**Abstract.** Substantial uncertainties in bedload transport predictions in steep streams have ~~triggered~~ encouraged intensive efforts ~~to develop~~ towards the development of surrogate monitoring technologies. One such system, the Swiss plate geophone (SPG), has been deployed and calibrated in numerous steep ~~water courses~~ channels, mainly in the Alps. Calibration relationships linking the signal recorded by the SPG system to the ~~intensity and characteristics of transported bedload~~ transported bedload can vary substantially between different monitoring stations, likely due to site-specific factors such as ~~the~~ flow velocity and ~~the~~ bed roughness. Furthermore, recent ~~controlled-flume~~ experiments ~~on the SPG system~~ have shown that site-specific calibration relationships can be biased by elastic waves resulting from impacts occurring outside ~~of~~ the plate boundaries. Motivated by these findings, ~~here~~ we present ~~here~~ a hybrid calibration procedure derived from flume experiments and an extensive dataset of 308 ~~direct field calibration~~ measurements ~~from at~~ four different SPG field monitoring stations. Our main goal is to investigate the feasibility of a general, site-independent calibration procedure for inferring fractional bedload transport from the SPG signal. First, we use flume experiments to show that sediment size classes can be distinguished more accurately using a combination of vibrational frequency and amplitude information than by using amplitude information alone. Second, we apply this amplitude-frequency method to field measurements to derive general calibration coefficients for ten different grain-size fractions. The amplitude-frequency method results in more homogeneous signal responses across all sites and significantly improves the accuracy of fractional sediment flux and grain-size estimates. We attribute the remaining site-to-site discrepancies to large differences in flow velocity, and discuss further factors that may influence the accuracy of these bedload estimates.

## 1 Introduction

Flood events across Europe in the summer of 2021 have illustrated the threat of ~~flood~~ bedload transport-related hazards ~~like~~ including bedload transport to human life and infrastructure, especially in small and steep mountainous catchments (Badoux et al., 2014; Blöschl et al., 2020). Understanding sediment transport processes is also essential for efforts to return rivers to their near-natural state by restoring their continuity and re-establishing balanced sediment budgets (e.g. Brouwer and Sheremet, 2017; Pauli et al., 2018; Logar et al., 2019; Rachelly et al., 2021). However, monitoring and predicting bedload transport still represents a considerable challenge because of its large spatio-temporal variability (e.g. Mühlhofer, 1933;

Formatiert: Englisch (USA)

Einstein, 1937; Reid et al., 1985; Rickenmann, ~~2018~~2017; Ancy, 2020). This is especially true for steep streams, because they are poorly described by traditional bedload transport equations, which have mainly been developed for lower-gradient channels (e.g. Schneider et al., 2016). Predicting sediment transport in steep channels is challenging, notably due to the presence of macro-roughness elements affecting ~~both the flow resistance and~~ the flow energy (e.g. Manga and Kirchner, 2000; Yager et al., 2007, 2012; Bathurst, 2007; Nitsche et al., 2011; Rickenmann and Recking, 2011; Prancevic and Lamb, 2015). It is further complicated by a sediment supply that varies in both space and time, due in part to cycles of building and breaking of an armoring layer at the riverbed (e.g. Church et al., 1998; Dhont and Ancy, 2018; Rickenmann, 2020; Piantini et al., 2021).

Bedload transport equations established for lower-gradient streams typically result in ~~substantial errors spanning multiple orders of magnitude~~ when applied to steep streams, motivating the development of new indirect monitoring techniques for steep mountain channels (e.g. Gray et al., 2010; Rickenmann, 2017). Indirect monitoring techniques provide ~~large spatial complete~~ coverage of ~~selected~~ river transects at high temporal resolution, reduce personal risk related to in-stream sampling, and enable consistent data collection at widely varying flow conditions, including ~~during~~ flooding ~~events~~ (e.g. Gray et al., 2010; Rickenmann, 2017; Geay et al., 2020; Bakker et al., 2020; Choi et al., 2020; Le Guern et al., 2021). The drawback of these monitoring technologies ~~is that in order to provide~~with regards to absolute bedload transport ~~estimates quantitative measurements, lies in their they require~~eed for intensive calibration through direct bedload sampling with retention basins (Rickenmann and McArde, 2008), slot samplers (e.g. Habersack et al., 2017; Halfi et al., 2020) or mobile bag samplers (e.g. Bunte et al., 2004; Dell'Agnese et al., 2014; Hilldale et al., 2015; Mao et al., 2016; Kreisler et al., 2017; Nicollier et al., 2021<sup>a</sup>).

Among indirect monitoring techniques, the Swiss plate geophone (SPG) system has been deployed and tested in more than 20 steep gravel-bed streams and rivers, mostly in the European Alps (Rickenmann, 2017). Typically, linear or power-law calibration relationships have been developed between measured signal properties and bedload transport characteristics (Rickenmann et al., 2014; Wyss et al. 2016a; Kreisler et al., 2017; Kuhnle et al., 2017). Such calibration equations ~~facilitate permit absolute spatio-temporal estimates~~quantification of bedload fluxes (e.g. Dell'Agnese et al., 2014; Rickenmann et al., 2014; Hilldale et al., 2015; Halfi et al., 2020; Nicollier et al., 2021), ~~their variability in time and space (i.e. across a river section; e.g. Habersack et al., 2017; Rickenmann, 2020; Antoniazza et al., 2022), estimates of absolute estimates of bedload fluxes and~~bedload grain-size distributions (e.g. Mao et al., 2016; Barrière et al., 2015; Rickenmann et al., 2018), and the detection of the start and end of bedload transport (e.g. Turowski et al., 2011; Rickenmann, 2020). However, these equations ~~have required~~require a calibration ~~procedure~~ against independent bedload transport measurements ~~from at~~ each individual field site, because until now we have lacked generally applicable signal-to-bedload calibration equations that are valid ~~in multiple~~across field settings. Although ~~the~~ similarities between calibration relationships at various field sites are encouraging, it is not well understood why the linear calibration coefficients for total mass flux can vary by about a factor of 20 among individual samples from different sites, or by about a factor of six among the mean values from different sites (Rickenmann et al., 2014; Rickenmann and Fritschi, 2017). Given the substantial field effort required for calibration campaigns, a generally applicable calibration equation would represent a significant advance.

Numerous studies have reported successful calibration of impact plate systems in laboratory flumes (e.g. Bogen and Møen, 2003; Krein et al., 2008; Tsakiris et al., 2014; Mao et al., 2016; Wyss et al., 2016b,c; Kuhnle et al., 2017; Chen et al., 2022<sup>+</sup>), although transferring these flume-based calibrations to the field remains challenging. Nonetheless, ~~controlled~~-flume experiments are valuable because they allow ~~us~~to systematically explore relationships between the recorded signal, the transport rates of different sediment size fractions, and the hydraulic conditions. For example, the experiments of Wyss et al. (2016b) showed that higher flow velocities induce a weaker SPG signal response per unit of transported sediment. More recent ~~controlled~~-flume experiments have highlighted another important site-dependent factor influencing the SPG signal

80 response, namely the grain-size distribution (GSD) of the transported bedload (Nicollier et al., 2021<sup>a</sup>), where coarser grain  
81 mixtures were shown to yield a stronger signal response per unit bedload weight.

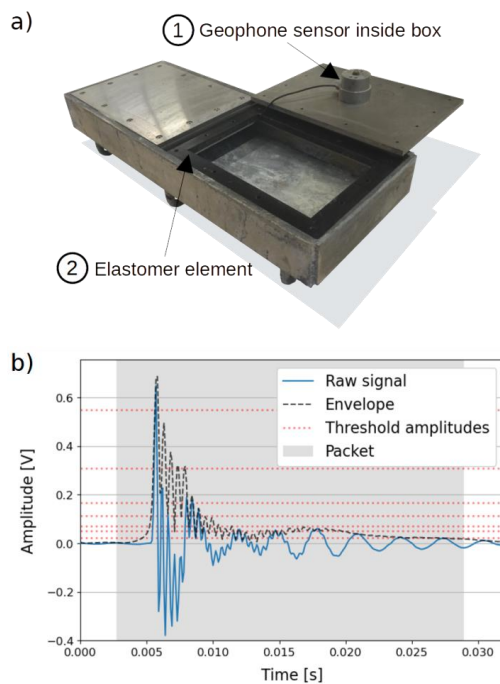

82 Subsequent impact tests and flume experiments showed that this grain-size dependence arises because the impacts  
83 plates are insufficiently isolated from their surroundings (Antoniazza et al., 2020; Nicollier et al., ~~2021b~~2022). The elastic  
84 wave generated by an impact on or near a plate was found to propagate over several plate lengths, contaminating the signals  
85 recorded by neighboring sensors within a multiple plate array. Nicollier et al. (~~2021b~~2022) introduced the notion of  
86 “apparent packets” (in opposition to “real” packets) to define the portions of the recorded signal that were generated by such  
87 extraneous particle impacts.

88 The main goal of this contribution is to examine the feasibility of a general, site-independent signal conversion  
89 procedure for fractional bedload flux estimates. We follow a comprehensive hybrid signal conversion approach that  
90 encompasses a set of full-scale ~~controlled~~-flume experiments conducted at an outdoor ~~flume~~-facility, as well as 308 field  
91 calibration measurements performed with direct sampling methods at four different bedload monitoring stations in  
92 Switzerland between 2009 and 2020. We present the amplitude-frequency (AF) method, aiming to reduce the bias introduced  
93 by apparent packets in the relationship between the signal characteristics and the particle size. Finally, we compare the  
94 performance of this novel AF method against the ~~purely~~-amplitude-histogram (AH) method developed by Wyss et al.  
95 (2016a) for both fractional and total bedload flux estimates, as well as for characteristic grain size estimates.

## 96 2 Methods

### 97 2.1 The SPG system

98 The Swiss plate geophone (SPG) consists of a geophone sensor fixed under a steel plate of standard dimensions 492 mm x  
99 358 mm x 15 mm (Fig. 1a; Rickenmann, 2017). The geophone (GS-20DX by Geospace technologies; www.geospace.com)  
100 uses a magnet moving inside an inertial coil (floating on springs) as an inductive element. The voltage induced by the  
101 moving magnet is directly proportional to its vertical velocity resulting from particle impacts on the plate. The SPG system  
102 can detect bedload particles with a minimum diameter of 10 mm (Rickenmann et al., 2014, 2020; Wyss et al., 2016a).  
103 Typically, a SPG array includes several plates ~~next to each other~~mounted side-by-side, acoustically isolated by elastomer  
104 elements and covering the river cross-section. The array is either embedded in a concrete sill or fixed at the downstream face  
105 of a check dam. A detailed description of the SPG system can be found in Rickenmann et al. (2014). For all the calibration  
106 measurements and flume experiments analyzed in this study, ranging in duration from a few seconds to one hour, the raw 10  
107 kHz geophone signal was recorded (Fig. 1b). In the normal operational recording mode with continuous data storage, Due to  
108 data storage limitations, field stations usually do not continuously record the full raw 10 kHz geophone signal. Instead, it is  
109 typically but only preprocessed, and summary values (Rickenmann et al., 2014), such as the maximum amplitude and the  
110 number of impulses, are recorded at one minute intervals. However, for the relatively short duration of a single calibration  
111 measurement, ranging from a few seconds to one hour, the full raw signal is recorded (Fig. 1b).

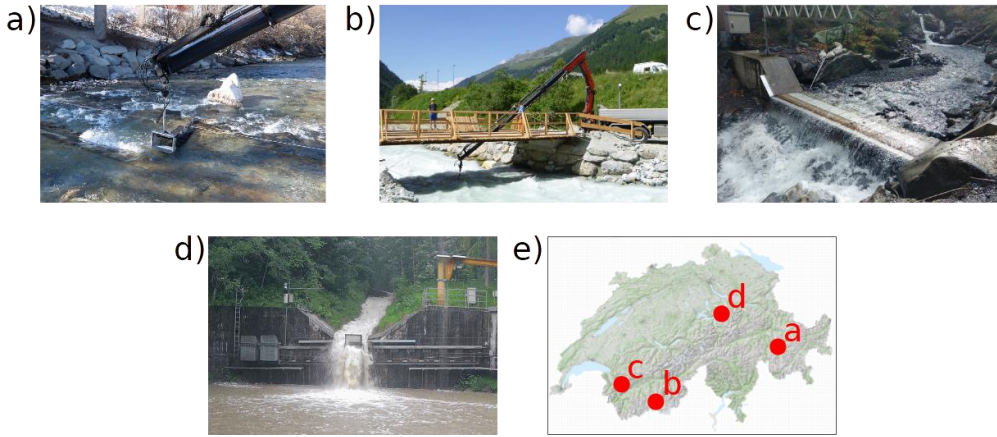

112

113 | Figure 1: (a) Swiss plate geophone (SPG) system before installation (see Fig. 3). Each plate is equipped with a uniaxial geophone  
 114 | sensor fixed in a watertight aluminum box (1) attached to the underside of the plate. The plates are acoustically isolated from each  
 115 | other by elastomer elements (2). (b) Example of a packet (grey area) detected by the SPG system. A packet begins 20 time steps  
 116 | (i.e., 2 ms) before the signal envelope crosses the lowest amplitude threshold of 0.0216 V and ends 20 time steps after the last  
 117 | crossing of the lowest amplitude threshold (see Sect. 2.4).  
 118

119 **2.2 Field calibration measurements**

120 | To test the AF and AH methods, this study uses 308 ~~field calibration~~ measurements from four Swiss bedload monitoring  
 121 | stations equipped with [the](#) SPG systems (Fig. 2; Table 1). Field calibration samples were collected at the Albula, Navisence  
 122 | and Avançon de Nant stations, and extensive calibration efforts have been undertaken at the fourth field station, [the](#)  
 123 | Erlenbach, since 2009 (Rickenmann et al., 2012). The Erlenbach offers an interesting comparison with the other sites due to  
 124 | different channel [morphology](#) and flow characteristics upstream of the SPG plates. Field calibrations ~~at each of the four sites~~  
 125 | [at the four sites](#) consisted ~~of~~ [in](#) the following steps: (i) direct bedload sampling downstream of an impact plate using either  
 126 | crane-mounted net samplers adapted from Bunte traps (Bunte et al., 2004; Dell’Agnese et al., 2014; Nicollier et al., 2019;  
 127 | Fig. 2a, b), automated basket samplers (Rickenmann et al., 2012; Fig. 2d) or manual basket samplers (Fig. 2c; [Antoniazza et](#)  
 128 | [al., 2022](#)), (ii) synchronous recording of the raw geophone signal, (iii) sieving and weighing of bedload samples using ten  
 129 | sieve classes (see [Sect. 2.4 Table 3](#)), and (iv) comparing the fractional bedload mass of each sample to the ~~packet histogram~~  
 130 | [data geophone signal](#) to derive the corresponding ~~calibration coefficients~~.  ~~$k_{b,t}$~~  A more detailed description of the sampling  
 131 | procedure is reported in Supporting Information S1, [including the mesh sizes used for bedload sampling. For the analysis,](#)  
 132 | [only particles larger than 9.5 mm were considered, being close to the SPG detection threshold. Streamflow information was](#)  
 133 | [derived from various stage sensors \(Table 1\). Flow velocity  \$V\_w\$  was introduced by Wyss et al. \(2016c\) as a possible](#)

134 governing parameter affecting the number of particles detected by the SPG system. Unfortunately, due to the lack of  
 135 continuous streamflow measurements at the Albula and Navisence sites, we were not able to account for the effect of the  
 136 flow velocity in the signal conversion procedure described in the present study.

### 157 2.3 ~~Controlled F~~ flume experiments

158 The first part of the signal conversion procedure described in this study is based on ~~controlled~~-flume experiments conducted  
159 at the outdoor flume facility of the Oskar von Miller institute of TU Munich in Obernach, Germany. ~~At this facility~~There, we  
160 reconstructed the bed ~~characteristics-slope and bed roughness~~ of the Albula, Navisence and Avançon de Nant field sites, one  
161 after another, in a flume test reach with dimensions of 24 m x 1 m equipped with two impact plates at the downstream end of  
162 a paved section (Fig. 3). ~~For Each site reconstruction, we tested used~~-bedload material collected during field calibration  
163 measurements, and we adjusted the flow velocity, flow depth, and bed roughness ( $D_{67}$  and  $D_{84}$ ) to match the respective field  
164 observations. A detailed description of the original flume setup and the performed experiments can be found in Nicollier et  
165 al. (2020). In ~~this-the present paper~~study, we primarily use ~~the single-grain-size-a set of~~ experiments conducted in 2018 with  
166 the flume configured to match conditions at the Albula field site (Table 2). ~~Single~~These experiments were single-grain-size  
167 experiments and consisted of feeding the flume with a fixed number of grains for each of the ten particle-size classes  
168 described in Sect. 2.2-4 ~~above~~below. Two different feeding systems were used, namely a vertical pipe and a tiltable basket  
169 (for particles larger than 31.4 mm). While these particles were ~~being~~-transported over the SPG system, the full raw geophone  
170 signal was recorded. The experiment duration ranged from 15 seconds for the smallest particles to around 1 min for the  
171 largest particles. Up to 33 repetitions were conducted until a representative range of amplitude and frequency values for each  
172 grain-size class ~~were-was~~ obtained (Nicollier et al., 2021<sup>a</sup>). The same procedure was repeated for two different flow  
173 velocities ( $V_f = 1.6 \text{ m s}^{-1}$  and  $2.4 \text{ m s}^{-1}$ ). The obtained information was then used to derive empirical relationships between  
174 the mean particle size  $D_{m,j}$  for a given grain-size class  $j$  and ~~the packet envelope's amplitude  $MaxAmp_{env}$~~  and the ratio  
175  $MaxAmp_{env} / f_{center}$  properties of the SPG signal, as described in Sect. 2.5.2 below.

176 To illustrate the AF and AH methods and their respective performance, we use a second set of flume experiments, ~~that~~  
177 which mimic the Avançon de Nant field site. The main difference to other experimental setups is the presence, but with the  
178 addition of a 4 m wooden partition wall along the center of the flume (Fig. 3) that shields one geophone plate from impacting  
179 particles (Nicollier et al., ~~2021b~~2022). This special setup facilitates the characterization of the signal propagated from an  
180 impacted plate to the neighboring non-impacted plate. With this modified setup, single-grain-size experiments were run ( $n =$   
181 51; Table 2) using grains from each of the 10 particle-size classes and bedload material sampled at the Avançon de Nant  
182 field site. The flow velocity was set to  $3 \text{ m s}^{-1}$  to facilitate particle transport through the narrower flume section and is  
183 therefore not representative ~~for-of~~ the Avançon de Nant site, where typical flow velocities were roughly  $1.3 \text{ m s}^{-1}$ .

184

Formatiert: Schriftart: Kursiv

185  
 186 **Figure 3:** Oblique view of the Obernach flume test reach with total length of 24 m and width of 1 m. The bed surface is paved with  
 187 particles with diameters equaling the characteristic  $D_{67}$  and  $D_{84}$  sizes of the natural beds of the reconstructed sites. Grains were  
 188 fed into the channel 8 m upstream from the SPG system location (G1 and G2) using either a vertical feed pipe or a tiltable basket  
 189 (1). The sensor plate G1 (in red) was shielded from direct particle impacts by the 4 m long ~~removable~~ partition wall (2). The  
 190 partition wall and the impact plates were decoupled from each other by a 2 mm vertical gap to prevent disturbances of the  
 191 recorded signal. Plexiglas walls (3) on each side of the flume facilitated video recordings of the experiments.

192  
 193 **Table 2: Flume and hydraulic characteristics for the reconstruction of the Albula and the Avançon de Nant field sites.**

Parameter	Units	Reconstructed field site setup	
		Albula (without partition wall)	Avaçon de Nant (with partition wall)
Flume width	m	1.02	1.02
Flume gradient of the natural bed	%	0.7	4.0
Bed surface $D_{67}$ <sup>a</sup>	mm	120	200
Bed surface $D_{84}$ <sup>a</sup>	mm	190	320
Number of $D_{67}$ -particles/m <sup>2</sup>	m <sup>-2</sup>	15.0	5.0
Number of $D_{84}$ -particles/m <sup>2</sup>	m <sup>-2</sup>	5.0	2.5
Min. water depth above SPG	m	0.79	0.35
Max. water depth above SPG	m	0.91	0.35
Min. flow velocity 10 cm above SPG <sup>b</sup>	m s <sup>-1</sup>	1.6	3.0
Max. flow velocity 10 cm above SPG <sup>b</sup>	m s <sup>-1</sup>	2.4	3.0
Min. unit discharge	m <sup>2</sup> s <sup>-1</sup>	1.6	0.8
Max. unit discharge	m <sup>2</sup> s <sup>-1</sup>	2.4	0.8
Number of different flow velocity settings	-	2	1
Total number of single-grain-size experiments	-	355	51
Total number of tested particles	-	10705	2485

 195 software (Detert and Weitbrecht, 2013).

196 <sup>b</sup> Flow velocities measured with the OTT MF Pro magnetic-inductive flow meter.

197 **2.4 The amplitude-histogram method**

198 Wyss et al. (2016a) introduced the packet-based amplitude-histogram (AH) method to derive grain-size information from  
 199 geophone signals. A packet is defined as a brief interval, typically lasting 5 to 30 milliseconds, reflecting a single particle  
 200 ~~impact of a particle~~ on a plate (Fig. 1b); it begins and ends ~~when 20 time steps before and after~~ the signal envelope crosses a  
 201 threshold amplitude of 0.0216 V. The signal envelope is computed in Python with the Hilbert transform (Jones et al., 2002),  
 202 yielding ~~the magnitude of the analytic signal a continuous time series reflecting, i.e.~~ the total energy ~~in the signal~~. Each  
 203 packet's maximum amplitude is then used to assign it to a predefined amplitude class  $j$  ~~delimited by amplitude-histogram~~  
 204 ~~thresholds~~  $th_{ah,j}$  (Table 3), yielding a packet-based amplitude histogram (e.g. Fig. 4 in Wyss et al., 2016a). Each amplitude  
 205 class  $j$  is related to a corresponding grain-size class through the following relationship between the mean amplitude  $A_{m,j}$  [V]  
 206 and the mean particle size  $D_{m,j}$  [mm]:

207 
$$A_{m,j} = 4.6 \cdot 10^{-4} \cdot D_{m,j}^{1.71} . \quad (1)$$

208 The coefficients in Eq. (1) were determined using 31 basket samples collected at the Erlenbach for which the maximum  
 209 geophone amplitude was analyzed as a function of the Bb-axis of the largest particle found in the sample (Wyss et al.,  
 210 2016a). The grain-size classes are delimited by the size of the meshes  $D_{sieve,j}$  used to sieve the bedload samples from field  
 211 calibration measurements. ~~For a given bedload sample, it~~ is assumed that the number of packets between two amplitude-  
 212 histogram thresholds  $th_{ah,j}$  is ~~related to a good proxy for~~ the fractional bedload mass between the respective sieve sizes (Wyss  
 213 et al., 2016a). In the present study, we have extended the seven size classes used by Wyss et al. (2016a) to ten classes, in  
 214 order to also assess the performance of the AH and AF methods for larger particles.

215  
 216 **Table 3: ~~Characteristics of the size classes  $j$  according to Wyss et al. (2016a) derived from with the sieve mesh sizes  $D_{sieve,j}$  (for~~  
 217 ~~classes 1 to 7) according to Wyss et al. (2016a), and the mean particle diameter  $D_{m,j}$ , and the amplitude-histogram thresholds  $th_{ah,j}$~~   
 218 ~~derived from Eq. (1), and. Additionally, the lower and upper amplitude-frequency thresholds  $th_{af,low,j}$  and  $th_{af,up,j}$  derived~~  
 219 ~~respectively from Eq. (4) and (5), respectively are provided (see Sect. 2.5.2). Particles in classes 8 to 10 were manually sorted on~~  
 220 ~~the basis of linearly extrapolated  $D_{m,j}$  values. The value of  $D_{m,j}$  for the largest class (10) in brackets is an estimate, because this size~~  
 221 ~~class is open-ended and thus as such, the mean varied somewhat from site to site.~~**

Class $j$ [-]	$D_{sieve,j}$ [mm]	$D_{m,j}$ [mm]	$th_{ah,j}$ [V]	$th_{af,low,j}$ [V]	$th_{af,up,j}$ [V Hz <sup>-1</sup> ]

## 223 2.5 The amplitude-frequency method

224 In a recent study, Nicollier et al. (2021b,2022) showed that the SPG system is sensitive to extraneous particle impacts despite  
225 the isolating effect of the elastomer. Extraneous signals at individual geophone plates can arise from impacts occurring on  
226 neighboring plates, or from impacts on the concrete sill surrounding the SPG array. While attenuated to some extent, the  
227 elastic waves generated by such impacts can reach multiple geophone sensors with enough energy to be recorded as  
228 “apparent” packets. Thus, packet histograms (i.e. counts of the number of packets per class  $j$ ) are subject to a certain bias,  
229 especially in the lower size classes. The degree of bias was found to depend mainly on two factors. First, coarser grain sizes  
230 of transported bedload were shown to generate more apparent packets. Second, more apparent packets were recorded, for a  
231 given bedload mass, at transects containing more SPG plates. Nicollier et al. (2021b,2022) showed that packet characteristics  
232 such as the start time, the amplitude and the frequency help in identifying apparent packets and filtering them out from the  
233 final packet histograms. This filtering method was subsequently applied to all four field calibration datasets (Albula,  
234 Navisence, Avançon de Nant and Erlenbach) and helped to reduce the differences between the site-specific mean calibration  
235 relationships for the total bedload flux by about 30% (Nicollier et al., 2021b,2022). Based on these observations, the present  
236 study proposes an amplitude-frequency (AF) method as an adaptation of the amplitude-histogram (AH) method presented by  
237 Wyss et al. (2016a). By introducing two-dimensional (amplitude and centroid frequency) size class thresholds, the new  
238 method aims to reduce the effect of apparent packets and improve the accuracy of fractional bedload flux estimates. Note  
239 that the procedure does not allow for the differentiation of multiple particles impacting one plate simultaneously, but the  
240 high recording frequency (10 kHz) of the SPG system minimizes its probability of occurrence.

### 241 2.5.1 Centroid frequency

242 According to the Hertz contact theory, the frequency at which a geophone plate vibrates is controlled by the size of the  
243 colliding particle (Johnson, 1985; Thorne, 1986; Bogen and Møen, 2003; Barrière et al., 2015; Rickenmann, 2017). In the  
244 present study, the frequency spectrum of a packet is characterized by the spectral centroid  $f_{\text{centroid}}$ . It represents the center of  
245 mass of the spectrum and is computed as:

$$246 f_{\text{centroid}} = \frac{\sum f_n \cdot A_{\text{FFT},n}}{\sum A_{\text{FFT},n}} \quad (2)$$

247 where  $A_{\text{FFT},n}$  [V·s] is the Fourier amplitude (computed with the Fast Fourier Transform FFT) corresponding to the frequency  
248  $f_n$  [Hz]. Following Wyss et al. (2016b), before applying the FFT, each packet is preprocessed in two steps. First, a cosine  
249 taper is applied at the edges of a max. 8 ms time window around the peak amplitude of each packet. Second, the signal  
250 contained in this time window is zero-padded on either side to reach an optimal number of sample points  $n_{\text{FFT}}$ . The taper is  
251 used to smooth the transition between the packet and the concatenated zeros, and to suppress spectral leakage, which results  
252 in a more accurate amplitude spectrum. The value of  $n_{\text{FFT}}$  was set to  $2^7$  in order to adequately resolve the amplitude  
253 spectrum of the raw signal contained in the max. 8 ms time window. This time window focuses on the first arrival waveform  
254 to obtain a more accurate evaluation of the high-frequency content of the packet (Nicollier et al., 2021b,2022). The single-  
255 sided Fourier transform of the processed packet is then computed in order to extract  $A_{\text{FFT}}$  and derive  $f_{\text{centroid}}$  (Eq. 2). A  
256 decrease in  $f_{\text{centroid}}$  with increasing particle size was observed for different bedload surrogate monitoring techniques  
257 (Belleudy et al., 2010; Uher and Benes, 2012; Barrière et al., 2015). Furthermore,  $f_{\text{centroid}}$  has the advantage of showing  
258 weaker dependency on the flow velocity and transport mode than the maximum registered packet amplitude (Wyss et al.  
259 2016b; Chen et al., 2021). As shown by Nicollier et al. (2021b,2022),  $f_{\text{centroid}}$  also contains information about the impact  
260 location of a packet-triggering particle. Because high frequencies are more rapidly attenuated than low frequencies along the

261 travel path of a seismic wave, (apparent) packets triggered by impacts on a given plate typically have higher  $f_{\text{centroid}}$  values  
 262 than packets triggered by impacts occurring beyond that plate's boundaries.

## 263 2.5.2 Flume-based amplitude-frequency thresholds

264 The ~~transported bedload particle~~ mass associated with an individual signal packet is strongly dependent on the size of the  
 265 impacting particle. Inferring sediment transport rates from SPG signals thus requires assigning each packet to a  
 266 corresponding sediment size class using threshold values of packet characteristics (Table 3). ~~Wyss et al. (2016a) derived~~  
 267 ~~size class thresholds (or AH thresholds) of packet peak amplitude from field measurements (Eq. 1). In the present study, we~~  
 268 ~~derive size class thresholds of packet amplitude and frequency take advantage from of~~ the single-grain-size experiments  
 269 ~~conducted at the flume facility (without the partition wall) using the Albula setup (Nicollier et al., 2021a) to derive size class~~  
 270 ~~thresholds combining packet amplitude and frequency (or AF thresholds). For each~~ Each packet is assigned to a given class  $j$   
 271 ~~delimited by the a~~ lower threshold  $th_{\text{af,low},j}$  ~~is~~ based on the maximum amplitude of the packet's envelope  $MaxAmp_{\text{env}}$  [V],  
 272 and ~~the an~~ upper threshold  $th_{\text{af,up},j}$  ~~is~~ based on the ratio  $MaxAmp_{\text{env}}/f_{\text{centroid}}$  [V Hz<sup>-1</sup>]. Compared to the raw signal, the  
 273 envelope has the advantage of returning the magnitude of the analytical signal and thus better outlines the waveform by  
 274 omitting the harmonic structure of the signal (Fig. 2b). Similar combinations of amplitude and frequency have been used to  
 275 infer particle sizes and improve the detectability of bedload particles in previous studies involving impact plates (Tsakiris et  
 276 al., 2014; Barrière et al., 2015; ~~Wyss et al., 2016b; Koshiba and Sumi, 2018) and pipe hydrophones (Choi et al., 2020).~~

277 The lower and upper amplitude-frequency (AF)-thresholds ~~are~~ obtained as follows. First, all packets recorded during  
 278 the single-grain-size experiments ~~(without the partition wall)~~ are filtered with respect to the following criterion adapted from  
 279 Nicollier et al. ~~(2021b2022):~~

$$280 \quad \text{Criterion: } f_{\text{centroid}} > a_c \cdot e^{(b_c \cdot MaxAmp_{\text{env}})}, \quad (3)$$

281 with  $a_c = 1980$  Hz and  $b_c = -1.58$  V<sup>-1</sup>. ~~The values of the linear coefficient  $a_c$  and the exponent  $b_c$  were obtained through an~~  
 282 ~~optimization process discussed below (Sect. 4.1), and were found to best separate apparent packets from real packets.~~  
 283 ~~Packets identified as apparent packets using this criterion that do not meet this criterion are considered as apparent packets~~  
 284 ~~and are ignored in the further analysis in order to obtain more accurate threshold values. Note that in the present study, the~~  
 285 ~~criterion in Eq. 3 has not been applied to the data when implementing the AH method developed by Wyss et al. (2016a).~~  
 286 ~~The values for the linear coefficient  $a_c$  and the exponent  $b_c$  were obtained through an optimization process discussed below.~~

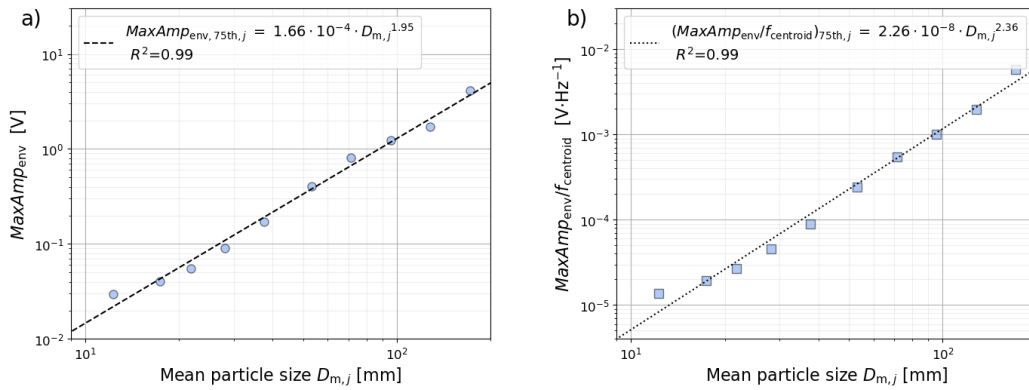

287 The next step consists in fitting a power-law least-squares regression line through the 75<sup>th</sup> percentile amplitude  
 288  $MaxAmp_{\text{env},75\text{th},j}$  and amplitude-frequency  $(MaxAmp_{\text{env}}/f_{\text{centroid}})_{75\text{th},j}$  values of ~~the packets detected for a given grain-~~  
 289 ~~size class  $j$  fed into the flume that met the filtering criterion each class  $j$~~  (Fig. 4), resulting in the following two equations:

$$290 \quad MaxAmp_{\text{env},75\text{th},j} = 1.66 \cdot 10^{-4} \cdot D_{\text{m},j}^{1.95}, \quad \text{and} \quad (4)$$

$$291 \quad \left( \frac{MaxAmp_{\text{env}}}{f_{\text{centroid}}} \right)_{75\text{th},j} = 2.26 \cdot 10^{-8} \cdot D_{\text{m},j}^{2.36}. \quad (5)$$

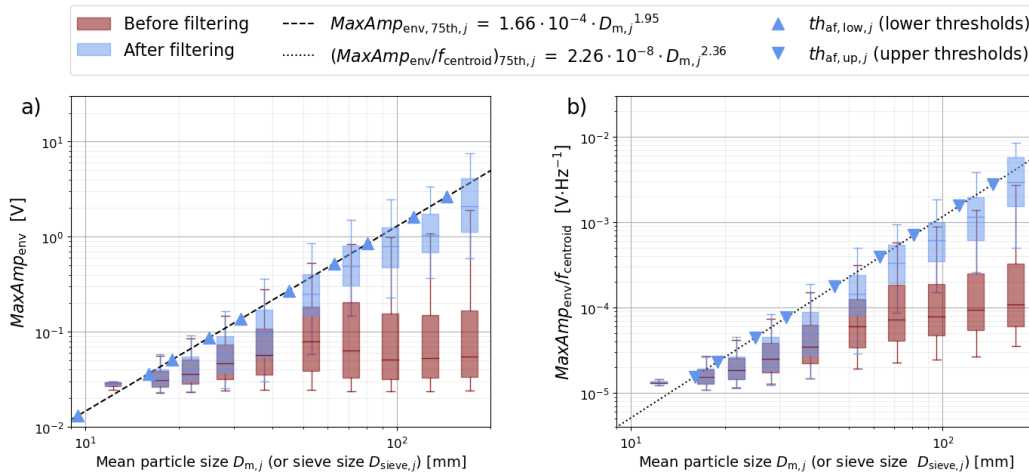

292 Finally, the lower ~~and upper~~ threshold values  $th_{\text{af,low},j}$  ~~and  $th_{\text{af,up},j}$~~  are obtained by replacing  $D_{\text{m},j}$  in Eq. (4) ~~and (5)~~  
 293 ~~with the lower ( $D_{\text{sieve},j}$ ) and upper ( $D_{\text{sieve},j+1}$ ) sieve sizes  $D_{\text{sieve},j}$ , while the upper threshold values  $th_{\text{af,up},j}$  are obtained by~~  
 294 ~~replacing  $D_{\text{m},j}$  in Eq. (5) with the upper sieve sizes  $D_{\text{sieve},j+1}$  respectively (Table 3 and triangles in Fig. 5). The advantage in~~  
 295 ~~fitting~~ Fitting functions such as Eq. (4) and (5) ~~is that they allow~~ allows for the computation of thresholds for any  
 296 classification of particle (sieve) sizes.

297 When considering all the packets detected for a given grain-size class, it was found that ~~Particularly for the largest~~  
 298 ~~particles,~~ apparent packets can greatly outnumber real packets. This is particularly pronounced for the largest grain sizes,  
 299 because the energy released by their impact, especially outside of the plate boundaries, is more likely to be detectable by the  
 300 geophone sensors. Due to signal attenuation, however, these numerous apparent packets have ~~their~~ relatively small  
 301 amplitudes, these apparent packets can ~~which~~ substantially dilutes the average signal response associated with the largest  
 302 grain sizes (see the red boxplots in Fig. 5). However, filtering out apparent packets reveals a rather clear relationship, which  
 303 would otherwise be obscured, between the mean particle size  $D_{m,j}$  and both the amplitude  $MaxAmp_{env}$  and the  
 304 ratio  $MaxAmp_{env}/f_{centroid}$  (see the blue boxplots in Fig. 5). Overall, the filtering with criterion (Eq. 3) at the Obernach  
 305 flume site eliminated about 61% of all the packets.

306  
 307 **Figure 4: Power-law least-squares regression relationships between the mean particle diameter  $D_{m,j}$  and the 75<sup>th</sup> percentile of the**  
 308 **packets' (a) amplitude  $MaxAmp_{env,75th,j}$  (a) and (b) and amplitude-frequency ( $MaxAmp_{env}/f_{centroid}$ )<sub>75th,j</sub> (b) values obtained from the**  
 309 **single-grain-size experiments after filtering out apparent packets using the filtering criterion in Eq. (3).**

310

311  
 312 **Figure 5: Range of signal responses obtained from the single-grain-size experiments for each individual grain-size class fed into the**  
 313 **flume before (red boxes) and after (blue boxes) filtering out apparent packets using the filtering criterion in Eq. (3), with (a) the**

314 maximum amplitude of the envelope  $MaxAmp_{env}$  and (b) the ratio  $MaxAmp_{env} / f_{centroid}$  as functions of the mean particle diameter  
 315  $D_{m,j}$ . In (a), the lower threshold values  $th_{af,low,j}$  are obtained by replacing  $D_{m,j}$  with the lower sieve sizes ( $D_{sieve,j}$ ) in the equation of  
 316 the dashed power-law regression line (Eq. 4). In (b), the upper threshold values  $th_{af,up,j}$  are obtained by replacing  $D_{m,j}$  with the  
 317 upper sieve sizes ( $D_{sieve,j+1}$ ) in the equation of the dotted power-law regression line (Eq. 5).

### 318 2.5.3 Application to field calibration measurements

319 The lower and upper thresholds  $th_{af,low,j}$  and  $th_{af,up,j}$  obtained from the filtered flume experiments can ~~also be used for~~  
 320 ~~transferred to~~ the field ~~calibration~~-datasets, if the SPG apparatus and the geophone data recording and preprocessing routines  
 321 are identical in both cases. The following steps ~~allow us to derive~~~~will now lead us to~~ the final general calibration coefficients  
 322  $k_{b,j,gen}$  (Fig. 6). First, for each field measurement  $i$ , the thresholds  $th_{af,low,j}$  and  $th_{af,up,j}$  are used for counting the number of  
 323 packets per class  $j$  from the recorded geophone signal. Second, a sample- and class-specific calibration coefficient  $k_{b,i,j}$  with  
 324 units [ $kg^{-1}$ ] is obtained by dividing the number of recorded packets  $PACK_{i,j}$  by the sampled fractional mass  $M_{meas,i,j}$  as  
 325 follows:

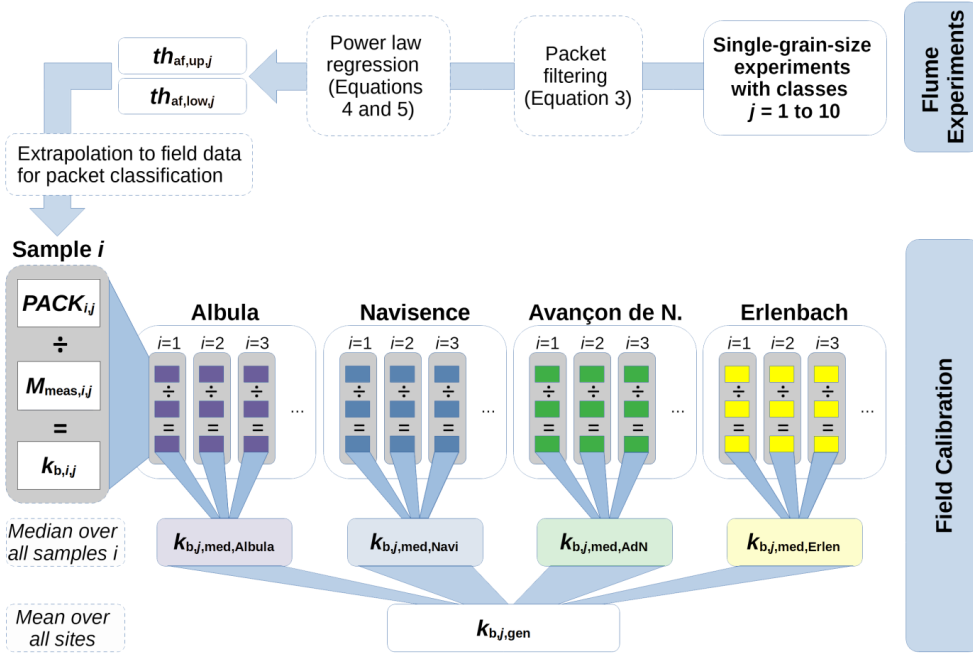

$$326 \quad k_{b,i,j} = \frac{PACK_{i,j}}{M_{meas,i,j}}. \quad (6)$$

327 Finally, the general calibration coefficient  $k_{b,j,gen}$  is computed for each class  $j$  using

$$328 \quad k_{b,j,gen} = \frac{1}{N_{stations}} \sum_{stations} k_{b,j,med,station}, \quad (7)$$

329 where  $k_{b,j,med,station}$  is the site-specific median calibration coefficient ~~computed over all samples  $i$~~ , and  $N_{stations}$  is the  
 330 number of stations. Even though the number of calibration measurements differs from site to site, each coefficient  
 331  $k_{b,j,med,station}$  in Eq. (7) is equally weighted in order to give the same importance to site-specific factors possibly affecting  
 332 the signal response at each site.

Formatiert: Schriftart: Kursiv

333

334 **Figure 6:** Workflow leading from the single-grain-size flume experiments with particles from ten size classes  $j$  (top right) to the  
 335 final array of general calibration coefficients  $k_{b,j,gen}$ . Central elements are the lower and upper threshold values  $th_{af,low,j}$  and  
 336  $th_{af,up,j}$ , the number of recorded packets  $PACK_{i,j}$  per sample  $i$  and class  $j$ , the sampled fractional mass  $M_{meas,i,j}$ , the sample- and  
 337 class- specific calibration coefficient  $k_{b,i,j}$ , and finally the site-specific median calibration coefficient  $k_{b,j,med,station}$ . To enable a  
 338 comparison with the AH method developed by Wyss et al. (2016a), the “Field Calibration” part of the workflow was also carried  
 339 out with the AH thresholds  $th_{ah,j}$  (see Table 3).

340 At this point, the single array of calibration coefficients  $k_{b,j,gen}$  is applied as follows to each field calibration  
 341 measurement  $i$  in order to obtain fractional bedload mass estimates  $M_{est,i,j}$ :

$$342 \quad M_{est,i,j} = k_{b,j,gen} \cdot PACK_{i,j} . \quad (8)$$

343 Rickenmann and Fritschi (2017) showed that bedload mass estimates derived from SPG measurements are more accurate at  
 344 higher transport rates. The estimated fractional bedload mass  $M_{est,i,j}$  can be converted to a unit fractional transport rate  
 345  $q_{b,est,i,j}$  [ $\text{kg m}^{-1} \text{s}^{-1}$ ] using:

$$346 \quad q_{b,est,i,j} = \frac{1}{w_p \cdot n_p} \cdot \frac{M_{est,i,j}}{\Delta t_i} . \quad (9)$$

347 where  $w_p$  is the standard width of an impact plate (0.5 m),  $n_p$  is the number of plates (which may include the whole transect,  
 348 or a section of particular interest), and  $\Delta t_i$  is the sampling duration in seconds. Finally, the estimated unit total bedload flux  
 349  $q_{b,tot,est,i}$  can be computed as follows:

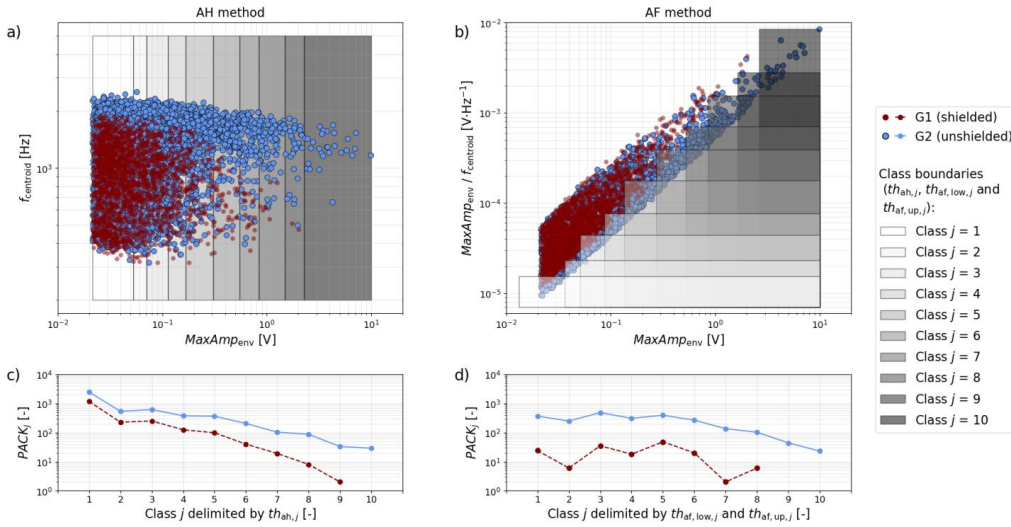

$$350 \quad q_{b,tot,est,i} = \sum_{j=1}^{10} q_{b,est,i,j} \quad (10)$$

351 Note that the exact same procedure was followed using the AH thresholds  $th_{ah,j}$  derived from Wyss et al. (2016a) (Eq. 1;  
352 Table 3) to compare the performance between the AH method and the new AF method.

### 353 3 Results

#### 354 3.1 Flume experiments

355 The flume experiments performed in the modified Avançon de Nant setup with the partition wall help to illustrate the  
356 performance of the two calibration methods. Fig. 7a and 7b show the amplitude and frequency characteristics of all packets  
357 detected by the SPG system during these experiments. Packets detected by the shielded sensor G1 all originate from impacts  
358 that occurred either on the concrete bed or on plate G2 (Figure 3; Nicollier et al., ~~2021b~~2022). Packets detected by the  
359 unshielded sensor G2 are considered as apparent if they are located in the area of the amplitude-frequency graph (Fig. 7a)  
360 where G1 and G2 packets overlap. Such packets are presumed to have been triggered by impacts on the concrete bed ~~too~~.  
361 This overlapping area arises from the fact that a seismic wave generated by an impact on the concrete bed follows a similar  
362 path towards both sensors, resulting in the recording of two apparent packets with comparable characteristics. The remaining  
363 packets, detected by G2 and located in the non-overlapping area of the amplitude-frequency graph, are considered ~~as real,~~  
364 ~~rather than apparent.~~ The difference in  $f_{centroid}$  between real and apparent packets (Fig. 7a) reflects the faster attenuation of  
365 higher frequencies during wave propagation, ~~as mentioned earlier.~~ Size class boundaries derived by the AH method of Wyss  
366 et al. (2016a) encompass all of the packets, both apparent and real (Fig. 7a). This is because the boundaries are defined  
367 solely by AH thresholds ( $th_{ah,j}$ ). By contrast, in the AF method proposed here, the two-dimensional class boundaries given  
368 by  $th_{af,low,j}$  and  $th_{af,up,j}$  cover only a fraction of all detected packets (Fig. 7b). Applying the step-like AF thresholds leads to  
369 a strong reduction of the number of packets  $PACK_j$  within each size class  $j$  for plate G1 (shielded), particularly for the  
370 smaller classes. Meanwhile, the AF thresholds had little effect on the number of detected packets for G2 (unshielded), except  
371 for a strong decrease for classes  $j = 1$  and 2, and a slight increase for classes  $j = 6$  to 10 (Fig. 7c and 7d). The AH thresholds  
372 encompass in total 1945 packets for the shielded geophone G1, and 4823 packets for the unshielded geophone plate G2. In  
373 comparison, the AF thresholds encompass in total 159 packets for the shielded geophone G1, and 2202 packets for the  
374 unshielded geophone plate G2 (counting the packets in the overlapping class boundaries only once). Considering apparent  
375 packets as noise and real packets as signal, applying the new AF method results in an increased signal to noise ratio, as  
376 shown by the larger vertical separation between the blue (signal) and red (noise) lines in Fig. 7d compared to Fig. 7c.

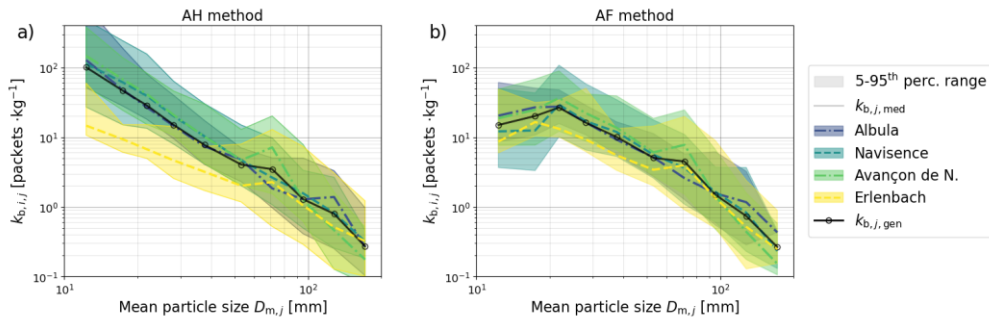

377

378 **Figure 7: Characteristics of the packets recorded during single-grain-size experiments conducted with the Avançon de Nant flume**  
 379 **setup using the partition wall, with the maximum amplitude of the envelope  $MaxAmp_{env}$  and the centroid frequency  $f_{centroid}$ . The**  
 380 **red and blue dots correspond to packets recorded by the shielded plate G1 and the unshielded plate G2, respectively. The grey**  
 381 **rectangles are the class boundaries delimited by the thresholds obtained for the AH method (a) and the AF method (b). The**  
 382 **number of packets  $PACK_j$  located within the class boundaries delimited by the AH thresholds and the AF thresholds are indicated**  
 383 **in (c) and (d), respectively.** In (a),  $f_{centroid}$  is shown as function of  $MaxAmp_{env}$  for information purposes only ~~and is not~~  
 384 ~~incorporated in the thresholds.~~ (c) and (d) represent the number of packets  $PACK_j$  located within the class boundaries shown in (a)  
 385 ~~and (b), respectively. Missing markers signify that no packet was detected within the corresponding AH or AF thresholds.~~

### 386 3.2 Field calibration coefficients

387 As discussed in the previous section, the number of packets  $PACK_{i,j}$  detected for a given class  $j$  varies together with the  
 388 thresholds  $th_{ah,j}$ ,  $th_{af,low,j}$  and  $th_{af,up,j}$ . Because the measured fractional bedload mass  $M_{meas,i,j}$  remains constant, the  
 389 calibration coefficients  $k_{b,i,j}$  will depend on the number of packets detected, and thus on the thresholds that are used to  
 390 classify them. We can make the following observations regarding the calibration coefficients  $k_{b,i,j}$  obtained using the AF  
 391 method (Fig. 8b) compared to the AH method (Fig. 8a). First, the  $k_{b,i,j}$  coefficients of the smaller size classes are  
 392 substantially lower, meaning that fewer packets per unit mass are detected. Second, for the larger size classes, slightly more  
 393 packets are detected per unit mass. Third, ~~considering all sites and all size classes  $j$ ,~~ the overall scatter of the  $k_{b,i,j}$   
 394 coefficients ~~across all sites~~ is smaller, ~~in particular for the six smallest classes  $j$ .~~ This is reflected in the decrease of the mean  
 395 coefficient of variation (CV) across all classes  $j$  and all sites from CV = 1.17 (in the AH method) to CV = 0.93 (in the AF  
 396 method). Fourth, the scatter of the site-specific  $k_{b,i,j}$  coefficients is usually smaller. This is supported by the change of the  
 397 mean CV across all classes from 0.89 to 0.54 for the Albul, from 0.83 to 0.75 for the Avançon de Nant and from 1.31 to  
 398 1.00 for the Erlenbach, between the AH and AF methods. The mean CV for the Navisence site however remains unchanged  
 399 at 0.85. The general coefficients  $k_{b,j,gen}$  obtained from the site-specific median coefficients  $k_{b,j,med}$  using Eq. (7) are listed  
 400 in Table 4.

425

We can now ~~insert~~ apply the general calibration coefficients  $k_{b,j,gen}$  in Eq. (8) to compute fractional bedload mass estimates  $M_{est,i,j}$  and subsequently ~~the estimates of the unit-fractional flux per unit width estimates~~  $q_{b,est,i,j}$  (Eq. 9) for every sample collected at the four field sites (Fig. 9). ~~Fig. 9 illustrates the accuracy of the bedload flux estimates obtained with the AF method for each sample across the grain size classes and the field sites.~~ The results obtained with the AH method can be found in Supplementary Information S3, and Table 5 provides further information on the performance of the two methods.

~~When applied to the field calibration data, the AF method generally yields more accurate flux estimates than the AH method does, particularly for the five smallest grain-size classes. This improvement is most notably reflected by the coefficient of determination  $R^2$  values, describing the accuracy of the estimates relative to the 1:1 line (Table 5).  $R^2$  increased from 0.4 to 0.71 for class  $j = 1$  and from 0.51 to 0.72 for class  $j = 2$ , but by contrast,  $R^2$  decreased slightly from 0.57 to 0.55 for class  $j = 8$ . The root-mean-square error (RMSE), which quantifies the expected error of the estimates, leads to similar observations (Table 5). The RMSE decreased from 0.094 kg m<sup>-1</sup> s<sup>-1</sup> to 0.068 kg m<sup>-1</sup> s<sup>-1</sup> for class  $j = 1$  and from 0.031 kg m<sup>-1</sup> s<sup>-1</sup> to 0.021 kg m<sup>-1</sup> s<sup>-1</sup> for class  $j = 2$ , but increased slightly from 0.037 to 0.039 for class  $j = 8$ . A further interesting result is the increase for the first eight classes of the percentage  $p_{factor_5}$  of all detected samples, whose estimated bedload fluxes differ by less than a factor of 5 from the measured values (Figure 9; Table 5).~~

426 Aside from these comparative observations, it is also worth mentioning the following more general findings that are valid for  
 427 both methods. i) For most size fractions, the relative scatter of the estimates (on the log-log plots) decreases with increasing  
 428 transport rates. (ii) At low transport rates, mass fluxes are generally overestimated, while at high transport rates they are  
 429 generally underestimated. This is shown by the dashed colored power-law regression lines shown in Fig. 9, described by the  
 430 corresponding linear coefficient  $a$  and exponent  $b$  in Table 5. (iii) As indicated by the yellow dots and regression lines in Fig.  
 431 9, mass fluxes for the Erlenbach closely follow the 1:1 line but tend to be slightly underestimated. (iv) The number of  
 432 measured ( $N_{\text{samples,meas}}$ ) and estimated ( $N_{\text{samples,est}}$ ) samples both decrease with increasing particle size. While more than  
 433 300 samples were measured and estimated for each of the five smallest grain-size classes, these numbers gradually decrease  
 434 to around 100 for the largest class  $j=10$ . Furthermore, samples for which either the measured or the estimated flux equals 0  
 435 are indicated as dots along the axes in Fig. 9. If the measured flux is zero but the estimated flux is positive, the sample can be  
 436 regarded as false positive (Fawcett, 2006). The difference between  $N_{\text{samples,meas}}$  and  $N_{\text{samples,est}}$  in Table 5 indicates that the  
 437 occurrence of such false positive samples increases with increasing particle size. Further performance metrics derived from  
 438 the confusion matrix can be found in the Supporting Information (Table S2).

439 The dashed colored power law regression lines shown in Fig. 9, described by the corresponding linear coefficient  $a$  and  
 440 exponent  $b$  (Table 5), indicate possible trends in over/under estimation at each field site. The coefficient of determination  $R^2$   
 441 describes the accuracy of the estimates relative to the 1:1 line. The root mean square error (RMSE) quantifies the expected  
 442 error of the estimates and is expressed in  $[\text{kg m}^{-2} \text{s}^{-1}]$ . When applied to the field calibration data, the AF method generally  
 443 yields more accurate flux estimates than the AH method does. This is most notably reflected by the  $R^2$  values and the  
 444 percentages  $p_{\text{factor}=2}$  and  $p_{\text{factor}=5}$  of all detected samples whose estimated bedload fluxes differ by less than a factor of 2 and  
 445 5, respectively, from the measured values (Table 5). The five smallest grain size classes were most strongly affected by these  
 446 improvements, whereas the estimates for the largest fractions ( $j=7$  to 10) were only slightly improved.

447 Aside from these comparative observations, it is also worth mentioning the following more general findings that are valid for  
 448 both methods: (i) for most size fractions, the relative scatter of the estimates (on the log-log plots) decreases with increasing  
 449 transport rates; (ii) at low transport rates, mass fluxes are generally overestimated, while at high transport rates they are  
 450 generally underestimated; (iii) mass fluxes for the Erlenbach closely follow the 1:1 line but tend to be slightly  
 451 underestimated; (iv) the number of measured ( $N_{\text{samples,meas}}$ ) and estimated ( $N_{\text{samples,est}}$ ) samples both decrease with  
 452 increasing particle size. Samples for which either the measured or the estimated flux equals 0 are indicated as dots along the  
 453 axes in Fig. 9. If the measured flux is zero but the estimated flux is positive, the sample can be regarded as false positive  
 454 (Fawcett, 2006). The difference between  $N_{\text{samples,meas}}$  and  $N_{\text{samples,est}}$  in Table 5 indicates that the occurrence of such false  
 455 positive samples increases with increasing particle size. Further performance metrics derived from the confusion matrix can  
 456 be found in the Supporting Information (Table S2).

458

459 **Figure 9:** Unit fractional transport rate estimates obtained with the AF method for each size class  $j$  and each station. The light grey  
 460 dots in the background indicate the estimates obtained with the AH method and are represented in more detail in the Supporting  
 461 Information (Fig. S1). Each **frame-panel** is annotated with the mean particle size  $D_{m,j}$  of the represented class. The solid black lines  
 462 correspond to the reference 1:1 line while the dotted lines delimit factors of 5 above and below **it** (from 0.2 to 5). The dashed  
 463 colored lines are power-law regression lines; the mean coefficients over all four sites are listed in Table 5. The dots along the axes  
 464 indicate samples for which either the measured or the estimated unit fractional flux equals 0. These samples are not considered for  
 465 the computation of the trend lines.

466

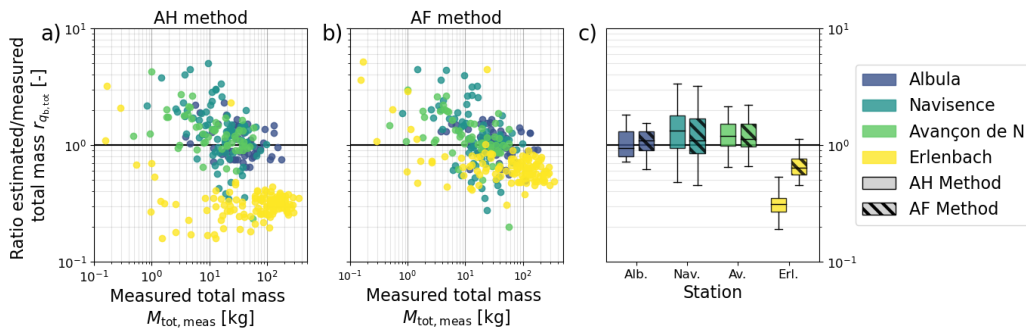

467 **Table 5:** Performance of the AH method and the AF method regarding fractional flux estimates for each class  $j$  with following  
 468 parameters: the linear coefficient  $a$ , the exponent  $b$  and the correlation coefficient  $r$  of the power-law regression lines visible in Fig.  
 469 9; the coefficient of determination  $R^2$ ; the root-mean-square error  $RMSE$ ; and the percentage of all detected samples for which the  
 470 estimated value differs from the measured value by less than a factor of 2 and 5  $p_{\text{factor}_2}$  and  $p_{\text{factor}_5}$ , respectively. These values  
 471 were first computed for each site separately and then averaged over all four sites. The number of measured  $N_{\text{samples,meas}}$  and the  
 472 number of estimated samples  $N_{\text{samples,est}}$  showing a positive unit fractional rate were summed over all four sites.

473

474 As indicated by Eq. (10), the unit total flux estimates are computed as the sum of the unit fractional flux estimates over  
475 all 10 classes. Fig. 10 shows the ratio  $r_{q_{b,\text{tot}}}$  between the estimated total flux  $q_{b,\text{tot,est}}$  and the measured total flux  $q_{b,\text{tot,meas}}$   
476 for all 308 calibration samples, as a function of the sampled total mass  $M_{\text{tot,meas}}$ . Here, the estimates for the Albul, the  
477 Navisence and the Avançon de Nant sites are slightly more accurate with the AF method than with the AH method, whereas  
478 the estimates for the Erlenbach improve substantially, with the median  $r_{q_{b,\text{tot}}}$  value increasing from 0.31 to 0.64. Note that  
479 the observations (i) to (iii) made earlier regarding the fractional flux estimates are also valid here. Fig. 10 also provides an  
480 interesting overview of the sampled masses at all four stations, reflecting the capacities of the different devices (automated  
481 and manual basket samplers and crane-mounted net sampler) used to collect the calibration samples.

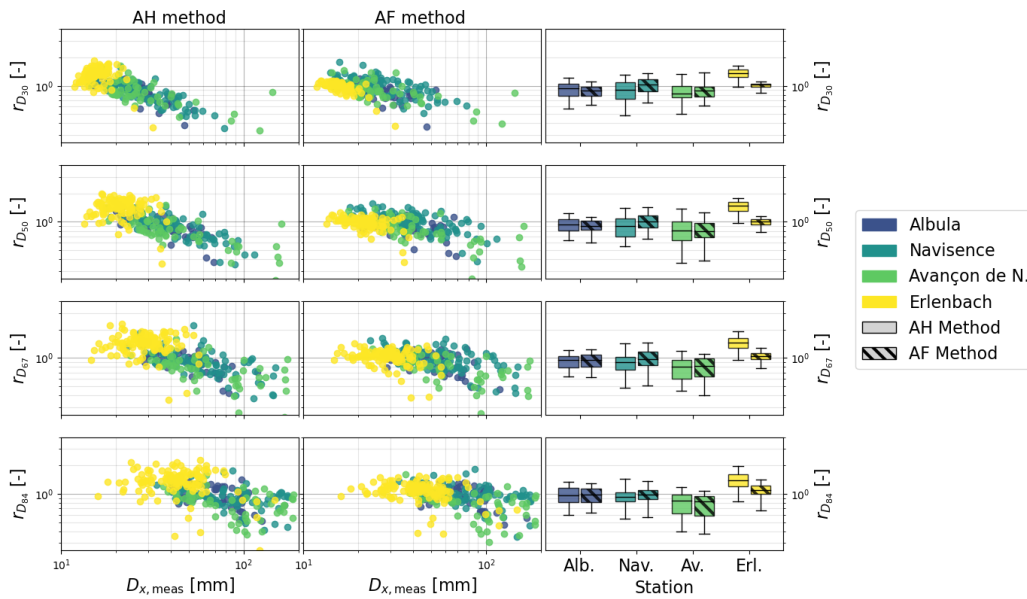

482

483 **Figure 10: Ratio  $r_{q_{b,\text{tot}}}$  between the estimated and the measured unit total mass flux as a function of the total sampled mass**  
484  **$M_{\text{tot,meas}}$ , for each collected sample  $i$  and each station, for the AH method (a) and the AF method (b). The boxplots on the right (c)**  
485 **indicate the range of  $r_{q_{b,\text{tot}}}$  values obtained for each station. The boxes in solid colors show the results obtained with the AH method**  
486 **and the hatched boxes show the results obtained with the AF method.**

### 487 3.4 Grain-size estimates

488 We can combine the SPG bedload flux estimates for all grain-size fractions and thus derive grain-size distributions, which  
489 can then be compared to the measured size distributions of each calibration sample. Fig. 11 compares the performance of the  
490 AH and the AF methods in estimating the characteristic grain sizes  $D_{30}$ ,  $D_{50}$ ,  $D_{67}$  and  $D_{84}$  (where  $D_x$  is the grain diameter for  
491 which  $x$  percent of the sampled bedload mass is finer). The accuracy of the estimates is indicated by the ratio  $r_{D_x}$  between the  
492 estimated and the measured characteristic grain size  $D_x$ . Compared to the AH method, the AF method mainly improves the

493 estimates of the four characteristic grain sizes for the Navisence and the Erlenbach sites, but has little effect at the other two  
 494 sites. The largest improvement is achieved for the Erlenbach site, with the median  $r_{D_{30}}$  changing from 1.37 to 1.02, the  
 495 median  $r_{D_{50}}$  changing from 1.48 to 1.01, the median  $r_{D_{67}}$  changing from 1.46 to 1.05 and the median  $r_{D_{84}}$  changing from  
 496 1.39 to 1.10. On the opposite, applying the AF method to the Avançon de Nant dataset slightly reduced the accuracy of the  
 497 characteristic grain-size estimates, with the median  $r_{D_{30}}$  changing from 0.83 to 0.88, the median  $r_{D_{50}}$  changing from 0.81 to  
 498 0.79, the median  $r_{D_{67}}$  changing from 0.80 to 0.82 and the median  $r_{D_{84}}$  changing from 0.85 to 0.83. The overall accuracy of  
 499 the estimates decreases with increasing characteristic size  $D_x$  for both methods, and for every characteristic size  $D_x$ , the  $D_x$   
 500 tends to be overestimated for finer grain mixtures and underestimated for coarser grain mixtures.

501  
 502 **Figure 11:** Ratio  $r_{D_x}$  between the estimated and the measured characteristic grain sizes  $D_{30}$ ,  $D_{50}$ ,  $D_{67}$  and  $D_{84}$  as a function of the  
 503 measured grain diameter  $D_{x, meas}$  for each collected sample  $i$  and each station using the AH method (column 1) and the AF method  
 504 (column 2).  $D_x$  is the grain diameter for which  $x$  percent of the sampled bedload is finer. The boxplots in column 3 indicate the  
 505 range of  $r_{D_x}$  values obtained for each station. The boxes in faded-solid colors show the results obtained with the AH method and  
 506 the hatched boxes in brighter colors show the results obtained with the AF method.

## 507 4 Discussion

### 508 4.1 The hybrid calibration procedure

509 Recent studies have pointed out the difficulty of transferring flume-based calibrations of the-impact plate systems to field  
 510 applications (e.g. Mao et al., 2016; Wyss et al., 2016c; Kuhnle et al., 2017). In the hybrid calibration approach presented  
 511 here, we took advantage of controlled-flume experiments, but only to obtain amplitude and amplitude-frequency thresholds  
 512 for each particle-size class, which were subsequently applied to field calibration datasets to derive the general calibration  
 513 coefficients  $k_{b,j, gen}$ .

514 Among the three sites reconstructed at the flume facility, only the experiments conducted in 2018 with the Albula setup  
515 were used for calibration purposes in the present study. Although the differences are small, the class thresholds derived from  
516 these experiments yielded slightly more accurate bedload flux estimates than the thresholds derived from the other site  
517 reconstructions. A possible explanation for this is the lower bed roughness used for the Albula site reconstruction as  
518 compared to the other two setups, which facilitated the transport of larger particles. The Albula setup was also less affected  
519 by lateral sorting of small particles (mainly classes  $j = 1$  to 4) toward the flume walls, which resulted in a weaker signal  
520 response. Additionally, the flow velocities used in this setup ( $V_c = 1.6$  and  $2.4 \text{ m s}^{-1}$ ) lie between the velocities measured  
521 during the field calibration campaigns at the Navisence and Avançon de Nant sites.

522 The entire hybrid calibration procedure was run iteratively until the optimal linear coefficient and exponent of the  
523 criterion (Eq. 3) used to filter out apparent packets were found (Fig. 6). As objective function, we used an equally weighted  
524 combination of parameters describing the accuracy of bedload flux and grain-size estimates, i.e.  $r$ ,  $R^2$ ,  $p_{\text{factor}_2}$ ,  $p_{\text{factor}_5}$ , and  
525  $RMSE$  as shown in Table 5, and  $r_{D_x}$  as shown in Fig. 11, and the accuracy  $is$  derived from the confusion matrix  
526 (Fawcett, 2006) as shown in Table S2 in Supporting Information. We looked for two types of optimal calibrations. The first  
527 type is a general calibration, for which we have presented the results in Sect. 3. This calibration combines all four stations in  
528 order to investigate the feasibility of a general signal conversion procedure applicable to multiple sites equipped with the  
529 SPG systems. The second type is a site-specific calibration aiming to improve the accuracy of bedload transport rate  
530 estimates at a single monitoring station, to be used for a more detailed analysis of bedload-related processes at a given site  
531 (details of these site-specific calibrations are available in Supporting Information Sect. S4 and S5).

532 The biases introduced by apparent packets can be removed by site-specific calibration of the coefficients  $k_{b,i,j}$ , so the  
533 AF and AH methods perform about equally well when calibrated separately to each individual site (see Supporting  
534 Information Sect. S4 and S5). This result supports the use of the AF method, considering the large proportion of packets left  
535 out by the AF thresholds (up to 91 % in the smallest class  $j = 1$ ; see Supporting Information Table S4). However, the  
536 abundance of apparent packets varies considerably from site to site, owing to differences in the channel geometry, the  
537 bedload grain-size distribution, and the construction details of the individual SPG installations. Because the AF method  
538 filters out a substantial fraction of these apparent packets, it yields substantially better general calibrations than the AH  
539 method does (see Table 5).

540 We also tested the performance of an adapted version of the AH method introduced by Rickenmann et al. (2018). This  
541 method was originally developed for the Erlenbach site and aimed to correct for the relationship between the signal response  
542 and the transport rate. In the present study, we applied this method to each field site. The only notable improvement  
543 introduced by the adapted AH method is the increased number of detected samples at the Erlenbach station, leading to more  
544 accurate estimates of the various characteristic grain sizes  $D_x$  at this site (Tables S8 and S9 in Supporting Information); the  
545 results for the other sites were not substantially improved.

#### 547 4.2 Two-dimensional size class thresholds

548 To understand the performance of the new AF method it is worth taking a closer look at the role of the size class thresholds.  
549 As shown in Fig. 7, replacing the upper amplitude thresholds with amplitude-frequency values results in the following two  
550 important changes. First, a dimension is added, which facilitates focusing on the narrow range of signal responses  
551 characteristic for real packets, and filtering out many of the apparent packets. Second, the areas of the amplitude-frequency  
552 domain covered by two adjacent classes can now overlap. Packets located in overlapping areas are assigned once to each  
553 class and therefore counted twice. This explains why both the number of detected packets  $PACK_j$  (Fig. 7c and 7d) and

Formatiert: Schriftart: Kursiv

554 subsequently the  $k_{b,j}$  values (Fig. 8) are slightly higher when the AF method (instead of the AH method) is applied to the  
555 larger size classes. Counting such packets twice is not unreasonable, given that the ranges of signal responses recorded  
556 during single-grain-size flume experiments for two contiguous grain-size classes significantly overlap, even after apparent  
557 packets are filtered out (Fig. 5). Overlapping class boundaries therefore result in a less strict classification of the few packets  
558 that are on the edges of the grain-size classes. In Fig. 7b, out of 2256 packets recorded by G2 (blue), 144 packets have been  
559 counted twice. But interestingly, this is not true of any of the 153 packets recorded by G1 (red) within the class boundaries.  
560 A further result supports the use of the two-dimensional size class thresholds. When applying the AF method, the  $k_{b,j}$   
561 coefficients obtained for the different sites (Fig. 8b) reach a maximum value at the third smallest size class. A similar yet  
562 stronger decrease towards the two smallest classes was described by Wyss et al. (2016b) and was related to the reduced  
563 detectability of the smallest particle sizes.

564 Through the reduced area covered by the new amplitude-frequency thresholds in Fig. 7b, a certain percentage of all the  
565 packets recorded during the field calibration experiments is neglected for general calibration: 55% at the Albula site, 63% at  
566 Navisence, 58% at Avançon de Nant and only 9% at Erlenbach. This suggests that the plates embedded at Erlenbach pick up  
567 less noise from their surroundings. A similar trend was observed by Nicollier et al. (2021b, 2022) when comparing the  
568 maximum amplitude registered by two adjacent plates for a given impact at the same location. This difference in noise  
569 detection levels is possibly accentuated by the number of impacted plates during bedload transport events. The SPG array  
570 embedded in the artificial U-shaped channel of the Erlenbach has the particularity that only 2 out of its 12 plates are usually  
571 impacted by bedload particles during floods (and only sediment crossing these two plates is caught by the automatic basket  
572 sampler). At the other sites, in contrast, while at the other stations ~~at every~~ 10 to 30 embedded plates are submerged by the  
573 flow and thus can potentially be impacted.

#### 574 4.3 Sampling uncertainties

575 Even though the AF method improved the overall accuracy of flux estimates for most classes (Table 5), some trends  
576 addressed in Sect. 3 suggest that factors other than the noise level also control the accuracy of the estimates. The dataset  
577 presented in this study includes 308 calibration measurements and is in our knowledge the largest dataset gathered for any  
578 impact plate system. Still, it appears that the number of collected samples is not sufficient to accurately assess the  
579 performance of the two methods for the three largest particle-size classes (Fig. 9; Table 5). This is mainly due ~~This is mainly~~  
580 relates to a higher proportion of large particles as compared to finer ones in typical sediment mixtures ~~due to the fact that in~~  
581 typical sediment mixtures, large particles are rarer than fine particles (Rickenmann et al., 2014; Mao et al., 2016). Earlier  
582 investigations have shown that a larger number of detected bedload particles reduces the scatter of total mass estimates by  
583 averaging over stochastic factors such as the impact location on a given impact plate, the particle transport mode (sliding,  
584 rolling, saltating, etc.; Chen et al., 2022), and the impact velocity (Rickenmann and McArdell, 2008; Turowski et al., 2013).  
585 A further uncertainty arises because these larger particles are transported at higher bed shear stresses (Einstein, 1950;  
586 Wilcock and Crowe, 2003), which also mobilize more total material and thus pose a serious challenge regarding the  
587 sampling efficiency of the calibration bedload samplers. Bunte and Abt (2005) and Bunte et al. (2019) have demonstrated  
588 that reducing the sampling duration with a bedload trap from 60 to 2 minutes decreases both the sampled unit total bedload  
589 flux  $q_{b,tot}$  and the sampled maximum particle size  $D_{max}$  by about half. In the present study, total bedload fluxes up to  $4 \text{ kg m}^{-1}$   
590  $\text{s}^{-1}$  were measured with the net sampler, meaning that the measurement duration had to be minimized to avoid overloading  
591 the sampler. At the Albula stream, for instance, only four samples contained particles of the largest class, and all four were  
592 sampled over a duration ranging from 1 to 2 minutes. As a comparison, the longest sampling duration was reached at the  
593 Navisence site and lasted 25 minutes. All this suggests that an optimal calibration of the SPG system requires balancing the

Formatiert: Abstand Nach: 0 Pt.

594 sampling duration and the number of collected particles. Note that uncertainties in the direct measurements do affect the  
595 accuracy of fractional sediment flux and grain-size estimates. Flume experiments could potentially be used to assess the  
596 sampling efficiency of the various calibration sampling methods, along with the detection efficiency of the SPG system.

#### 597 4.4 Transport rate

598 Two further trends are evident in the unit fractional flux estimates obtained for the seven smallest classes, for which most  
599 samples were detected ( $N_{\text{samples,est}} / N_{\text{samples,meas}} > 96\%$ ; Table 5). First, the relative scatter (on the log-log plots) of the  
600 fractional flux estimates around the power-law regression lines in Fig. 9 is smaller at higher transport rates. Second, both  
601 total and fractional fluxes are generally overestimated at low transport rates and underestimated at high transport rates (Fig. 9  
602 and 10), ~~which also correspond to the largest calibration samples.~~ These findings agree with results from previous calibration  
603 campaigns with the SPG system (Rickenmann and Fritschi, 2017; Rickenmann et al., 2018), but a comprehensive  
604 explanation for these trends is still missing. The following hypotheses can be ~~put forward~~ raised to explain the relationship  
605 between the mass flux estimates and the transport rate  $q_b$ : (i) The SPG system may suffer from signal saturation when the  
606 transport rate is too high, as has been document in the Japanese pipe microphone system (Mizuyama et al., 2011; Choi,  
607 2020). In our SPG data, we have observed long packets containing multiple large peaks corresponding to several impacts  
608 occurring so quickly after one another that they were not detected as separate packets. One can expect that the probability of  
609 occurrence of such packets increases together with the transport rate, with the transport of large particles (which typically  
610 generate packets of longer durations), and with the occurrence of sliding and rolling particles (Chen et al., 2022<sup>+</sup>). The long  
611 packets ~~take the place of~~ obscure the multiple shorter packets that would otherwise be individually counted, ~~thus, they~~  
612 leading to underestimated mass fluxes for a given  $k_{b,j}$  value. The development of a procedure to identify such packets and  
613 attribute the therein contained peaks to individual impacts could represent an interesting aim for future research. (ii) Field  
614 observations of bedload sheets being transported over plates at high transport rates were made at the Vallon de Nant site. In  
615 the presence of bedload sheets, one can expect that the detection rate of transported particles is hampered by multiple particle  
616 layers (Rickenmann et al. 1997; Turowski and Rickenmann, 2009), kinetic sieving (e.g. Frey and Church, 2011) or  
617 percolation processes (e.g. Recking et al., 2009). As such, it would be reasonable to expect a stronger signal response at  
618 lower transport rates (Fig. 10).

619 We are not able to give a clear explanation for the overestimates of the characteristic grain size  $D_x$  for finer grain  
620 mixtures and underestimates for coarser grain mixtures (as shown in Fig. 11). A similar trend was also observed by  
621 Rickenmann et al. (2018) for calibration measurements originating from the Erlenbach. We ~~speculate~~ expect that the  
622 decrease of the detection rate along with increasing transport intensity, as mentioned above, may partly explain this  
623 phenomenon.

#### 624 4.5 Effect of the flow velocity

625 A recurrent feature in the results presented above is an offset between the estimates obtained for the Erlenbach and those  
626 obtained for the three other stations. A similar offset was observed earlier for linear calibration relations ~~for~~ of total bedload  
627 mass between the Erlenbach and other field sites with more natural approach flow conditions (Rickenmann et al., 2014).  
628 Although applying the new amplitude-frequency method has reduced the offset in the present study significantly, it remains  
629 visible for both fractional and total bedload flux estimates (Fig. 9, 10, and 12). At the Erlenbach site, the last 35 meters  
630 upstream of the SPG system consist of an artificial bed with a steep channel slope of 16%, ~~consisting~~ made of large flat  
631 embedded boulders (Roth et al., 2016). This explains the supercritical flow regime with a Froude number around 5.1 (Wyss

632 et al., 2016c) and a flow velocity  $V_f$  around  $5 \text{ m s}^{-1}$  at the check dam with the geophone sensors (Table S1). Bedload particle  
633 velocity  $V_p$  was introduced by Wyss et al. (2016b,c) as a possible governing parameter affecting the number of particles  
634 detected by the SPG system, fast moving particles being less likely to collide against the Swiss plate geophone than slower  
635 moving ones, which are more frequently in contact with the bed. For the present study, we used  $V_f$  as a proxy for  $V_p$ , even  
636 though bedload particles generally travel more slowly than the fluid ~~that surrounds~~surrounding them (Ancey et al., 2008;  
637 Chatanantavet et al., 2013; Auel et al., 2017). Past flume experiments (Wyss et al., ~~2016a~~2016b; Kuhnle et al., 2017) have  
638 shown that the calibration coefficient  $k_{b,j}$  can vary with the flow velocity  $V_f$ , such that a three-fold increase in  $V_f$  can lead to a  
639 two-fold decrease of  $k_{b,j}$ . The better detectability of particles that one could expect from the higher impact energy (Wyss et  
640 al. 2016b) seems to be insufficient to compensate for the strong reduction of the number of impacts on a plate as flow  
641 velocity increases. This possibly arises from the fact that larger flow velocities (without increased turbulence) may also lead  
642 to flatter saltation trajectories, thus decreasing the vertical component of the impact force. Furthermore, bed morphology,  
643 bed roughness and flow velocity play important roles in determining particle transport mode, i.e., sliding, rolling, or saltating  
644 (e.g. Bagnold, 1973; Lajeunesse et al., 2010). Although high flow velocities generally favor the saltating mode (Ancey et al.,  
645 2002; Chen et al., 2022), the shallow flow depths measured at the Erlenbach (in average ~~40-0.1~~em; Wyss et al. 2016b) may  
646 limit the hop height of larger particles (Amir et al., 2017). Considering all these aspects, we hypothesize that the generally  
647 underestimated transport rates observed for the Erlenbach site mainly arise from the exceptionally high flow velocity,  
648 shallow water depths and the related transport mode (Fig. 12). Continuous streamflow velocity measurements are lacking at  
649 the Albul and Navisence sites, hampering a more detailed analysis of the ~~if~~ relationships between flow velocities and  
650 detection rates. Another improvable aspect is the low variability between the site-specific calibration relationships of the  
651 three natural sites already before the implementation the AF method (Fig. 8a). It would have been interesting to test the  
652 method on a larger number (and variety) of sites. Unfortunately, these four chosen sites are currently the only ones at which  
653 a full geophone signal has been recorded during calibration measurements.

654

655 **Figure 12:** Ratio  $r_{q_{b,tot}}$  between the estimated and the measured unit total mass flux as a function of the mean flow velocity  $V_f$ , for  
 656 each collected sample and each station, for the AH method (a) and the AF method (b). The indicated flow velocity corresponds to  
 657 in situ measurements ~~made-performed~~ during (or close in time to) the corresponding calibration measurement. ~~For better~~  
 658 ~~readability, a random scatter ranging from  $0.2 m \cdot s^{-1}$  to  $0.2 m \cdot s^{-1}$  was added to~~ Due to the stable flow velocity of  $5 m \cdot s^{-1}$  measured at  
 659 the Erlenbach site, ~~the range of  $r_{q_{b,tot}}$  values is represented as a boxplot. The yellow circles correspond to outliers.~~

660 **4.6 K-fold cross-validation**

661 In a last stage, we tested the robustness of the AH and AF methods by splitting the dataset into calibration and validation  
 662 ~~datasubsets~~. ~~Given that~~Because the number of calibration measurements is relatively small and varies between stations, we  
 663 applied a 4-fold cross-validation technique (e.g. Khosravi et al., 2020). The field calibration measurements were distributed  
 664 over four folds, each containing an equal number of calibration measurements from each site (Supporting Information Fig.  
 665 S4). One after another, the folds were used as validation datasets while the remaining three folds were used for calibration.  
 666 General calibration coefficients  $k_{b,j,gen}$  were obtained from the calibration dataset and subsequently applied to the validation  
 667 data to derive flux estimates. Even though each fold contains a total of only 48 samples (12 per site), the results obtained  
 668 with the 4-fold cross-validation procedure support our conclusion that including frequency information in the packet  
 669 classification procedure improves the mean accuracy of the estimates over all sites, in particular for the smaller five to six  
 670 size classes  $j$  (Supporting Information Table S10). Nicollier et al. (2021+2022) found ~~that the true size of particles generating~~  
 671 ~~apparent packets is mostly underestimated~~that most apparent packets are detected as belonging to smaller size classes than  
 672 ~~the particles that caused them~~, due to the attenuation of the vibrations as they propagate (see Fig. 7). It is therefore  
 673 reasonable that the AF method mainly improves the flux estimates for these smaller classes.

674 **5 Conclusion**

675 The Swiss plate geophone (SPG) is a bedload surrogate monitoring system that has been installed in several gravel-bed  
676 streams and was calibrated using direct sampling techniques. While most site-specific calibration relationships for total mass  
677 flux are robust across ~~several~~multiple orders of magnitude, the mean calibration coefficients can still vary by about a factor  
678 of six between different sites. In this study, we derived a general procedure to convert SPG signals into fractional bedload  
679 fluxes using an extensive dataset comprising ~~controlled~~ flume experiments as well as 308 field calibration measurements  
680 from four field sites. The proposed hybrid approach is based on previous findings (Antoniazza et al., 2020; Nicollier et al.,  
681 ~~2021b~~2022) that the SPG system is biased by elastic waves that propagate through the apparatus and generate noise in the  
682 form of spurious “apparent” packets. We introduced the amplitude-frequency (AF) method as an alternative to the  
683 amplitude-histogram (AH) method developed by Wyss et al. (2016a). Packets recorded during single-grain-size flume  
684 experiments were first filtered to exclude apparent packets, and then used to derive grain-size class thresholds for packet  
685 classification. We found that filtering out apparent packets results in more consistent relationships between particle diameter  
686 and amplitude-frequency characteristics of the SPG signal. Furthermore, we showed that including frequency information in  
687 size class thresholds helps in excluding apparent packets and thus improves the signal-to-noise ratio. In a second stage, we  
688 applied these flume-based thresholds to field calibration measurements and derived general calibration coefficients  
689 applicable at all four sites for ten different grain-size fractions. The AH method, by contrast, requires site-specific calibration  
690 because it cannot account for the site-to-site differences in the abundance of apparent packets. Averaged over the ten grain-  
691 size fractions, the bedload masses of 69% and 96% of the samples ~~were~~was estimated within an offset of a factor of two and  
692 five, respectively, relative to the measured sampled masses. The remaining discrepancies between the site-specific results are  
693 mainly attributed to large differences in flow (and probably particle) velocity. Finally, the sampled mass, the transport rate  
694 and the sampling efficiency were identified as further factors possibly influencing the accuracy of mass flux and grain-size  
695 estimates.

696 The presented results are highly encouraging regarding future applications of surrogate monitoring methods to  
697 investigate bedload transport processes. The findings also underline the valuable contribution of flume experiments to our  
698 understanding of the relationship between bedload transport and the recorded SPG signal. But above all, this study highlights  
699 the requirements for obtaining calibrations that are transferable across sites: accurate and numerous direct sampling  
700 measurements with long sampling durations and large sampled masses, sensors insulated from surrounding noise sources,  
701 and highly resolved temporal information about the stream flow, to identify and account for variations in the transport  
702 conditions.

703 **Notation**

704	$a_c$	Linear coefficient of the criterion
705	$A_{FFT}$	Fourier amplitude
706	$A_{m,j}$	Mean amplitude registered for particle-size class $j$
707	$b_c$	Linear coefficient of the criterion
708	$\Delta t_i$	Sampling duration
709	$D_{m,j}$	Mean particle diameter for particle-size class $j$
710	$D_{sieve,j}$	Lower sieve size retaining particle class $j$
711	$D_x$	Characteristic grain size
712	$f_{centroid}$	Centroid frequency

713	$i$	Sample index
714	$j$	Particle-size class index
715	$k_{b,i,j}$	Sample- and class-specific calibration coefficient
716	$k_{b,j,med,station}$	Median calibration coefficient for particle-size class $j$ and a given station
717	$k_{b,j,gen}$	General calibration coefficient for particle-size class $j$
718	$M_{est,i,j}$	Estimated fractional mass per sample and per class
719	$M_{meas,i,j}$	Sampled fractional mass per sample and per class
720	$MaxAmp_{env}$	Maximum registered amplitude within a packet
721	$N_{samples,est}$	Number of detected samples
722	$N_{stations}$	Number of stations
723	$PACK_{i,j}$	Number of recorded packets per sample and per class
724	$p_{factor,x}$	Percentage of all detected samples for which the estimated and the measured values differ from each other by less than a factor of $x$
725		
726	$q_{b,est,i,j}$	Estimated unit fractional transport rate per sample and per class
727	$q_{b,meas,i,j}$	Measured unit fractional transport rate per sample and per class
728	$q_{b,tot,est,i}$	Estimated unit total bedload flux per sample
729	$q_{b,tot,meas,i}$	Measured unit total bedload flux per sample
730	$R^2$	Coefficient of determination
731	$r$	Correlation coefficient
732	$r_x$	Ratio between estimated and measured values $x$
733	$th_{ah,j}$	Amplitude-histogram thresholds
734	$th_{af,low,j}$	Lower amplitude-frequency thresholds
735	$th_{af,up,j}$	Upper amplitude-frequency thresholds
736	$V_f$	Mean flow velocity
737	$w_p$	Standard width of an impact plate

#### 738 Data availability

739 The dataset presented in this paper is available online on the EnviDat repository  
740 <https://www.envidat.ch/#/metadata/sediment-transport-observations-in-swiss-mountain-streams>.

#### 741 Author contribution

742 Tobias Nicollier designed and carried out the field and flume experiments, developed the presented workflow and prepared  
743 the manuscript with contributions from all co-authors. Gilles Antoniazza designed and carried out the field experiments at  
744 the Vallon de Nant site. Lorenz Ammann helped developing the methodology and contributed to the formal analysis. Dieter  
745 Rickenmann contributed to the conceptualization and the supervision of the presented work, contributed to the design of the  
746 methodology, and provided support during the field and flume experiments. James W. Kirchner contributed to the  
747 development of the methodology and significantly contributed to the preparation of the initial draft.

748 **Acknowledgements**

749 This study was supported by Swiss National Science Foundation (SNSF) grant 200021L\_172606, and by Deutsche  
750 Forschungsgemeinschaft (DFG) grant RU 1546/7-1. The authors are grateful to Arnd Hartlieb, to the students of the TU  
751 Munich, and to the technical staff of the Oskar von Miller Institute for helping to set up and perform the flume experiments.  
752 They also warmly thank Norina Andres, Mehdi Mattou, Nicolas Steeb, Florian Schläfli, Konrad Eppel and Jonas von  
753 Wartburg for their efforts and motivation during the field calibration campaigns. Special thanks go to [Stefan Boss for his](#)  
754 [support with the measurement systems at all sites, and to](#) Andreas Schmucki, who never gave up repairing the net sampler.  
755 Alexandre Badoux is further thanked for his valuable suggestions regarding an earlier version of the manuscript.

756 **Competing interests**

757 The authors declare that they have no conflict of interest.
