Abstract. Substantial uncertainties in bedload transport predictions in steep streams have encouraged intensive efforts towards the development of surrogate monitoring technologies. One such system, the Swiss plate geophone (SPG), has been deployed and calibrated in numerous steep channels, mainly in the Alps. Calibration relationships linking the signal recorded by the SPG system to the intensity and characteristics of transported bedload can vary substantially between different monitoring stations, likely due to site-specific factors such as flow velocity and bed roughness. Furthermore, recent flume experiments on the SPG system have shown that site-specific calibration relationships can be biased by elastic waves resulting from impacts occurring outside of the plate boundaries. Motivated by these findings, we present a hybrid calibration procedure derived from flume experiments and an extensive dataset of 308 direct field measurements at four different SPG monitoring stations. Our main goal is to investigate the feasibility of a general, site-independent calibration procedure for inferring fractional bedload transport from the SPG signal. First, we use flume experiments to show that sediment size classes can be distinguished more accurately using a combination of vibrational frequency and amplitude information than by using amplitude information alone. Second, we apply this amplitude-frequency method to field measurements to derive general calibration coefficients for ten different grain-size fractions. The amplitude-frequency method results in more homogeneous signal responses across all sites and significantly improves the accuracy of fractional sediment flux and grain-size estimates. We attribute the remaining site-to-site discrepancies to large differences in flow velocity and discuss further factors that may influence the accuracy of these bedload estimates.

1 Introduction

Flood events across Europe in the summer of 2021 have illustrated the threat of bedload transport-related hazards to human life and infrastructure, especially in small and steep mountainous catchments (Badoux et al., 2014; Blöschl et al., 2020). Understanding sediment transport processes is also essential for efforts to return rivers to their near-natural state by restoring their continuity and re-establishing balanced sediment budgets (e.g. Brouwer and Sheremet, 2017; Pauli et al., 2018; Logar et al., 2019; Rachely et al., 2021). However, monitoring and predicting bedload transport still represents a considerable challenge because of its large spatio-temporal variability (e.g. Mühlhofer, 1933; Einstein, 1937; Reid et al., 1985; Rickenmann, 2017; Ancy, 2020). This is especially true for steep streams, because they are poorly described by traditional

38 bedload transport equations, which have mainly been developed for lower-gradient channels (e.g. Schneider et al., 2016).
39 Predicting sediment transport in steep channels is challenging, notably due to the presence of macro-roughness elements
40 affecting the flow energy (e.g. Manga and Kirchner, 2000; Yager et al., 2007, 2012; Bathurst, 2007; Nitsche et al., 2011;
41 Rickenmann and Recking, 2011; Prancevic and Lamb, 2015). It is further complicated by a sediment supply that varies in
42 both space and time, due in part to cycles of building and breaking of an armoring layer at the riverbed (e.g. Church et al.,
43 1998; Dhont and Ancey, 2018; Rickenmann, 2020; Piantini et al., 2021).

44 Bedload transport equations established for lower-gradient streams typically result in errors spanning multiple orders of
45 magnitude when applied to steep streams, motivating the development of new indirect monitoring techniques for steep
46 mountain channels (e.g. Gray et al., 2010; Rickenmann, 2017). Indirect monitoring techniques provide complete coverage of
47 selected river transects at high temporal resolution, reduce personal risk related to in-stream sampling, and enable consistent
48 data collection at widely varying flow conditions, including during flooding events (e.g. Gray et al., 2010; Rickenmann,
49 2017; Geay et al., 2020; Bakker et al., 2020; Choi et al., 2020; Le Guern et al., 2021). The drawback of these monitoring
50 technologies with regards to absolute bedload transport estimates lies in their need for intensive calibration through direct
51 bedload sampling with retention basins (Rickenmann and McArdeU, 2008), slot samplers (e.g. Habersack et al., 2017; Halfi
52 et al., 2020) or mobile bag samplers (e.g. Bunte et al., 2004; Dell'Agnese et al., 2014; Hilldale et al., 2015; Mao et al., 2016;
53 Kreisler et al., 2017; Nicollier et al., 2021).

54 Among indirect monitoring techniques, the Swiss plate geophone (SPG) system has been deployed and tested in more
55 than 20 steep gravel-bed streams and rivers, mostly in the European Alps (Rickenmann, 2017). Typically, linear or power-
56 law calibration relationships have been developed between measured signal properties and bedload transport characteristics
57 (Rickenmann et al., 2014; Wyss et al. 2016a; Kreisler et al., 2017; Kuhnle et al., 2017). Such calibration equations permit
58 absolute quantification of bedload fluxes (e.g. Dell'Agnese et al., 2014; Rickenmann et al., 2014; Hilldale et al., 2015; Halfi
59 et al., 2020; Nicollier et al., 2021), their variability in time and space (i.e. across a river section; e.g. Habersack et al., 2017;
60 Rickenmann, 2020; Antoniazza et al., 2022), estimates of bedload grain-size distribution (e.g. Mao et al., 2016; Barrière et
61 al., 2015; Rickenmann et al., 2018), and the detection of the start and end of bedload transport (e.g. Turowski et al., 2011;
62 Rickenmann, 2020). However, these equations require a calibration procedure against independent bedload transport
63 measurements at each individual field site, because until now we have lacked generally applicable signal-to-bedload
64 calibration equations that are valid across field settings. Although similarities between calibration relationships at various
65 field sites are encouraging, it is not well understood why the linear calibration coefficients for total mass flux can vary by
66 about a factor of 20 among individual samples from different sites, or by about a factor of six among the mean values from
67 different sites (Rickenmann et al., 2014; Rickenmann and Fritschi, 2017). Given the substantial field effort required for
68 calibration campaigns, a generally applicable calibration equation would represent a significant advance.

69 Numerous studies have reported successful calibration of impact plate systems in laboratory flumes (e.g. Bogen and
70 Møen, 2003; Krein et al., 2008; Tsakiris et al., 2014; Mao et al., 2016; Wyss et al., 2016b,c; Kuhnle et al., 2017; Chen et al.,
71 2022), although transferring these flume-based calibrations to the field remains challenging. Nonetheless, flume experiments
72 are valuable because they allow to systematically explore relationships between the recorded signal, the transport rates of
73 different sediment size fractions, and the hydraulic conditions. For example, the experiments of Wyss et al. (2016b) showed
74 that higher flow velocities induce a weaker SPG signal response per unit of transported sediment. More recent flume
75 experiments have highlighted another important site-dependent factor influencing the SPG signal response, namely the
76 grain-size distribution (GSD) of the transported bedload (Nicollier et al., 2021), where coarser grain mixtures were shown to
77 yield a stronger signal response per unit bedload weight.

78 Subsequent impact tests and flume experiments showed that this grain-size dependence arises because the impacts
79 plates are insufficiently isolated from their surroundings (Antoniazza et al., 2020; Nicollier et al., 2022). The elastic wave

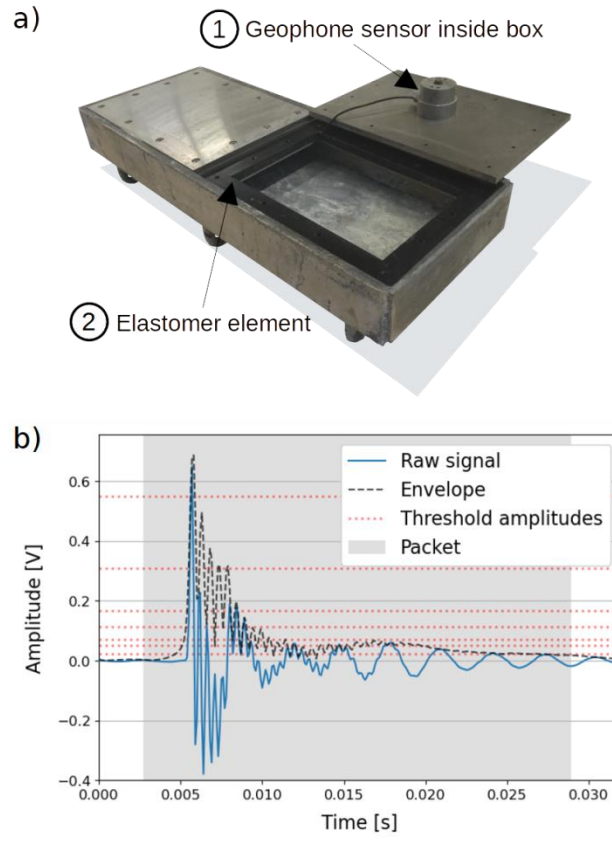

80 generated by an impact on or near a plate was found to propagate over several plate lengths, contaminating the signals
81 recorded by neighboring sensors within a multiple plate array. Nicollier et al. (2022) introduced the notion of “apparent
82 packets” (in opposition to “real” packets) to define the portions of the recorded signal that were generated by such
83 extraneous particle impacts.

84 The main goal of this contribution is to examine the feasibility of a general, site-independent signal conversion
85 procedure for fractional bedload flux estimates. We follow a comprehensive hybrid signal conversion approach that
86 encompasses a set of full-scale flume experiments conducted at an outdoor facility, as well as 308 field calibration
87 measurements performed with direct sampling methods at four different bedload monitoring stations in Switzerland between
88 2009 and 2020. We present the amplitude-frequency (AF) method, aiming to reduce the bias introduced by apparent packets
89 in the relationship between the signal characteristics and the particle size. Finally, we compare the performance of this novel
90 AF method against the amplitude-histogram (AH) method developed by Wyss et al. (2016a) for both fractional and total
91 bedload flux estimates.

92 **2 Methods**

93 **2.1 The SPG system**

94 The Swiss plate geophone (SPG) consists of a geophone sensor fixed under a steel plate of standard dimensions 492 mm x
95 358 mm x 15 mm (Fig. 1a; Rickenmann, 2017). The geophone (GS-20DX by Geospace technologies; www.geospace.com)
96 uses a magnet moving inside an inertial coil (floating on springs) as an inductive element. The voltage induced by the
97 moving magnet is directly proportional to its vertical velocity resulting from particle impacts on the plate. The SPG system
98 can detect bedload particles with a minimum diameter of 10 mm (Rickenmann et al., 2014, 2020; Wyss et al., 2016a).
99 Typically, a SPG array includes several plates mounted side-by-side, acoustically isolated by elastomer elements and
100 covering the river cross-section. The array is either embedded in a concrete sill or fixed at the downstream face of a check
101 dam. A detailed description of the SPG system can be found in Rickenmann et al. (2014). For all the calibration
102 measurements and flume experiments analyzed in this study, ranging in duration from a few seconds to one hour, the raw 10
103 kHz geophone signal was recorded (Fig. 1b).

Figure 1: (a) Swiss plate geophone (SPG) system before installation. Each plate is equipped with a uniaxial geophone sensor fixed in a watertight aluminum box (1) attached to the underside of the plate. The plates are acoustically isolated from each other by elastomer elements (2). (b) Example of a packet (grey area) detected by the SPG system. A packet begins 20 time steps (i.e. 2 ms) before the signal envelope crosses the lowest amplitude threshold of 0.0216 V and ends 20 time steps after the last crossing of the lowest amplitude threshold (see Sect. 2.4).

111 2.2 Field calibration measurements

112 To test the AF and AH methods, this study uses 308 field measurements from four Swiss bedload monitoring stations
 113 equipped with the SPG system (Fig. 2; Table 1). Field calibration samples were collected at the Albula, Navisence and
 114 Avançon de Nant stations, and extensive calibration efforts have been undertaken at the fourth field station, the Erlenbach,
 115 since 2009 (Rickenmann et al., 2012). The Erlenbach offers an interesting comparison with the other sites due to different
 116 channel morphology and flow characteristics upstream of the SPG plates. Field calibrations at the four sites consisted in the
 117 following steps: (i) direct bedload sampling downstream of an impact plate using either crane-mounted net samplers adapted
 118 from Bunte traps (Bunte et al., 2004; Dell’Agnese et al., 2014; Nicollier et al., 2019; Fig. 2a, b), automated basket samplers
 119 (Rickenmann et al., 2012; Fig. 2d) or manual basket samplers (Fig. 2c; Antoniazza et al., 2022), (ii) synchronous recording
 120 of the raw geophone signal, (iii) sieving and weighing of bedload samples using ten sieve classes (see Sect. 2.4), and (iv)
 121 comparing the fractional bedload mass of each sample to the geophone signal to derive the corresponding calibration
 122 coefficients. A more detailed description of the sampling procedure is reported in Supporting Information S1, including the
 123 mesh sizes used for bedload sampling. For the analysis, only particles larger than 9.5 mm were considered, being close to the
 124 SPG detection threshold. Streamflow information was derived from various stage sensors (Table 1). Flow velocity V_w was
 125 introduced by Wyss et al. (2016c) as a possible governing parameter affecting the number of particles detected by the SPG

126 system. Unfortunately, due to the lack of continuous streamflow measurements at the Albula and Navisence sites, we were
 127 not able to account for the effect of the flow velocity in the signal conversion procedure described in the present study.

144 2.3 Flume experiments

145 The first part of the signal conversion procedure described in this study is based on flume experiments conducted at the
146 outdoor flume facility of the Oskar von Miller institute of TU Munich in Obernach, Germany. There, we reconstructed the
147 bed slope and bed roughness of the Albula, Navisence and Avançon de Nant field sites, one after another, in a flume test
148 reach with dimensions of 24 m x 1 m equipped with two impact plates at the downstream end of a paved section (Fig. 3). For
149 each site reconstruction, we tested bedload material collected during field calibration measurements, and we adjusted the
150 flow velocity, flow depth, and bed roughness (D_{67} and D_{84}) to match the respective field observations. A detailed description
151 of the original flume setup and the performed experiments can be found in Nicollier et al. (2020). In the present study, we
152 primarily use a set of experiments conducted in 2018 with the flume configured to match conditions at the Albula field site
153 (Table 2). These experiments were single-grain-size experiments and consisted of feeding the flume with a fixed number of
154 grains for each of the ten particle-size classes described in Sect. 2.4 below. Two different feeding systems were used, namely
155 a vertical pipe and a tiltable basket (for particles larger than 31.4 mm). While these particles were transported over the SPG
156 system, the full raw geophone signal was recorded. The experiment duration ranged from 15 seconds for the smallest
157 particles to around 1 min for the largest particles. Up to 33 repetitions were conducted until a representative range of
158 amplitude and frequency values for each grain-size class was obtained (Nicollier et al., 2021). The same procedure was
159 repeated for two different flow velocities ($V_f = 1.6 \text{ m s}^{-1}$ and 2.4 m s^{-1}). The obtained information was then used to derive
160 empirical relationships between the mean particle size $D_{m,j}$ for a given grain-size class j and properties of the SPG signal, as
161 described in Sect. 2.5.2 below.

162 To illustrate the AF and AH methods and their respective performance, we use a second set of flume experiments,
163 which mimics the Avançon de Nant field site. The main difference to other experimental setups is the presence of a 4 m
164 wooden partition wall along the center of the flume (Fig. 3) that shields one geophone plate from impacting particles
165 (Nicollier et al., 2022). This special setup facilitates the characterization of the signal propagated from an impacted plate to
166 the neighboring non-impacted plate. With this modified setup, single-grain-size experiments were run ($n = 51$; Table 2)
167 using grains from each of the 10 particle-size classes and bedload material sampled at the Avançon de Nant field site. The
168 flow velocity was set to 3 m s^{-1} to facilitate particle transport through the narrower flume section and is therefore not
169 representative of the Avançon de Nant site, where typical flow velocities were roughly 1.3 m s^{-1} .

170
 171 **Figure 3: Oblique view of the Obernach flume test reach with total length of 24 m and width of 1 m. The bed surface is paved with**
 172 **particles with diameters equaling the characteristic D_{67} and D_{84} sizes of the natural beds of the reconstructed sites. Grains were**
 173 **fed into the channel 8 m upstream from the SPG system location (G1 and G2) using either a vertical feed pipe or a tiltable basket**
 174 **(1). The sensor plate G1 (in red) was shielded from direct particle impacts by the 4 m long partition wall (2). The partition wall**
 175 **and the impact plates were decoupled from each other by a 2 mm vertical gap to prevent disturbances of the recorded signal.**
 176 **Plexiglas walls (3) on each side of the flume facilitated video recordings of the experiments.**

177
 178 **Table 2: Flume and hydraulic characteristics for the reconstruction of the Albula and the Avançon de Nant field sites.**

Parameter	Units	Reconstructed field site setup	
		Albula (without partition wall)	Avaçon de Nant (with partition wall)
Flume width	m	1.02	1.02
Flume gradient of the natural bed	%	0.7	4.0
Bed surface D_{67} ^a	mm	120	200
Bed surface D_{84} ^a	mm	190	320
Number of D_{67} -particles/m ²	m ⁻²	15.0	5.0
Number of D_{84} -particles/m ²	m ⁻²	5.0	2.5
Min. water depth above SPG	m	0.79	0.35
Max. water depth above SPG	m	0.91	0.35
Min. flow velocity 10 cm above SPG ^b	m s ⁻¹	1.6	3.0
Max. flow velocity 10 cm above SPG ^b	m s ⁻¹	2.4	3.0
Min. unit discharge	m ² s ⁻¹	1.6	0.8
Max. unit discharge	m ² s ⁻¹	2.4	0.8
Number of different flow velocity settings	-	2	1
Total number of single-grain-size experiments	-	355	51
Total number of tested particles	-	10705	2485

 180 software (Detert and Weitbrecht, 2013).

181 ^b Flow velocities measured with the OTT MF Pro magnetic-inductive flow meter.

182 2.4 The amplitude-histogram method

183 Wyss et al. (2016a) introduced the packet-based amplitude-histogram (AH) method to derive grain-size information from
 184 geophone signals. A packet is defined as a brief interval, typically lasting 5 to 30 milliseconds, reflecting a single particle
 185 impact on a plate (Fig. 1b); it begins and ends 20 time steps before and after the signal envelope crosses a threshold
 186 amplitude of 0.0216 V. The signal envelope is computed in Python with the Hilbert transform (Jones et al., 2002), yielding
 187 the magnitude of the analytic signal, i.e. the total energy. Each packet's maximum amplitude is then used to assign it to a
 188 predefined amplitude class j delimited by amplitude-histogram thresholds $th_{ah,j}$ (Table 3), yielding a packet-based amplitude
 189 histogram (e.g. Fig. 4 in Wyss et al., 2016a). Each amplitude class j is related to a corresponding grain-size class through the
 190 following relationship between the mean amplitude $A_{m,j}$ [V] and the mean particle size $D_{m,j}$ [mm]:

$$191 \quad A_{m,j} = 4.6 \cdot 10^{-4} \cdot D_{m,j}^{1.71} . \quad (1)$$

192 The coefficients in Eq. (1) were determined using 31 basket samples collected at the Erlenbach for which the maximum
 193 geophone amplitude was analyzed as a function of the b-axis of the largest particle found in the sample (Wyss et al., 2016a).
 194 The grain-size classes are delimited by the size of the meshes $D_{sieve,j}$ used to sieve the bedload samples from field
 195 calibration measurements. For a given bedload sample, it is assumed that the number of packets between two amplitude-
 196 histogram thresholds $th_{ah,j}$ is a good proxy for the fractional bedload mass between the respective sieve sizes (Wyss et al.,
 197 2016a). In the present study, we have extended the seven size classes used by Wyss et al. (2016a) to ten classes, in order to
 198 also assess the performance of the AH and AF methods for larger particles.

199
 200 **Table 3: Characteristics of the size classes j according to Wyss et al. (2016a) with the sieve mesh sizes $D_{sieve,j}$, the mean particle**
 201 **diameter $D_{m,j}$, and the amplitude-histogram thresholds $th_{ah,j}$ derived from Eq. (1). Additionally, the lower and upper amplitude-**
 202 **frequency thresholds $th_{af,low,j}$ and $th_{af,up,j}$ derived respectively from Eq. (4) and (5) are provided (see Sect. 2.5.2). The value of $D_{m,j}$**
 203 **for the largest class (10) in brackets is an estimate, because this size class is open-ended and as such, the mean varied somewhat**
 204 **from site to site.**

Class j [-]	$D_{sieve,j}$ [mm]	$D_{m,j}$ [mm]	$th_{ah,j}$ [V]	$th_{af,low,j}$ [V]	$th_{af,up,j}$ [V Hz ⁻¹]
1	9.5	12.3	0.0216	0.0132	$1.55 \cdot 10^{-5}$
2	16.0	17.4	0.0527	0.0364	$2.33 \cdot 10^{-5}$
3	19.0	21.8	0.0707	0.0509	$4.45 \cdot 10^{-5}$
4	25.0	28.1	0.1130	0.0868	$7.67 \cdot 10^{-5}$

205

206 2.5 The amplitude-frequency method

207 In a recent study, Nicollier et al. (2022) showed that the SPG system is sensitive to extraneous particle impacts despite the
 208 isolating effect of the elastomer. Extraneous signals at individual geophone plates can arise from impacts occurring on

209 neighboring plates, or from impacts on the concrete sill surrounding the SPG array. While attenuated to some extent, the
 210 elastic waves generated by such impacts can reach multiple geophone sensors with enough energy to be recorded as apparent
 211 packets. Thus, packet histograms (i.e. counts of the number of packets per class j) are subject to a certain bias, especially in
 212 the lower size classes. The degree of bias was found to depend mainly on two factors. First, coarser grain sizes of transported
 213 bedload were shown to generate more apparent packets. Second, more apparent packets were recorded, for a given bedload
 214 mass, at transects containing more SPG plates. Nicollier et al. (2022) showed that packet characteristics such as the start
 215 time, the amplitude and the frequency help in identifying apparent packets and filtering them out from the final packet
 216 histograms. This filtering method was subsequently applied to all four field calibration datasets (Albula, Navisence, Avançon
 217 de Nant and Erlenbach) and helped to reduce the differences between the site-specific mean calibration relationships for the
 218 total bedload flux by about 30% (Nicollier et al., 2022). Based on these observations, the present study proposes an
 219 amplitude-frequency (AF) method as an adaptation of the amplitude-histogram (AH) method presented by Wyss et al.
 220 (2016a). By introducing two-dimensional (amplitude and centroid frequency) size class thresholds, the new method aims to
 221 reduce the effect of apparent packets and improve the accuracy of fractional bedload flux estimates. Note that the procedure
 222 does not allow for the differentiation of multiple particles impacting one plate simultaneously, but the high recording
 223 frequency (10 kHz) of the SPG system minimizes its probability of occurrence.

224 2.5.1 Centroid frequency

225 According to the Hertz contact theory, the frequency at which a geophone plate vibrates is controlled by the size of the
 226 colliding particle (Johnson, 1985; Thorne, 1986; Bogen and Møen, 2003; Barrière et al., 2015; Rickenmann, 2017). In the
 227 present study, the frequency spectrum of a packet is characterized by the spectral centroid f_{centroid} . It represents the center of
 228 mass of the spectrum and is computed as:

$$229 \quad f_{\text{centroid}} = \frac{\sum f_n \cdot A_{\text{FFT},n}}{\sum A_{\text{FFT},n}} \quad (2)$$

230 where $A_{\text{FFT},n}$ [V·s] is the Fourier amplitude (computed with the Fast Fourier Transform FFT) corresponding to the frequency
 231 f_n [Hz]. Following Wyss et al. (2016b), before applying the FFT, each packet is preprocessed in two steps. First, a cosine
 232 taper is applied at the edges of a max. 8 ms time window around the peak amplitude of each packet. Second, the signal
 233 contained in this time window is zero-padded on either side to reach an optimal number of sample points n_{FFT} . The taper is
 234 used to smooth the transition between the packet and the concatenated zeros, and to suppress spectral leakage, which results
 235 in a more accurate amplitude spectrum. The value of n_{FFT} was set to 2^7 in order to adequately resolve the amplitude
 236 spectrum of the raw signal contained in the max. 8 ms time window. This time window focuses on the first arrival waveform
 237 to obtain a more accurate evaluation of the high-frequency content of the packet (Nicollier et al., 2022). The single-sided
 238 Fourier transform of the processed packet is then computed in order to extract A_{FFT} and derive f_{centroid} (Eq. 2). A decrease
 239 in f_{centroid} with increasing particle size was observed for different bedload surrogate monitoring techniques (Belleudy et al.,
 240 2010; Uher and Benes, 2012; Barrière et al., 2015). Furthermore, f_{centroid} has the advantage of showing weaker dependency
 241 on the flow velocity and transport mode than the maximum registered packet amplitude (Wyss et al. 2016b; Chen et al.,
 242 2022). As shown by Nicollier et al. (2022), f_{centroid} also contains information about the impact location of a packet-
 243 triggering particle. Because high frequencies are more rapidly attenuated than low frequencies along the travel path of a
 244 seismic wave, (apparent) packets triggered by impacts on a given plate typically have higher f_{centroid} values than packets
 245 triggered by impacts occurring beyond that plate's boundaries.

246 2.5.2 Flume-based amplitude-frequency thresholds

247 The particle mass associated with an individual signal packet is strongly dependent on the size of the impacting particle.
 248 Inferring sediment transport rates from SPG signals thus requires assigning each packet to a corresponding sediment size
 249 class using threshold values of packet characteristics (Table 3). Wyss et al. (2016a) derived size class thresholds (or AH
 250 thresholds) of packet peak amplitude from field measurements (Eq. 1). In the present study, we take advantage of the single-
 251 grain-size experiments conducted at the flume facility (without the partition wall) (Nicollier et al., 2021) to derive size class
 252 thresholds combining packet amplitude and frequency (or AF thresholds). Each packet is assigned to a given class j
 253 delimited by a lower threshold $th_{af,low,j}$ based on the maximum amplitude of the packet's envelope $MaxAmp_{env}$ [V], and an
 254 upper threshold $th_{af,up,j}$ based on the ratio $MaxAmp_{env}/f_{centroid}$ [V Hz⁻¹]. Compared to the raw signal, the envelope has the
 255 advantage of returning the magnitude of the analytical signal and thus better outlines the waveform by omitting the harmonic
 256 structure of the signal (Fig. 2b). Similar combinations of amplitude and frequency have been used to infer particle sizes and
 257 improve the detectability of bedload particles in previous studies involving impact plates (Tsakiris et al., 2014; Barrière et
 258 al., 2015; Wyss et al., 2016b; Koshiba and Sumi, 2018) and pipe hydrophones (Choi et al., 2020).

259 The lower and upper amplitude-frequency thresholds are obtained as follows. First, all packets recorded during the
 260 single-grain-size experiments are filtered with respect to the following criterion adapted from Nicollier et al. (2022):

$$261 \quad \text{Criterion: } f_{centroid} > a_c \cdot e^{(b_c \cdot MaxAmp_{env})}, \quad (3)$$

262 with $a_c = 1980$ Hz and $b_c = -1.58$ V⁻¹. The values of the linear coefficient a_c and the exponent b_c were obtained through an
 263 optimization process discussed below (Sect. 4.1), and were found to best separate apparent packets from real packets.
 264 Packets identified as apparent packets using this criterion are ignored in the further analysis in order to obtain more accurate
 265 threshold values. Note that in the present study, the criterion in Eq. 3 has not been applied to the data when implementing the
 266 AH method developed by Wyss et al. (2016a).

267 The next step consists in fitting a power-law least-squares regression line through the 75th percentile amplitude
 268 $MaxAmp_{env,75th,j}$ and amplitude-frequency $(MaxAmp_{env}/f_{centroid})_{75th,j}$ values of the packets detected for a given grain-
 269 size class j fed into the flume that met the filtering criterion (Fig. 4), resulting in the following two equations:

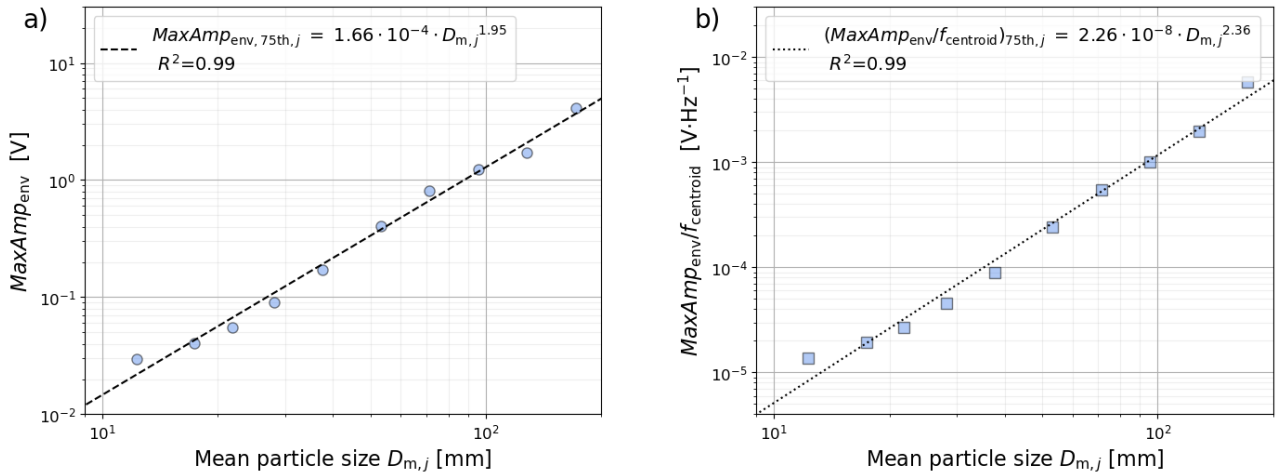

$$270 \quad MaxAmp_{env,75th,j} = 1.66 \cdot 10^{-4} \cdot D_{m,j}^{1.95}, \text{ and} \quad (4)$$

$$271 \quad \left(\frac{MaxAmp_{env}}{f_{centroid}} \right)_{75th,j} = 2.26 \cdot 10^{-8} \cdot D_{m,j}^{2.36}. \quad (5)$$

272 Finally, the lower threshold values $th_{af,low,j}$ are obtained by replacing $D_{m,j}$ in Eq. (4) with the lower sieve sizes
 273 $D_{sieve,j}$, while the upper threshold values $th_{af,up,j}$ are obtained by replacing $D_{m,j}$ in Eq. (5) with the upper sieve sizes
 274 $D_{sieve,j+1}$ (Table 3 and triangles in Fig. 5). Fitting functions such as Eq. (4) and (5) allows for the computation of thresholds
 275 for any classification of particle (sieve) sizes.

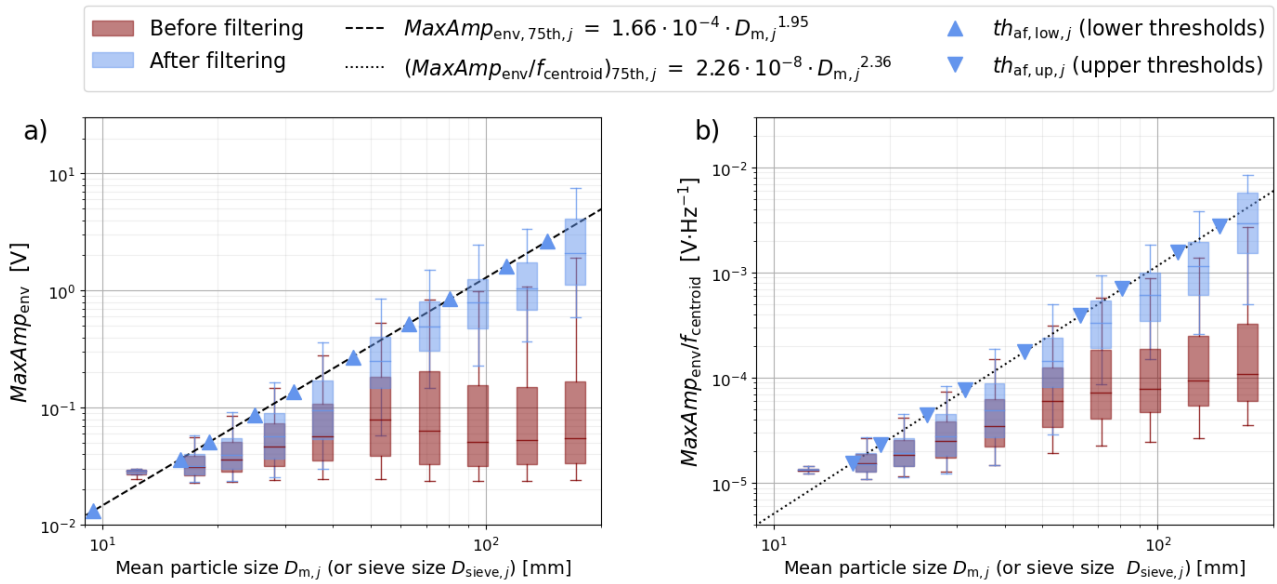

276 When considering all the packets detected for a given grain-size class, it was found that apparent packets can greatly
 277 outnumber real packets. This is particularly pronounced for the largest grain sizes, because the energy released by their
 278 impact, especially outside of the plate boundaries, is more likely to be detectable by the geophone sensors. Due to signal
 279 attenuation, however, these numerous apparent packets have relatively small amplitudes, which substantially dilutes the
 280 average signal response associated with the largest grain sizes (Fig. 5). However, filtering out apparent packets reveals a
 281 rather clear relationship, which would otherwise be obscured, between the mean particle size $D_{m,j}$ and both the amplitude

282 $MaxAmp_{env}$ and the ratio $MaxAmp_{env}/f_{centroid}$ (Fig. 5). Overall, the filtering with criterion (Eq. 3) at the Obernach flume
 283 site eliminated about 61% of all the packets.

284
 285 **Figure 4: Power-law least-squares regression relationships between the mean particle diameter $D_{m,j}$ and the 75th percentile of the**
 286 **packets' amplitude $MaxAmp_{env,75th,j}$ (a) and amplitude-frequency $(MaxAmp_{env}/f_{centroid})_{75th,j}$ (b) values obtained from the single-**
 287 **grain-size experiments after filtering out apparent packets using the filtering criterion in Eq. (3).**

288

289
 290 **Figure 5: Range of signal responses obtained for each individual grain-size class fed into the flume before (red boxes) and after**
 291 **(blue boxes) filtering out apparent packets using the filtering criterion in Eq. (3), with (a) the maximum amplitude of the envelope**
 292 **$MaxAmp_{env}$ and (b) the ratio $MaxAmp_{env}/f_{centroid}$ as functions of the mean particle diameter $D_{m,j}$. In (a), the lower threshold**
 293 **values $th_{af,low,j}$ are obtained by replacing $D_{m,j}$ with the lower sieve sizes ($D_{sieve,j}$) in the equation of the dashed power-law regression**
 294 **line (Eq. 4). In (b), the upper threshold values $th_{af,up,j}$ are obtained by replacing $D_{m,j}$ with the upper sieve sizes ($D_{sieve,j+1}$) in the**
 295 **equation of the dotted power-law regression line (Eq. 5).**

296 **2.5.3 Application to field calibration measurements**

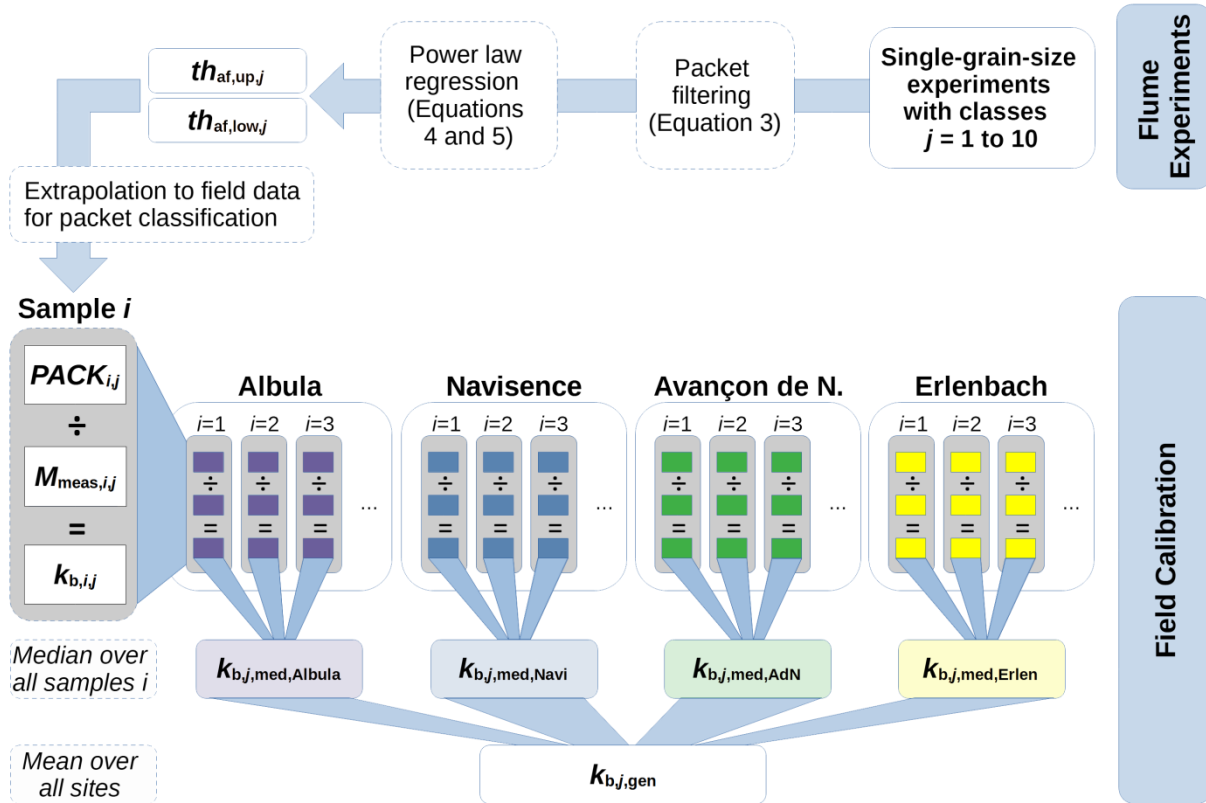

297 The lower and upper thresholds $th_{af,low,j}$ and $th_{af,up,j}$ obtained from the filtered flume experiments can be transferred to the
 298 field datasets if the SPG apparatus and the geophone data recording and preprocessing routines are identical in both cases.
 299 The following steps allow us to derive the final general calibration coefficients $k_{b,j,gen}$ (Fig. 6). First, for each field
 300 measurement i , the thresholds $th_{af,low,j}$ and $th_{af,up,j}$ are used for counting the number of packets per class j from the
 301 recorded geophone signal. Second, a sample- and class-specific calibration coefficient $k_{b,i,j}$ with units $[kg^{-1}]$ is obtained by
 302 dividing the number of recorded packets $PACK_{i,j}$ by the sampled fractional mass $M_{meas,i,j}$ as follows:

303
$$k_{b,i,j} = \frac{PACK_{i,j}}{M_{meas,i,j}}. \quad (6)$$

304 Finally, the general calibration coefficient $k_{b,j,gen}$ is computed for each class j using

305
$$k_{b,j,gen} = \frac{1}{N_{stations}} \sum_{stations} k_{b,j,med,station} , \quad (7)$$

306 where $k_{b,j,med,station}$ is the site-specific median calibration coefficient computed over all samples i , and $N_{stations}$ is the
 307 number of stations. Even though the number of calibration measurements differs from site to site, each coefficient
 308 $k_{b,j,med,station}$ in Eq. (7) is equally weighted in order to give the same importance to site-specific factors possibly affecting
 309 the signal response at each site.

310
 311 **Figure 6: Workflow leading from the single-grain-size flume experiments with particles from ten size classes j (top right) to the**
 312 **final array of general calibration coefficients $k_{b,j,gen}$. Central elements are the lower and upper threshold values $th_{af,low,j}$ and**
 313 **$th_{af,up,j}$, the number of recorded packets $PACK_{i,j}$ per sample i and class j , the sampled fractional mass $M_{meas,i,j}$, the sample- and**
 314 **class- specific calibration coefficient $k_{b,i,j}$, and finally the site-specific median calibration coefficient $k_{b,j,med,station}$. To enable a**

315 comparison with the AH method developed by Wyss et al. (2016a), the “Field Calibration” part of the workflow was also carried
 316 out with the AH thresholds $th_{ah,j}$ (see Table 3).

317 At this point, the single array of calibration coefficients $k_{b,j,gen}$ is applied as follows to each field calibration
 318 measurement i in order to obtain fractional bedload mass estimates $M_{est,i,j}$:

$$319 \quad M_{est,i,j} = k_{b,j,gen} \cdot PACK_{i,j} \quad (8)$$

320 Rickenmann and Fritschi (2017) showed that bedload mass estimates derived from SPG measurements are more accurate at
 321 higher transport rates. The estimated fractional bedload mass $M_{est,i,j}$ can be converted to a unit fractional transport rate
 322 $q_{b,est,i,j}$ [$kg\ m^{-1}\ s^{-1}$] using:

$$323 \quad q_{b,est,i,j} = \frac{1}{w_p \cdot n_p} \cdot \frac{M_{est,i,j}}{\Delta t_i} \quad (9)$$

324 where w_p is the standard width of an impact plate (0.5 m), n_p is the number of plates (which may include the whole transect,
 325 or a section of particular interest), and Δt_i is the sampling duration in seconds. Finally, the estimated unit total bedload flux
 326 $q_{b,tot,est,i}$ can be computed as follows:

$$327 \quad q_{b,tot,est,i} = \sum_{j=1}^{10} q_{b,est,i,j} \quad (10)$$

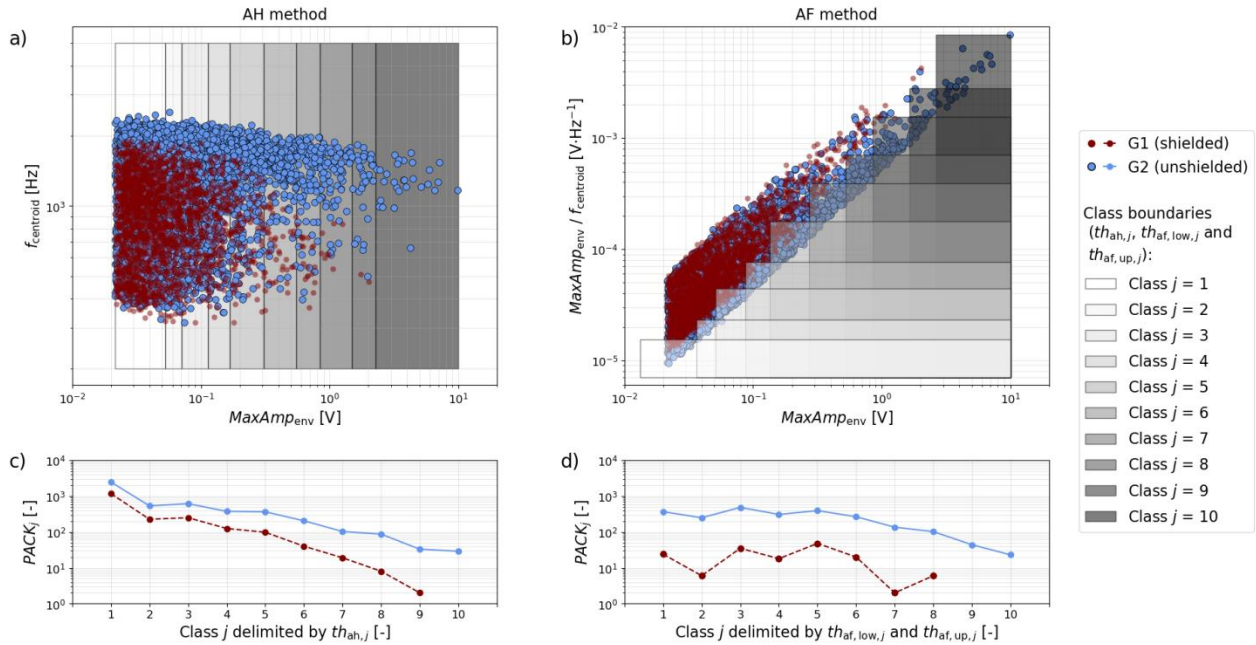

328 Note that the exact same procedure was followed using the AH thresholds $th_{ah,j}$ derived from Wyss et al. (2016a) (Eq. 1;
 329 Table 3) to compare the performance between the AH method and the new AF method.

330 3 Results

331 3.1 Flume experiments

332 The flume experiments performed in the modified Avançon de Nant setup with the partition wall help to illustrate the
 333 performance of the two calibration methods. Fig. 7a and 7b show the amplitude and frequency characteristics of all packets
 334 detected by the SPG system during these experiments. Packets detected by the shielded sensor G1 all originate from impacts
 335 that occurred either on the concrete bed or on plate G2 (Figure 3; Nicollier et al., 2022). Packets detected by the unshielded
 336 sensor G2 are considered as apparent if they are located in the area of the amplitude-frequency graph (Fig. 7a) where G1 and
 337 G2 packets overlap. Such packets are presumed to have been triggered by impacts on the concrete bed. This overlapping area
 338 arises from the fact that a seismic wave generated by an impact on the concrete bed follows a similar path towards both
 339 sensors, resulting in the recording of two apparent packets with comparable characteristics. The remaining packets, detected
 340 by G2 and located in the non-overlapping area of the amplitude-frequency graph, are considered real. The difference in
 341 $f_{centroid}$ between real and apparent packets (Fig. 7a) reflects the faster attenuation of higher frequencies during wave
 342 propagation. Size class boundaries derived by the AH method of Wyss et al. (2016a) encompass all of the packets, both
 343 apparent and real (Fig. 7a). This is because the boundaries are defined solely by AH thresholds ($th_{ah,j}$). By contrast, in the
 344 AF method proposed here, the two-dimensional class boundaries given by $th_{af,low,j}$ and $th_{af,up,j}$ cover only a fraction of all
 345 detected packets (Fig. 7b). Applying the step-like AF thresholds leads to a strong reduction of the number of packets $PACK_j$
 346 within each size class j for plate G1 (shielded), particularly for the smaller classes. Meanwhile, the AF thresholds had little
 347 effect on the number of detected packets for G2 (unshielded), except for a strong decrease for classes $j = 1$ and 2, and a slight

348 increase for classes $j = 6$ to 10 (Fig. 7c and 7d). The AH thresholds encompass in total 1945 packets for the shielded
 349 geophone G1, and 4823 packets for the unshielded geophone plate G2. In comparison, the AF thresholds encompass in total
 350 159 packets for the shielded geophone G1, and 2202 packets for the unshielded geophone plate G2 (counting the packets in
 351 the overlapping class boundaries only once). Considering apparent packets as noise and real packets as signal, applying the
 352 new AF method results in an increased signal to noise ratio, as shown by the larger vertical separation between the blue
 353 (signal) and red (noise) lines in Fig. 7d compared to Fig. 7c.

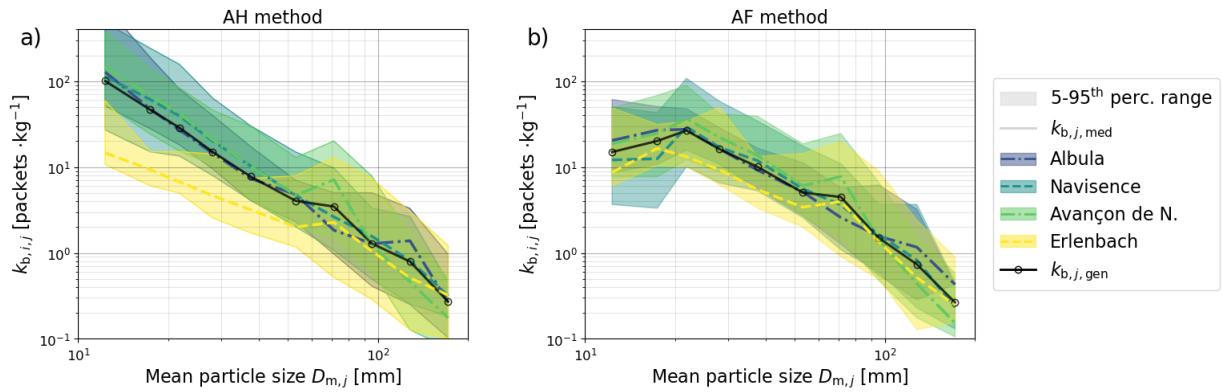

354
 355 **Figure 7: Characteristics of the packets recorded during single-grain-size experiments conducted with the Avançon de Nant flume**
 356 **setup using the partition wall, with the maximum amplitude of the envelope $MaxAmp_{env}$ and the centroid frequency $f_{centroid}$. The**
 357 **red and blue dots correspond to packets recorded by the shielded plate G1 and the unshielded plate G2, respectively. The grey**
 358 **rectangles are the class boundaries delimited by the thresholds obtained for the AH method (a) and the AF method (b). The**
 359 **number of packets $PACK_j$ located within the class boundaries delimited by the AH thresholds and the AF thresholds are indicated**
 360 **in (c) and (d), respectively. In (a), $f_{centroid}$ is shown as function of $MaxAmp_{env}$ for information purposes only.**

361 3.2 Field calibration coefficients

362 As discussed in the previous section, the number of packets $PACK_{i,j}$ detected for a given class j varies together with the
 363 thresholds $th_{ah,j}$, $th_{af,low,j}$ and $th_{af,up,j}$. Because the measured fractional bedload mass $M_{meas,i,j}$ remains constant, the
 364 calibration coefficients $k_{b,i,j}$ will depend on the number of packets detected, and thus on the thresholds that are used to
 365 classify them. We can make the following observations regarding the calibration coefficients $k_{b,i,j}$ obtained using the AF
 366 method compared to the AH method (Fig. 8). First, the $k_{b,i,j}$ coefficients of the smaller size classes are substantially lower,
 367 meaning that fewer packets per unit mass are detected. Second, for the larger size classes, slightly more packets are detected
 368 per unit mass. Third, the overall scatter of the $k_{b,i,j}$ coefficients across all sites is smaller, in particular for the six smallest
 369 classes j . This is reflected in the decrease of the mean coefficient of variation (CV) across all classes j and all sites from CV
 370 = 1.17 (in the AH method) to CV = 0.93 (in the AF method). Fourth, the scatter of the site-specific $k_{b,i,j}$ coefficients is
 371 usually smaller. This is supported by the change of the mean CV across all classes from 0.89 to 0.54 for the Albula, from
 372 0.83 to 0.75 for the Avançon de Nant and from 1.31 to 1.00 for the Erlenbach, between the AH and AF methods. The mean

373 CV for the Navisence site however remains unchanged at 0.85. The general coefficients $k_{b,j,gen}$ obtained from the site-
 374 specific median coefficients $k_{b,j,med}$ using Eq. (7) are listed in Table 4.

375
 376 **Figure 8: The $k_{b,i,j}$ calibration coefficients obtained with the AH method (a) and the AF method (b) for each field site. The colored**
 377 **areas indicate the range between the 5th and the 95th percentile $k_{b,i,j}$ values, the full lines indicate the site-specific median**
 378 **coefficients $k_{b,j,med}$ and the black dashed lines indicate the final general calibration coefficients $k_{b,j,gen}$ as a function of the mean**
 379 **particle diameter $D_{m,j}$ of each grain-size class j .**

380

381 **Table 4: General calibration coefficients $k_{b,j,gen}$ obtained for each grain-size class j with the AH method and the AF method using**
 382 **Eq. (7). $D_{m,j}$ indicates the mean particle diameter of each grain-size class j .**

	Method	Units	$j = 1$	$j = 2$	$j = 3$	$j = 4$	$j = 5$	$j = 6$	$j = 7$	$j = 8$	$j = 9$	$j = 10$
$D_{m,j}$	-	mm	12.3	17.4	21.8	28.1	37.6	53.2	71.3	95.5	127.9	171.5

383

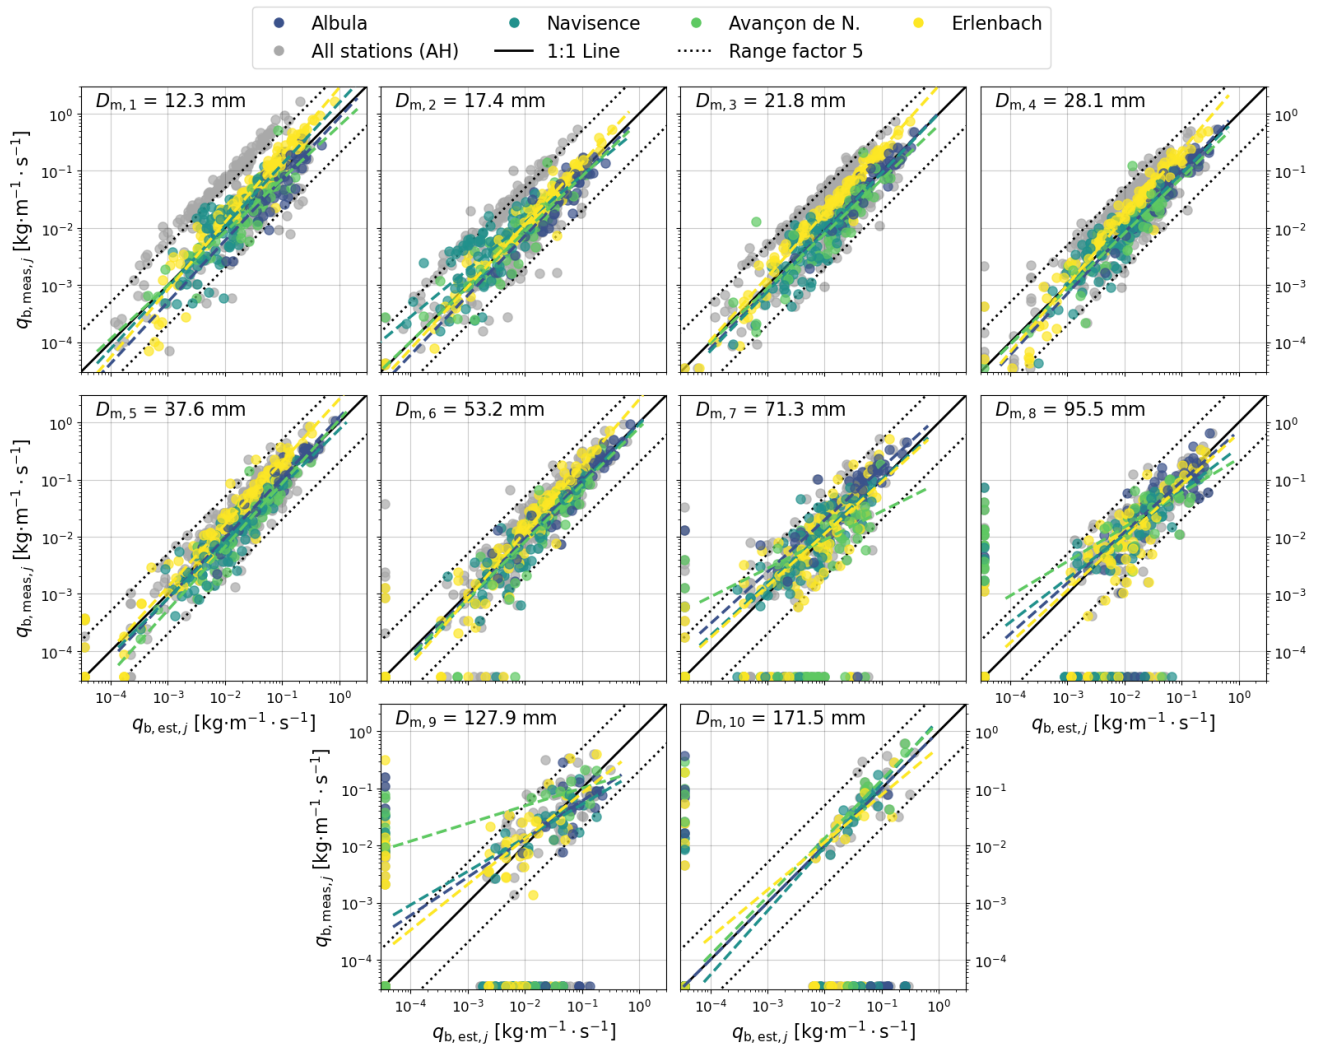

384 3.3 Bedload flux estimates

385 We can now apply the general calibration coefficients $k_{b,j,gen}$ in Eq. (8) to compute fractional bedload mass estimates $M_{est,i,j}$
 386 and subsequently estimates of the fractional flux per unit width $q_{b,est,i,j}$ (Eq. 9) for every sample collected at the four field
 387 sites (Fig. 9). The results obtained with the AH method can be found in Supplementary Information S3, and Table 5 provides
 388 further information on the performance of the two methods.

389 When applied to the field calibration data, the AF method generally yields more accurate flux estimates than the AH
 390 method does, particularly for the five smallest grain-size classes. This improvement is most notably reflected by the
 391 coefficient of determination R^2 values, describing the accuracy of the estimates relative to the 1:1 line (Table 5). R^2 increased
 392 from 0.4 to 0.71 for class $j = 1$ and from 0.51 to 0.72 for class $j = 2$, but by contrast, R^2 decreased slightly from 0.57 to 0.55
 393 for class $j = 8$. The root-mean-square error ($RMSE$), which quantifies the expected error of the estimates, leads to similar
 394 observations (Table 5). The $RMSE$ decreased from $0.094 \text{ kg m}^{-1} \text{ s}^{-1}$ to $0.068 \text{ kg m}^{-1} \text{ s}^{-1}$ for class $j = 1$ and from $0.031 \text{ kg m}^{-1} \text{ s}^{-1}$
 395 to $0.021 \text{ kg m}^{-1} \text{ s}^{-1}$ for class $j = 2$, but increased slightly from 0.037 to 0.039 for class $j = 8$. A further interesting result is the
 396 increase for the first eight classes of the percentage p_{factor_5} of all detected samples, whose estimated bedload fluxes differ
 397 by less than a factor of 5 from the measured values (Figure 9; Table 5).

398 Aside from these comparative observations, it is also worth mentioning the following more general findings that are
 399 valid for both methods. i) For most size fractions, the relative scatter of the estimates (on the log-log plots) decreases with
 400 increasing transport rates. (ii) At low transport rates, mass fluxes are generally overestimated, while at high transport rates
 401 they are generally underestimated. This is shown by the dashed colored power-law regression lines shown in Fig. 9,
 402 described by the corresponding linear coefficient a and exponent b in Table 5. (iii) As indicated by the yellow dots and
 403 regression lines in Fig. 9, mass fluxes for the Erlenbach closely follow the 1:1 line but tend to be slightly underestimated.
 404 (iv) The number of measured ($N_{\text{samples,meas}}$) and estimated ($N_{\text{samples,est}}$) samples both decrease with increasing particle size.
 405 While more than 300 samples were measured and estimated for each of the five smallest grain-size classes, these numbers
 406 gradually decrease to around 100 for the largest class $j = 10$. Furthermore, samples for which either the measured or the
 407 estimated flux equals 0 are indicated as dots along the axes in Fig. 9. If the measured flux is zero but the estimated flux is
 408 positive, the sample can be regarded as false positive (Fawcett, 2006). The difference between $N_{\text{samples,meas}}$ and $N_{\text{samples,est}}$
 409 in Table 5 indicates that the occurrence of such false positive samples increases with increasing particle size. Further
 410 performance metrics derived from the confusion matrix can be found in the Supporting Information (Table S2).

411
 412

413
 414 **Figure 9: Unit fractional transport rate estimates obtained with the AF method for each size class j and each station. The light grey**
 415 **dots in the background indicate the estimates obtained with the AH method and are represented in more detail in the Supporting**

416 Information (Fig. S1). Each panel is annotated with the mean particle size $D_{m,j}$ of the represented class. The solid black lines
 417 correspond to the reference 1:1 line while the dotted lines delimit factors of 5 above and below it (from 0.2 to 5). The dashed
 418 colored lines are power-law regression lines; the mean coefficients over all four sites are listed in Table 5. The dots along the axes
 419 indicate samples for which either the measured or the estimated unit fractional flux equals 0. These samples are not considered for
 420 the computation of the trend lines.

421
 422 Table 5: Performance of the AH method and the AF method regarding fractional flux estimates for each class j with following
 423 parameters: the linear coefficient a , the exponent b and the correlation coefficient r of the power-law regression lines visible in Fig.
 424 9; the coefficient of determination R^2 ; the root-mean-square error $RMSE$; and the percentage of all detected samples for which the
 425 estimated value differs from the measured value by less than a factor of 2 and 5 p_{factor_2} and p_{factor_5} , respectively. These values
 426 were first computed for each site separately and then averaged over all four sites. The number of measured $N_{\text{samples,meas}}$ and the
 427 number of estimated samples $N_{\text{samples,est}}$ showing a positive unit fractional rate were summed over all four sites.

428

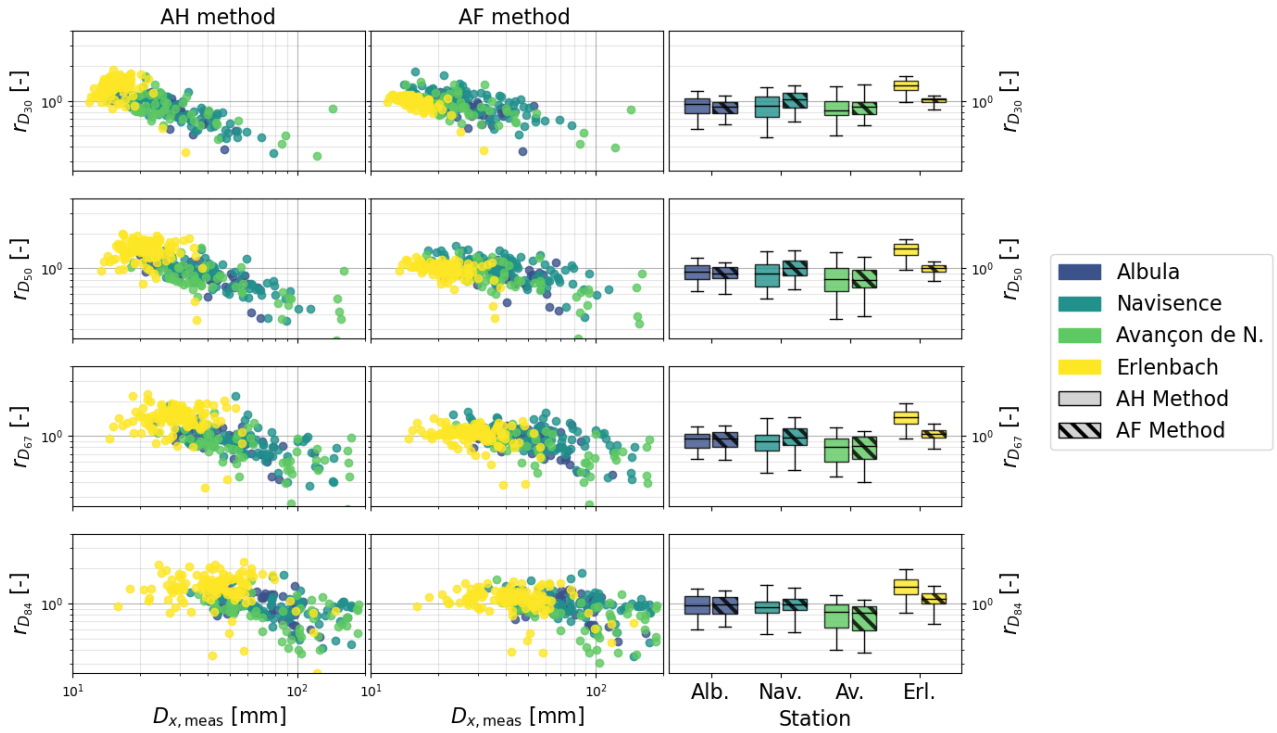

429 As indicated by Eq. (10), the unit total flux estimates are computed as the sum of the unit fractional flux estimates over
 430 all 10 classes. Fig. 10 shows the ratio $r_{q_{b,\text{tot}}}$ between the estimated total flux $q_{b,\text{tot,est}}$ and the measured total flux $q_{b,\text{tot,meas}}$
 431 for all 308 calibration samples, as a function of the sampled total mass $M_{\text{tot,meas}}$. Here, the estimates for the Albula, the
 432 Navisence and the Avançon de Nant sites are slightly more accurate with the AF method than with the AH method, whereas
 433 the estimates for the Erlenbach improve substantially, with the median $r_{q_{b,\text{tot}}}$ value increasing from 0.31 to 0.64. Note that
 434 the observations (i) to (iii) made earlier regarding the fractional flux estimates are also valid here. Fig. 10 also provides an
 435 interesting overview of the sampled masses at all four stations, reflecting the capacities of the different devices (automated
 436 and manual basket samplers and crane-mounted net sampler) used to collect the calibration samples.

437

 441 **and the hatched boxes show the results obtained with the AF method.**

442 3.4 Grain-size estimates

443 We can combine the SPG bedload flux estimates for all grain-size fractions and thus derive grain-size distributions, which
 444 can then be compared to the measured size distributions of each calibration sample. Fig. 11 compares the performance of the
 445 AH and the AF methods in estimating the characteristic grain sizes D_{30} , D_{50} , D_{67} and D_{84} (where D_x is the grain diameter for
 446 which x percent of the sampled bedload mass is finer). The accuracy of the estimates is indicated by the ratio r_{D_x} between the
 447 estimated and the measured characteristic grain size D_x . Compared to the AH method, the AF method mainly improves the
 448 estimates of the four characteristic grain sizes for the Navisence and the Erlenbach sites, but has little effect at the other two
 449 sites. The largest improvement is achieved for the Erlenbach site, with the median $r_{D_{30}}$ changing from 1.37 to 1.02, the
 450 median $r_{D_{50}}$ changing from 1.48 to 1.01, the median $r_{D_{67}}$ changing from 1.46 to 1.05 and the median $r_{D_{84}}$ changing from
 451 1.39 to 1.10. On the opposite, applying the AF method to the Avançon de Nant dataset slightly reduced the accuracy of the
 452 characteristic grain-size estimates, with the median $r_{D_{30}}$ changing from 0.83 to 0.88, the median $r_{D_{50}}$ changing from 0.81 to
 453 0.79, the median $r_{D_{67}}$ changing from 0.80 to 0.82 and the median $r_{D_{84}}$ changing from 0.85 to 0.83. The overall accuracy of
 454 the estimates decreases with increasing characteristic size D_x for both methods, and for every characteristic size D_x , the D_x
 455 tends to be overestimated for finer grain mixtures and underestimated for coarser grain mixtures.

456

457 **Figure 11:** Ratio r_{D_x} between the estimated and the measured characteristic grain sizes D_{30} , D_{50} , D_{67} and D_{84} as a function of the
 458 measured grain diameter $D_{x, \text{meas}}$ for each collected sample i and each station using the AH method (column 1) and the AF method
 459 (column 2). D_x is the grain diameter for which x percent of the sampled bedload is finer. The boxplots in column 3 indicate the
 460 range of r_{D_x} values obtained for each station. The boxes in solid colors show the results obtained with the AH method and the
 461 hatched boxes show the results obtained with the AF method.

462 4 Discussion

463 4.1 The hybrid calibration procedure

464 Recent studies have pointed out the difficulty of transferring flume-based calibrations of impact plate systems to field
 465 applications (e.g. Mao et al., 2016; Wyss et al., 2016c; Kuhnle et al., 2017). In the hybrid calibration approach presented
 466 here, we took advantage of flume experiments to obtain amplitude and amplitude-frequency thresholds for each particle-size
 467 class, which were subsequently applied to field calibration datasets to derive the general calibration coefficients $k_{b,j, \text{gen}}$.

468 The entire hybrid calibration procedure was run iteratively until the optimal linear coefficient and exponent of the
 469 criterion (Eq. 3) used to filter out apparent packets were found (Fig. 6). As objective function, we used an equally weighted
 470 combination of parameters describing the accuracy of bedload flux and grain-size estimates, i.e. r , R^2 , p_{factor_2} , p_{factor_5} , and
 471 $RMSE$ as shown in Table 5, and r_{D_x} as shown in Fig. 11. The accuracy is derived from the confusion matrix (Fawcett, 2006)
 472 as shown in Table S2 in Supporting Information. We looked for two types of optimal calibrations. The first type is a general
 473 calibration, for which we have presented the results in Sect. 3. This calibration combines all four stations in order to
 474 investigate the feasibility of a general signal conversion procedure applicable to multiple sites equipped with the SPG
 475 system. The second type is a site-specific calibration aiming to improve the accuracy of bedload transport rate estimates at a
 476 single monitoring station, to be used for a more detailed analysis of bedload-related processes at a given site (details of these
 477 site-specific calibrations are available in Supporting Information Sect. S4 and S5).

478 The biases introduced by apparent packets can be removed by site-specific calibration of the coefficients $k_{b,i,j}$, so the
479 AF and AH methods perform about equally well when calibrated separately to each individual site (see Supporting
480 Information Sect. S4 and S5). This result supports the use of the AF method, considering the large proportion of packets left
481 out by the AF thresholds (up to 91 % in the smallest class $j = 1$; see Supporting Information Table S4). However, the
482 abundance of apparent packets varies considerably from site to site, owing to differences in the channel geometry, the
483 bedload grain-size distribution, and the construction details of the individual SPG installations. Because the AF method
484 filters out a substantial fraction of these apparent packets, it yields substantially better general calibrations than the AH
485 method does (see Table 5).

486 We also tested the performance of an adapted version of the AH method introduced by Rickenmann et al. (2018). This
487 method was originally developed for the Erlenbach site and aimed to correct for the relationship between the signal response
488 and the transport rate. In the present study, we applied this method to each field site. The only notable improvement
489 introduced by the adapted AH method is the increased number of detected samples at the Erlenbach station, leading to more
490 accurate estimates of the various characteristic grain sizes D_x at this site (Tables S8 and S9 in Supporting Information); the
491 results for the other sites were not substantially improved.

492

493 4.2 Two-dimensional size class thresholds

494 To understand the performance of the new AF method it is worth taking a closer look at the role of the size class thresholds.
495 As shown in Fig. 7, replacing the upper amplitude thresholds with amplitude-frequency values results in the following two
496 important changes. First, a dimension is added, which facilitates focusing on the narrow range of signal responses
497 characteristic for real packets, and filtering out many of the apparent packets. Second, the areas of the amplitude-frequency
498 domain covered by two adjacent classes can now overlap. Packets located in overlapping areas are assigned once to each
499 class and therefore counted twice. This explains why both the number of detected packets $PACK_j$ (Fig. 7c and 7d) and
500 subsequently the $k_{b,j}$ values (Fig. 8) are slightly higher when the AF method (instead of the AH method) is applied to the
501 larger size classes. Counting such packets twice is not unreasonable, given that the ranges of signal responses recorded
502 during single-grain-size flume experiments for two contiguous grain-size classes significantly overlap, even after apparent
503 packets are filtered out (Fig. 5). Overlapping class boundaries therefore result in a less strict classification of the few packets
504 that are on the edges of the grain-size classes. In Fig. 7b, out of 2256 packets recorded by G2 (blue), 144 packets have been
505 counted twice. But interestingly, this is not true of any of the 153 packets recorded by G1 (red) within the class boundaries.
506 A further result supports the use of the two-dimensional size class thresholds. When applying the AF method, the $k_{b,j}$
507 coefficients obtained for the different sites (Fig. 8b) reach a maximum value at the third smallest size class. A similar yet
508 stronger decrease towards the two smallest classes was described by Wyss et al. (2016b) and was related to the reduced
509 detectability of the smallest particle sizes.

510 Through the reduced area covered by the new amplitude-frequency thresholds in Fig. 7b, a certain percentage of all the
511 packets recorded during the field calibration experiments is neglected for general calibration: 55% at the Albula site, 63% at
512 Navisence, 58% at Avançon de Nant and only 9% at Erlenbach. This suggests that the plates embedded at Erlenbach pick up
513 less noise from their surroundings. A similar trend was observed by Nicollier et al. (2022) when comparing the maximum
514 amplitude registered by two adjacent plates for a given impact at the same location. This difference in noise detection levels
515 is possibly accentuated by the number of impacted plates during bedload transport events. The SPG array embedded in the
516 artificial U-shaped channel of the Erlenbach has the particularity that only 2 out of its 12 plates are usually impacted by

517 bedload particles during floods (and only sediment crossing these two plates is caught by the automatic basket sampler). At
518 the other sites, in contrast, every 10 to 30 embedded plates are submerged by the flow and thus can potentially be impacted.

519 **4.3 Sampling uncertainties**

520 Even though the AF method improved the overall accuracy of flux estimates for most classes (Table 5), some trends
521 addressed in Sect. 3 suggest that factors other than the noise level also control the accuracy of the estimates. The dataset
522 presented in this study includes 308 calibration measurements and is in our knowledge the largest dataset gathered for any
523 impact plate system. Still, it appears that the number of collected samples is not sufficient to accurately assess the
524 performance of the two methods for the three largest particle-size classes (Fig. 9; Table 5). This mainly relates to a higher
525 proportion of large particles as compared to finer ones in typical sediment mixtures (Rickenmann et al., 2014; Mao et al.,
526 2016). Earlier investigations have shown that a larger number of detected bedload particles reduces the scatter of total mass
527 estimates by averaging over stochastic factors such as the impact location on a given impact plate, the particle transport
528 mode (sliding, rolling, saltating, etc.; Chen et al., 2022), and the impact velocity (Rickenmann and McArdeU, 2008;
529 Turowski et al., 2013). A further uncertainty arises because these larger particles are transported at higher bed shear stresses
530 (Einstein, 1950; Wilcock and Crowe, 2003), which also mobilize more total material and thus pose a serious challenge
531 regarding the sampling efficiency of the calibration bedload samplers. Bunte and Abt (2005) and Bunte et al. (2019) have
532 demonstrated that reducing the sampling duration with a bedload trap from 60 to 2 minutes decreases both the sampled unit
533 total bedload flux $q_{b, \text{tot}}$ and the sampled maximum particle size D_{max} by about half. In the present study, total bedload fluxes
534 up to $4 \text{ kg m}^{-1} \text{ s}^{-1}$ were measured with the net sampler, meaning that the measurement duration had to be minimized to avoid
535 overloading the sampler. At the Albula stream, for instance, only four samples contained particles of the largest class, and all
536 four were sampled over a duration ranging from 1 to 2 minutes. As a comparison, the longest sampling duration was reached
537 at the Navisence site and lasted 25 minutes. All this suggests that an optimal calibration of the SPG system requires
538 balancing the sampling duration and the number of collected particles. Note that uncertainties in the direct measurements do
539 affect the accuracy of fractional sediment flux and grain-size estimates. Flume experiments could potentially be used to
540 assess the sampling efficiency of the various calibration sampling methods, along with the detection efficiency of the SPG
541 system.

542 **4.4 Transport rate**

543 Two further trends are evident in the unit fractional flux estimates obtained for the seven smallest classes, for which most
544 samples were detected ($N_{\text{samples, est}} / N_{\text{samples, meas}} > 96\%$; Table 5). First, the relative scatter (on the log-log plots) of the
545 fractional flux estimates around the power-law regression lines in Fig. 9 is smaller at higher transport rates. Second, both
546 total and fractional fluxes are generally overestimated at low transport rates and underestimated at high transport rates (Fig. 9
547 and 10). These findings agree with results from previous calibration campaigns with the SPG system (Rickenmann and
548 Fritschi, 2017; Rickenmann et al., 2018), but a comprehensive explanation for these trends is still missing. The following
549 hypotheses can be raised to explain the relationship between the mass flux estimates and the transport rate q_b : (i) The SPG
550 system may suffer from signal saturation when the transport rate is too high, as has been documented in the Japanese pipe
551 microphone system (Mizuyama et al., 2011; Choi, 2020). In our SPG data, we have observed long packets containing
552 multiple large peaks corresponding to several impacts occurring so quickly after one another that they were not detected as
553 separate packets. One can expect that the probability of occurrence of such packets increases together with the transport rate,
554 with the transport of large particles (which typically generate packets of longer durations), and with the occurrence of sliding

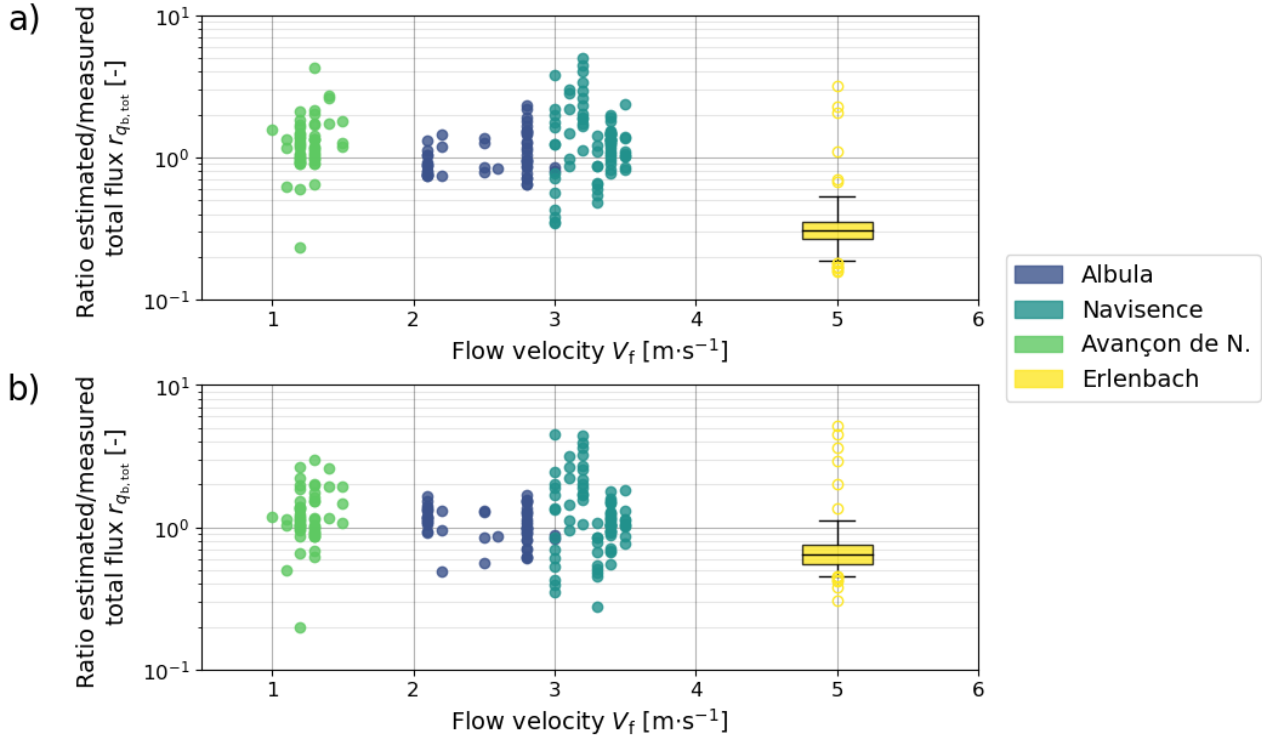

555 and rolling particles (Chen et al., 2022). The long packets obscure the multiple shorter packets that would otherwise be
556 individually counted, leading to underestimated mass fluxes for a given $k_{b,j}$ value. The development of a procedure to
557 identify such packets and attribute the therein contained peaks to individual impacts could represent an interesting aim for
558 future research. (ii) Field observations of bedload sheets being transported over plates at high transport rates were made at
559 the Vallon de Nant site. In the presence of bedload sheets, one can expect that the detection rate of transported particles is
560 hampered by multiple particle layers (Rickenmann et al. 1997; Turowski and Rickenmann, 2009), kinetic sieving (e.g. Frey
561 and Church, 2011) or percolation processes (e.g. Recking et al., 2009). As such, it would be reasonable to expect a stronger
562 signal response at lower transport rates (Fig. 10).

563 We are not able to give a clear explanation for the overestimates of the characteristic grain size D_x for finer grain
564 mixtures and underestimates for coarser grain mixtures (as shown in Fig. 11). A similar trend was also observed by
565 Rickenmann et al. (2018) for calibration measurements originating from the Erlenbach. We expect that the decrease of the
566 detection rate along with increasing transport intensity, as mentioned above, may partly explain this phenomenon.

567 **4.5 Effect of the flow velocity**

568 A recurrent feature in the results presented above is an offset between the estimates obtained for the Erlenbach and those
569 obtained for the three other stations. A similar offset was observed earlier for linear calibration relations of total bedload
570 mass between the Erlenbach and other field sites with more natural approach flow conditions (Rickenmann et al., 2014).
571 Although applying the new amplitude-frequency method has reduced the offset in the present study significantly, it remains
572 visible for both fractional and total bedload flux estimates (Fig. 9, 10, and 12). At the Erlenbach site, the last 35 meters
573 upstream of the SPG system consist of an artificial bed with a steep channel slope of 16%, made of large flat embedded
574 boulders (Roth et al., 2016). This explains the supercritical flow regime with a Froude number around 5.1 (Wyss et al.,
575 2016c) and a flow velocity V_f around 5 m s^{-1} at the check dam with the geophone sensors (Table S1). Bedload particle
576 velocity V_p was introduced by Wyss et al. (2016b, c) as a possible governing parameter affecting the number of particles
577 detected by the SPG system, fast moving particles being less likely to collide against the Swiss plate geophone than slower
578 moving ones, which are more frequently in contact with the bed. For the present study, we used V_f as a proxy for V_p , even
579 though bedload particles generally travel more slowly than the fluid surrounding them (Ancey et al., 2008; Chatanantavet et
580 al., 2013; Auel et al., 2017). Past flume experiments (Wyss et al., 2016b; Kuhnle et al., 2017) have shown that the calibration
581 coefficient $k_{b,j}$ can vary with the flow velocity V_f , such that a three-fold increase in V_f can lead to a two-fold decrease of $k_{b,j}$.
582 The better detectability of particles that one could expect from the higher impact energy (Wyss et al. 2016b) seems to be
583 insufficient to compensate for the strong reduction of the number of impacts on a plate as flow velocity increases. This
584 possibly arises from the fact that larger flow velocities (without increased turbulence) may also lead to flatter saltation
585 trajectories, thus decreasing the vertical component of the impact force. Furthermore, bed morphology, bed roughness and
586 flow velocity play important roles in determining particle transport mode, i.e., sliding, rolling, or saltating (e.g. Bagnold,
587 1973; Lajeunesse et al., 2010). Although high flow velocities generally favor the saltating mode (Ancey et al., 2002; Chen et
588 al., 2022), the shallow flow depths measured at the Erlenbach (in average 0.1 m; Wyss et al. 2016b) may limit the hop height
589 of larger particles (Amir et al., 2017). Considering all these aspects, we hypothesize that the generally underestimated
590 transport rates observed for the Erlenbach site mainly arise from the exceptionally high flow velocity, shallow water depths
591 and the related transport mode (Fig. 12). Continuous streamflow measurements are lacking at the Albula and Navisence
592 sites, hampering a more detailed analysis of the relationship between flow velocities and detection rates. Another improvable
593 aspect is the low variability between the site-specific calibration relationships of the three natural sites already before the

594 implementation the AF method (Fig. 8a). It would have been interesting to test the method on a larger number (and variety)
 595 of sites. Unfortunately, these four chosen sites are currently the only ones at which a full geophone signal has been recorded
 596 during calibration measurements.

597
 598 **Figure 12:** Ratio $r_{q_{b,tot}}$ between the estimated and the measured unit total mass flux as a function of the mean flow velocity V_f , for
 599 each collected sample and each station, for the AH method (a) and the AF method (b). The indicated flow velocity corresponds to
 600 in situ measurements performed during (or close in time to) the corresponding calibration measurement. Due to the stable flow
 601 velocity of 5 m s^{-1} measured at the Erlenbach site, the range of $r_{q_{b,tot}}$ values is represented as a boxplot. The yellow circles
 602 correspond to outliers.

603 4.6 K-fold cross-validation

604 In a last stage, we tested the robustness of the AH and AF methods by splitting the dataset into calibration and validation
 605 subsets. Because the number of calibration measurements is relatively small and varies between stations, we applied a 4-fold
 606 cross-validation technique (e.g. Khosravi et al., 2020). The field calibration measurements were distributed over four folds,
 607 each containing an equal number of calibration measurements from each site (Supporting Information Fig. S4). One after
 608 another, the folds were used as validation datasets while the remaining three folds were used for calibration. General
 609 calibration coefficients $k_{b,j,gen}$ were obtained from the calibration dataset and subsequently applied to the validation data to
 610 derive flux estimates. Even though each fold contains a total of only 48 samples (12 per site), the results obtained with the 4-
 611 fold cross-validation procedure support our conclusion that including frequency information in the packet classification
 612 procedure improves the mean accuracy of the estimates over all sites, in particular for the smaller five to six size classes j
 613 (Supporting Information Table S10). Nicollier et al. (2022) found that the true size of particles generating apparent packets is
 614 mostly underestimated, due to the attenuation of the vibrations as they propagate (see Fig. 7). It is therefore reasonable that
 615 the AF method mainly improves the flux estimates for these smaller classes.

616 5 Conclusion

617 The Swiss plate geophone (SPG) is a bedload surrogate monitoring system that has been installed in several gravel-bed
618 streams and was calibrated using direct sampling techniques. While most site-specific calibration relationships for total mass
619 flux are robust across multiple orders of magnitude, the mean calibration coefficients can still vary by about a factor of six
620 between different sites. In this study, we derived a general procedure to convert SPG signals into fractional bedload fluxes
621 using an extensive dataset comprising flume experiments as well as 308 field calibration measurements from four field sites.
622 The proposed hybrid approach is based on previous findings (Antoniazza et al., 2020; Nicollier et al., 2022) that the SPG
623 system is biased by elastic waves that propagate through the apparatus and generate noise in the form of spurious “apparent”
624 packets. We introduced the amplitude-frequency (AF) method as an alternative to the amplitude-histogram (AH) method
625 developed by Wyss et al. (2016a). Packets recorded during single-grain-size flume experiments were first filtered to exclude
626 apparent packets, and then used to derive grain-size class thresholds for packet classification. We found that filtering out
627 apparent packets results in more consistent relationships between particle diameter and amplitude-frequency characteristics
628 of the SPG signal. Furthermore, we showed that including frequency information in size class thresholds helps in excluding
629 apparent packets and thus improves the signal-to-noise ratio. In a second stage, we applied these flume-based thresholds to
630 field calibration measurements and derived general calibration coefficients applicable at all four sites for ten different grain-
631 size fractions. The AH method, by contrast, requires site-specific calibration because it cannot account for the site-to-site
632 differences in the abundance of apparent packets. Averaged over the ten grain-size fractions, the bedload mass of 69% and
633 96% of the samples was estimated within an offset of a factor of two and five, respectively, relative to the measured sample
634 mass. The remaining discrepancies between the site-specific results are mainly attributed to large differences in flow (and
635 probably particle) velocity. Finally, the sampled mass, the transport rate and the sampling efficiency were identified as
636 further factors possibly influencing the accuracy of mass flux and grain-size estimates.

637 The presented results are highly encouraging regarding future applications of surrogate monitoring methods to
638 investigate bedload transport processes. The findings also underline the valuable contribution of flume experiments to our
639 understanding of the relationship between bedload transport and the recorded SPG signal. But above all, this study highlights
640 the requirements for obtaining calibrations that are transferable across sites: accurate and numerous direct sampling
641 measurements with long sampling durations and large sampled masses, sensors insulated from surrounding noise sources,
642 and highly resolved temporal information about the stream flow, to identify and account for variations in the transport
643 conditions.

644 Notation

645	a_c	Linear coefficient of the criterion
646	A_{FFT}	Fourier amplitude
647	$A_{m,j}$	Mean amplitude registered for particle-size class j
648	b_c	Linear coefficient of the criterion
649	Δt_i	Sampling duration
650	$D_{m,j}$	Mean particle diameter for particle-size class j
651	$D_{\text{sieve},j}$	Lower sieve size retaining particle class j
652	D_x	Characteristic grain size
653	f_{centroid}	Centroid frequency
654	i	Sample index

655	j	Particle-size class index
656	$k_{b,i,j}$	Sample- and class-specific calibration coefficient
657	$k_{b,j,med,station}$	Median calibration coefficient for particle-size class j and a given station
658	$k_{b,j,gen}$	General calibration coefficient for particle-size class j
659	$M_{est,i,j}$	Estimated fractional mass per sample and per class
660	$M_{meas,i,j}$	Sampled fractional mass per sample and per class
661	$MaxAmp_{env}$	Maximum registered amplitude within a packet
662	$N_{samples,est}$	Number of detected samples
663	$N_{stations}$	Number of stations
664	$PACK_{i,j}$	Number of recorded packets per sample and per class
665	$p_{factor,x}$	Percentage of all detected samples for which the estimated and the measured values differ from each other by less than a factor of x
666		
667	$q_{b,est,i,j}$	Estimated unit fractional transport rate per sample and per class
668	$q_{b,meas,i,j}$	Measured unit fractional transport rate per sample and per class
669	$q_{b,tot,est,i}$	Estimated unit total bedload flux per sample
670	$q_{b,tot,meas,i}$	Measured unit total bedload flux per sample
671	R^2	Coefficient of determination
672	r	Correlation coefficient
673	r_x	Ratio between estimated and measured values x
674	$th_{ah,j}$	Amplitude-histogram thresholds
675	$th_{af,low,j}$	Lower amplitude-frequency thresholds
676	$th_{af,up,j}$	Upper amplitude-frequency thresholds
677	V_f	Mean flow velocity
678	w_p	Standard width of an impact plate

679 **Data availability**

680 The dataset presented in this paper is available online on the EnviDat repository

681 <https://www.envidat.ch/#/metadata/sediment-transport-observations-in-swiss-mountain-streams>.

682 **Author contribution**

683 Tobias Nicollier designed and carried out the field and flume experiments, developed the presented workflow and prepared
684 the manuscript with contributions from all co-authors. Gilles Antoniazza designed and carried out the field experiments at
685 the Vallon de Nant site. Lorenz Ammann helped developing the methodology and contributed to the formal analysis. Dieter
686 Rickenmann contributed to the conceptualization and the supervision of the presented work, contributed to the design of the
687 methodology, and provided support during the field and flume experiments. James W. Kirchner contributed to the
688 development of the methodology and significantly contributed to the preparation of the initial draft.

689 **Acknowledgements**

690 This study was supported by Swiss National Science Foundation (SNSF) grant 200021L_172606, and by Deutsche
691 Forschungsgemeinschaft (DFG) grant RU 1546/7-1. The authors are grateful to Arnd Hartlieb, to the students of the TU
692 Munich, and to the technical staff of the Oskar von Miller Institute for helping to set up and perform the flume experiments.
693 They also warmly thank Norina Andres, Mehdi Mattou, Nicolas Steeb, Florian Schläfli, Konrad Eppel and Jonas von
694 Wartburg for their efforts and motivation during the field calibration campaigns. Special thanks go to Stefan Boss for his
695 support with the measurement systems at all sites, and to Andreas Schmucki, who never gave up repairing the net sampler.
696 Alexandre Badoux is further thanked for his valuable suggestions regarding an earlier version of the manuscript.

697 **Competing interests**

698 The authors declare that they have no conflict of interest.
