates for most classes (Table 5), some trends
538 addressed in Sect. 3 suggest that factors other than the noise level also control the accuracy of the estimates. The dataset
539 presented in this study includes 308 calibration measurements and is in our knowledge the largest dataset gathered for an
540 impact plate system. Still, it appears that the number of collected samples is not sufficient to accurately assess the
541 performance of the two methods for the three largest particle-size classes (Fig. 9; Table 5). This is mainly due to the fact that
542 in typical sediment mixtures, large particles are rarer than fine particles (Rickenmann et al., 2014; Mao et al., 2016). Earlier
543 investigations have shown that a larger number of detected bedload particles reduces the scatter of total mass estimates by
544 averaging over stochastic factors such as the impact location on a given impact plate, the particle transport mode (sliding,
545 rolling, saltating, etc.), and the impact velocity (Rickenmann and McArdell, 2008; Turowski et al., 2013). A further
546 uncertainty arises because these larger particles are transported at higher bed shear stresses (Einstein, 1950; Wilcock and
547 Crowe, 2003), which also mobilize more total material and thus pose a serious challenge regarding the sampling efficiency
548 of the calibration bedload samplers. Bunte and Abt (2005) and Bunte et al. (2019) have demonstrated that reducing the
549 sampling duration with a bedload trap from 60 to 2 minutes decreases both the sampled unit total bedload flux $q_{b,tot}$ and the
550 sampled maximum particle size D_{max} by about half. In the present study, total bedload fluxes up to $4 \text{ kg m}^{-1} \text{ s}^{-1}$ were measured
551 with the net sampler, meaning that the measurement duration had to be minimized to avoid overloading the sampler. At the
552 Albula stream, for instance, only four samples contained particles of the largest class, and all four were sampled over a
553 duration ranging from 1 to 2 minutes. As a comparison, the longest sampling duration was reached at the Navisence site and
554 lasted 25 minutes. All this suggests that an optimal calibration of the SPG system requires balancing the sampling duration

Formatiert: Abstand Nach: 0 Pt.

555 and the number of collected particles. Note that uncertainties in the direct measurements have a direct impact on the
556 accuracy of fractional sediment flux and grain-size estimates. Flume experiments could potentially be used to assess the
557 sampling efficiency of the various calibration sampling methods, along with the detection efficiency of the SPG system.

558 4.4 Transport rate

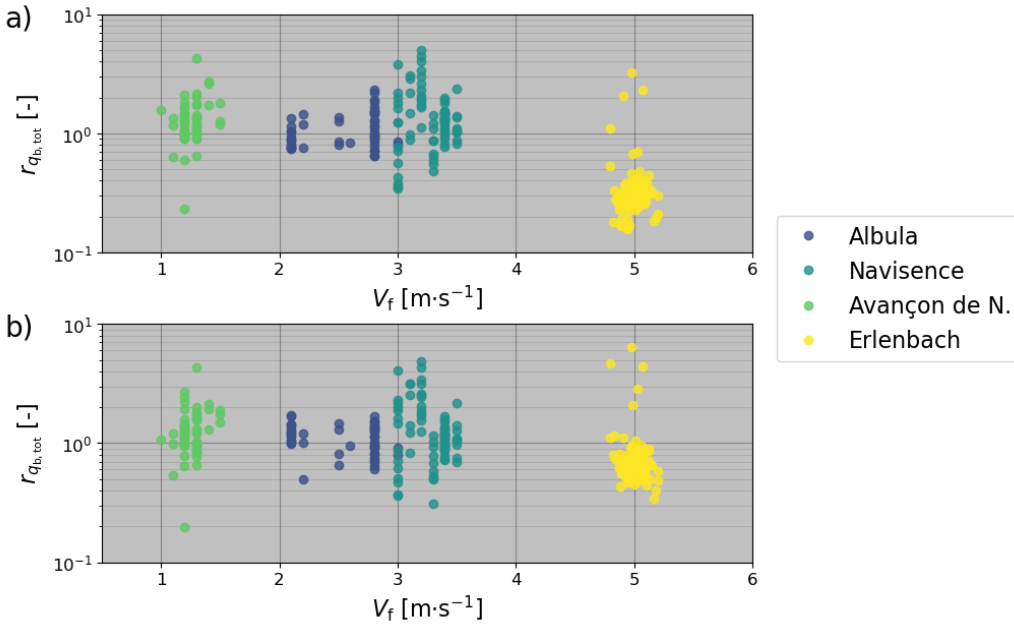

559 Two further trends are evident in the unit fractional flux estimates obtained for the seven smallest classes, for which most
560 samples were detected ($N_{\text{samples,est}} / N_{\text{samples,meas}} > 96\%$; Table 5). First, the relative scatter (on the log-log plots) of the
561 fractional flux estimates around the power-law regression lines in Fig. 9 is smaller at higher transport rates. Second, both
562 total and fractional fluxes are generally overestimated at low transport rates and underestimated at high transport rates (Fig. 9
563 and 10), which also correspond to the largest calibration samples. These findings agree with results from previous calibration
564 campaigns with the SPG system (Rickenmann and Fritschi, 2017; Rickenmann et al., 2018) but a comprehensive explanation
565 for these trends is still missing. The following hypotheses can be put forward to explain the relationship between the mass
566 flux estimates and the transport rate q_b : (i) The SPG system may suffer from signal saturation when the transport rate is too
567 high, as has been document in the Japanese pipe microphone system (Mizuyama et al., 2011; Choi, 2020). In our SPG data,
568 we have observed long packets containing multiple large peaks corresponding to several impacts occurring so quickly after
569 one another that they were not detected as separate packets. One can expect that the probability of occurrence of such
570 packets increases together with the transport rate, with the transport of large particles (which typically generate packets of
571 longer durations), and with the occurrence of sliding and rolling particles (Chen et al., 2022). The long packets take the
572 place of multiple shorter packets that would otherwise be individually counted; thus, they lead to underestimated mass fluxes
573 for a given $k_{b,j}$ value. The development of a procedure to identify such packets and attribute the therein contained peaks to
574 individual impacts could represent an interesting goal for future research. (ii) Field observations of bedload sheets being
575 transported over plates at high transport rates were made at the Vallon de Nant site. In the presence of bedload sheets, one
576 can expect that the detection rate of transported particles is hampered by multiple particle layers (Rickenmann et al. 1997;
577 Turowski and Rickenmann, 2009), kinetic sieving (e.g. Frey and Church, 2011) or percolation processes (e.g. Recking et al.,
578 2009). Given these hypotheses, it would be reasonable to expect a stronger signal response at lower transport rates (Fig. 10)

579 We are not able to give a clear explanation for the overestimates of the characteristic grain size D_x for finer grain
580 mixtures and underestimates for coarser grain mixtures (as shown in Fig. 11). A similar trend was also observed by
581 Rickenmann et al. (2018) for calibration measurements originating from the Erlenbach. We speculate that the decrease of the
582 detection rate along with increasing transport intensity, as mentioned above, may partly explain this phenomenon.

583 4.5 Effect of the flow velocity

584 A recurrent feature in the results presented above is an offset between the estimates obtained for the Erlenbach and those
585 obtained for the three other stations. A similar offset was observed earlier for linear calibration relations for total bedload
586 mass between the Erlenbach and other field sites with more natural approach flow conditions (Rickenmann et al., 2014).
587 Although applying the new amplitude-frequency method has reduced the offset in the present study significantly, it remains
588 visible for both fractional and total bedload flux estimates (Fig. 9, 10, and 12). At the Erlenbach site, the last 35 meters
589 upstream of the SPG system consist of an artificial bed with a steep channel slope of 16%, ~~consisting-made~~ of large flat
590 embedded boulders (Roth et al., 2016). This explains the supercritical flow regime with a Froude number around 5.1 (Wyss
591 et al., 2016c) and a flow velocity V_f around 5 m s⁻¹ at the check dam with the geophone sensors (Table S1). Bedload particle
592 velocity V_p was introduced by Wyss et al. (2016b,c) as a possible governing parameter affecting the number of particles
593 detected by the SPG system. fast moving particles being less likely to collide against the Swiss plate geophone than slower

594 moving ones, which are more frequently in contact with the bed. For the present study, we used V_f as a proxy for V_p , even
595 though bedload particles generally travel more slowly than the fluid that surrounds them (Ancey et al., 2008; Chatanantavet
596 et al., 2013; Auel et al., 2017). Past flume experiments (Wyss et al., ~~2016a~~2016b; Kuhnle et al., 2017) have shown that the
597 calibration coefficient $k_{b,j}$ can vary with the flow velocity V_f , such that a three-fold increase in V_f can lead to a two-fold
598 decrease of $k_{b,j}$. The better detectability of particles that one could expect from the higher impact energy (Wyss et al. 2016b)
599 seems to be insufficient to compensate the strong reduction of the number of impacts on a plate with increasing flow
600 velocities. This possibly arises from the fact that larger flow velocities (without increased turbulence) may also lead to flatter
601 saltation trajectories, thus decreasing the vertical component of the impact force. Furthermore, bed morphology, bed
602 roughness and flow velocity play important roles in determining particle transport mode, i.e., sliding, rolling, or saltating
603 (e.g. Bagnold, 1973; Lajeunesse et al., 2010). Although high flow velocities generally favor the saltating mode (Ancey et al.,
604 2002; Chen et al., 2022), the shallow flow depths measured at the Erlenbach (in average ~~40~~0.1 em; Wyss et al. 2016b) may
605 limit the hop height of larger particles (Amir et al., 2017). Considering all these aspects, we hypothesize that the generally
606 underestimated transport rates observed for the Erlenbach site mainly arise from the exceptionally high flow velocity and the
607 related transport mode (Fig. 12). Continuous flow velocity measurements are lacking at the Albula and Navisence sites,
608 hampering a more detailed analysis of their relationships between flow velocities and detection rates.

609
610 **Figure 12:** Ratio $r_{q_{b,tot}}$ between the estimated and the measured unit total mass flux as a function of the mean flow velocity V_f , for
611 each collected sample and each station, for the AH method (a) and the AF method (b). The indicated flow velocity corresponds to
612 in situ measurements made during (or close in time to) the corresponding calibration measurement. For better readability, a
613 random scatter ranging from -0.2 m s^{-1} to 0.2 m s^{-1} was added to the stable flow velocity of 5 m s^{-1} measured at the Erlenbach site.

614 4.6 K-fold cross-validation

615 In a last stage, we tested the robustness of the AH and AF methods by splitting the dataset into calibration and validation
616 data. Given that the number of calibration measurements is relatively small and varies between stations, we applied a 4-fold
617 cross-validation technique (e.g. Khosravi et al., 2020). The field calibration measurements were distributed over four folds,

618 each containing an equal number of calibration measurements from each site (Supporting Information Fig. S4). One after
619 another, the folds were used as validation datasets while the remaining three folds were used for calibration. General
620 calibration coefficients $k_{b,j,gen}$ were obtained from the calibration dataset and subsequently applied to the validation data to
621 derive flux estimates. Even though each fold contains a total of only 48 samples (12 per site), the results obtained with the 4-
622 fold cross-validation procedure support our conclusion that including frequency information in the packet classification
623 procedure improves the mean accuracy of the estimates over all sites, in particular for the smaller five to six size classes j
624 (Supporting Information Table S10). Nicollier et al. (2021b,2022) found that most apparent packets are detected as belonging
625 to smaller size classes than the particles that caused them, due to the attenuation of the vibrations as they propagate (see Fig.
626 7). It is therefore reasonable that the AF method mainly improves the flux estimates for these smaller classes.

627 5 Conclusion

628 The Swiss plate geophone (SPG) is a bedload surrogate monitoring system that has been installed in several gravel-bed
629 streams and was calibrated using direct sampling techniques. While most site-specific calibration relationships for total mass
630 flux are robust across ~~several-multiple~~ orders of magnitude, the mean calibration coefficients can still vary by about a factor
631 of six between different sites. In this study, we derived a general procedure to convert SPG signals into fractional bedload
632 fluxes using an extensive dataset comprising controlled flume experiments as well as 308 field calibration measurements
633 from four field sites. The proposed hybrid approach is based on previous findings (Antoniazza et al., 2020; Nicollier et al.,
634 2021b,2022) that the SPG system is biased by elastic waves that propagate through the apparatus and generate noise in the
635 form of spurious “apparent” packets. We introduced the amplitude-frequency (AF) method as an alternative to the
636 amplitude-histogram (AH) method developed by Wyss et al. (2016a). Packets recorded during single-grain-size flume
637 experiments were first filtered to exclude apparent packets, and then used to derive grain-size class thresholds for packet
638 classification. We found that filtering out apparent packets results in more consistent relationships between particle diameter
639 and amplitude-frequency characteristics of the SPG signal. Furthermore, we showed that including frequency information in
640 size class thresholds helps in excluding apparent packets and thus improves the signal-to-noise ratio. In a second stage, we
641 applied these flume-based thresholds to field calibration measurements and derived general calibration coefficients
642 applicable at all four sites for ten different grain-size fractions. The AH method, by contrast, requires site-specific calibration
643 because it cannot account for the site-to-site differences in the abundance of apparent packets. Averaged over the ten grain-
644 size fractions, the bedload masses of 69% and 96% of the samples were estimated within an offset of a factor of two and
645 five, respectively, relative to the measured sampled masses. The remaining discrepancies between the site-specific results are
646 mainly attributed to large differences in flow (and probably particle) velocity. Finally, the sampled mass, the transport rate
647 and the sampling efficiency were identified as further factors possibly influencing the accuracy of mass flux and grain-size
648 estimates.

649 The presented results are highly encouraging regarding future applications of surrogate monitoring methods to
650 investigate bedload transport processes. The findings also underline the valuable contribution of flume experiments to our
651 understanding of the relationship between bedload transport and the recorded SPG signal. But above all, this study highlights
652 the requirements for obtaining calibrations that are transferable across sites: accurate and numerous direct sampling
653 measurements with long sampling durations and large sampled masses, sensors insulated from surrounding noise sources,
654 and highly resolved temporal information about the stream flow, to identify and account for variations in the transport
655 conditions.

656 **Notation**

657	a_c	Linear coefficient of the criterion
658	A_{FFT}	Fourier amplitude
659	$A_{m,j}$	Mean amplitude registered for particle-size class j
660	b_c	Linear coefficient of the criterion
661	Δt_i	Sampling duration
662	$D_{m,j}$	Mean particle diameter for particle-size class j
663	$D_{\text{sieve},j}$	Lower sieve size retaining particle class j
664	D_x	Characteristic grain size
665	f_{centroid}	Centroid frequency
666	i	Sample index
667	j	Particle-size class index
668	$k_{b,i,j}$	Sample- and class-specific calibration coefficient
669	$k_{b,j,\text{med,station}}$	Median calibration coefficient for particle-size class j and a given station
670	$k_{b,j,\text{gen}}$	General calibration coefficient for particle-size class j
671	$M_{\text{est},i,j}$	Estimated fractional mass per sample and per class
672	$M_{\text{meas},i,j}$	Sampled fractional mass per sample and per class
673	$\text{MaxAmp}_{\text{env}}$	Maximum registered amplitude within a packet
674	$N_{\text{samples,est}}$	Number of detected samples
675	N_{stations}	Number of stations
676	$\text{PACK}_{i,j}$	Number of recorded packets per sample and per class
677	p_{factor_x}	Percentage of all detected samples for which the estimated and the measured values differ from each other by less than a factor of x
678		
679	$q_{b,\text{est},i,j}$	Estimated unit fractional transport rate per sample and per class
680	$q_{b,\text{meas},i,j}$	Measured unit fractional transport rate per sample and per class
681	$q_{b,\text{tot,est},i}$	Estimated unit total bedload flux per sample
682	$q_{b,\text{tot,meas},i}$	Measured unit total bedload flux per sample
683	R^2	Coefficient of determination
684	r	Correlation coefficient
685	r_x	Ratio between estimated and measured values x
686	$th_{\text{ah},j}$	Amplitude-histogram thresholds
687	$th_{\text{af,low},j}$	Lower amplitude-frequency thresholds
688	$th_{\text{af,up},j}$	Upper amplitude-frequency thresholds
689	V_f	Mean flow velocity
690	w_p	Standard width of an impact plate

691 **Data availability**

692 The dataset presented in this paper is available online on the EnviDat repository
693 <https://www.envidat.ch/#/metadata/sediment-transport-observations-in-swiss-mountain-streams>.

694 **Author contribution**

695 Tobias Nicollier designed and carried out the field and flume experiments, developed the presented workflow and prepared
696 the manuscript with contributions from all co-authors. Gilles Antoniazza designed and carried out the field experiments at
697 the Vallon de Nant site. Lorenz Ammann helped developing the methodology and contributed to the formal analysis. Dieter
698 Rickenmann contributed to the conceptualization and the supervision of the presented work, contributed to the design of the
699 methodology, and provided support during the field and flume experiments. James W. Kirchner contributed to the
700 development of the methodology and significantly contributed to the preparation of the initial draft.

703 Forschungsgemeinschaft (DFG) grant RU 1546/7-1. The authors are grateful to Arnd Hartlieb, to the students of the TU
704 Munich, and to the technical staff of the Oskar von Miller Institute for helping to set up and perform the flume experiments.
705 They also warmly thank Norina Andres, Mehdi Mattou, Nicolas Steeb, Florian Schläfli, Konrad Eppel and Jonas von
706 Wartburg for their efforts and motivation during the field calibration campaigns. Special thanks go to [Stefan Boss for his](#)
707 [support with the measurement systems at all sites, and to](#) Andreas Schmucki, who never gave up repairing the net sampler.
708 Alexandre Badoux is further thanked for his valuable suggestions regarding an earlier version of the manuscript.

709 **Competing interests**

710 The authors declare that they have no conflict of interest.
