Abstract
Massive sediment pulses in catchments are a key alpine multi-risk component. Substantial sediment redistribution in alpine catchments frequently causes flooding, river erosion, and landsliding, and affects infrastructure such as dam reservoirs as well as aquatic ecosystems and water quality. While systematic rock slope failure inventories have been collected in several countries, the subsequent cascading sediment redistribution is virtually unaccessed.

This contribution reports for the first time the massive sediment redistribution triggered by the multi-stage failure of more than 150,000 m³ from the Hochvogel dolomite peak during the summer of 2016. We applied change detection techniques on seven 3D-coregistered high-resolution true-orthophotos and digital surface models (DSM) obtained through digital aerial photogrammetry later optimized for precise volume calculation in steep terrain. The analysis of seismic information from surrounding stations revealed the temporal evolution of the cliff fall.

We identified the proportional contribution of >600 rockfall events (>1 m³) from 4 rock slope catchments with different aspects and their volume estimates. In a sediment cascade approach, we evaluated erosion, transport, and deposition from the rockface to the upper channelized erosive debris flow channel, then to the widened dispersive debris flow channel, and finally to the outlet into the braided sediment-supercharged Jochbach river. We observe the decadal flux of more than 400,000 m³ of sediment with massive sediment pulses that (i) respond with reaction times of 0–4 years and relaxation times beyond 10 years, (ii) with faster response times of 0–2 years in the upper catchment and more than 2 years response times in the lower catchments, (iii) the inversion of sedimentary (10²–10³ mm/a) to massive erosive regimes (10² mm/a) within single years and the (iv) dependency of redistribution to rainfall frequency and intensity. This study provides generic information on spatial and temporal patterns of massive sediment pulses in highly-charged alpine catchments.

large format aerial photogrammetry, rockfall, massive sediment redistribution, increased debris flow activity, alpine catchment, Hochvogel.
Introduction

Mechanisms and scales of sediment propagation throughout space and time in sediment cascades are paramount to the development of prevention and mitigation measures. Several studies have focused on sediment cascades on fluvial landscapes (e.g., (Burt and Allison, 2010; Joyce et al., 2018)) however, few quantitative studies have been undertaken in active mountain environments controlled by landsliding (e.g., (Wichmann et al., 2009; Heckmann et al., 2016; Clapuyt et al., 2019). Landslides provide and condition the input of sediment volumes. Despite their relevance in the sediment cascades, landslide deposit residence times, cascade sediment pulses, and redistribution controlling factors are rarely quantified due to the sudden, unpredictable, and spatially distributed occurrence.

Sediment delivery from rockfalls to the drainage network has significant implications for catchment scale sediment fluxes and landform evolution (Benda and Dunne, 1997; Tucker, 2004). Despite this, there is a lack of systematic studies focused on the short-term temporal and spatial development of mechanisms that link and maintain sediment continuity within hillslopes. Attempts to better understand short-term erosion rates and sediment yield at a basin scale include spatial pattern analysis (Schrott et al., 2003), sediment budgets (Joyce et al., 2018), numerical modeling (Wichmann et al., 2009; Heckmann and Schwanghart, 2013), and application of the connectivity framework (Wichmann et al., 2009; Fryirs, 2013). These approaches incorporate both spatial and temporal variability in the operation of the sediment cascades at a diversity of scales, however, lack key observations on rare and high-magnitude events. On the other hand, debris flows serve as a link to hillslope-channel coupling by connecting large parts of rock walls to the channel network (Heckmann and Schwanghart, 2013). Debris flows rapidly mobilize < $10^2$ to > $10^9$ m$^3$ of sediment (Jakob, 2005) along great distances reaching infrastructure and populated areas. While debris flows are typically considered transport-limited processes (Gregory and Lewin, 2014), numerical simulations suggest that continuous delivery of sediment from upslope areas to the location where debris flows are initiated maintains the supply of material available for transport, thus, impacting the persistence and magnitude of sediment pulses in the system (Heckmann and Schwanghart, 2013). Several studies have collected data from massive rock slope failures (e.g., (Dussauge-Peisser et al., 2002; Heckmann et al., 2012; Fischer et al., 2012; Krautblatter et al., 2012; Guerin et al., 2020) which are a major landscape evolution process and significantly contribute to sediment yields by sporadic production of a considerable ($<$ $10^7$ m$^3$ km$^{-1}$ yr$^{-1}$) amount of debris (McSaveney, 2002; Korup et al., 2010; Krautblatter et al., 2012). However, few studies have quantitatively assessed the subsequent cascading sediment redistribution and reaction and relaxation times in highly active alpine catchments. Recent high-magnitude rockfalls in the European Alps raised attention to the potential of catastrophic cascading sediment transport. The 2011 and 2017 rockslides in the upper Val Bondasca, Swiss Alps, were preceded by an unusually high debris flow activity that reached the town of Bondo (Baer et al., 2017; Mergili et al., 2020). A total of 99 buildings were damaged by the multiple debris flows that occurred on August 2017 with an assumed economical loss of around 41 million francs (NNZ, 2017). In the coming decades with enhanced rainstorm activity, massive sediment redistribution in alpine catchments will be a key hazard and challenge in alpine communities, thus, constraining rates and sediment cascades response times to suddenly increased sediment input by landsliding is paramount for prediction and early warning.

This paper reports the massive sediment redistribution triggered by the multi-stage failure from the Hochvogel dolomite peak during the summer of 2016. We evaluate the spatio-temporal morphodynamics at a catchment scale...
before and after the cliff fall by means of multi-temporal high-resolution aerial photogrammetry between 2010 and 2020. The (multi-)annual photogrammetric surveys provide information on detachment areas and failed volumes, but the time resolution is limited to the recurrence interval between two consecutive surveys. To overcome this limitation, we use high-resolution seismic records capturing relevant rockfall events (e.g., (Hibert et al., 2011; Lacroix and Helmstetter, 2011; Manconi et al., 2016; Fuchs et al., 2018; Dietze et al., 2017a)). The combination of seismic information with high-resolution wide-extent photogrammetric reconstructions resulted in (i) identification of the spatial and temporal contribution of rockfall material from the four rock slope catchments that constitute the Hochvogel summit, (ii) quantification of (multi-)annual series of sediment budgets erosion rates before and after the cliff fall evidencing the dramatic inversion of deposition and erosion processes, (iii) time series of sediment cascading and (iv) estimation of the system reaction time and redistribution controls with respect to rainstorm intensity and frequencies. To our knowledge, this paper is the first to show the cascading sediment response of an alpine catchment to a massive rock slope failure. This enables a better understanding of catchment morphodynamic responses to high magnitude rock fall, propagation, and persistence of sediment waves through alpine catchment system and future hazard scenarios where increased sediment availability and seasonal extreme heavy rainfall are expected.

2 Study area

The Hochvogel peak (47°21’N, 10°26’E, 2592 m a.s.l), is a prominent summit in the Northern Calcareous Alps and a popular destination for hikers. The Hochvogel massif consists of Hauptdolomit, a brittle, variably bituminous carbonate rock with pronounced bedding (dm-m) and incidental marly interlayers. The rock mass is tectonically stressed and highly weathered. A meter-size fracture at the summit poses a catastrophic rock failure scenario (Leinauer et al., 2020, 2021) directly impacting the Weittal valley (Figure 1).

Four slopes constitute the pyramidal-shaped summit with orientations towards northeast, west, southeast, and southwest and mean inclinations between 43° to 47°. The southwestern slope is distinguished by its current almost vertical wall and upper negative slope reaching the peak of the summit. Slope processes occurring at the southwestern slope are transferred to the Weittal catchment which extends over 1.9 km$^2$ with an elevation difference of more than 1,300 m. The area directly affected by slope instabilities occurring at the southwestern slope covers 378,642 m$^2$ between 2010 to 2021 and is divided into four morpho-dynamic components (Figure 1a) rock face: with strong slope changes, serve as the source of sediment production (primary and secondary rockfalls), upper channelized erosive debris flow channel: characterized by a mean slope of 42°, promotes temporal accumulation of sediment in an incipient slope talus. A confined asymmetric valley follows the slope talus limited to the east by vertical walls of almost 60 m in height. At the same time, to the west, sporadic minor pulses of sediment are produced by erosion of the base of an older slope deposit gently oriented southwest.

widened dispersive debris flow channel: geographically limited by the intersection of the Weittal and Wildenbach streams, starts by a rock wall confined valley which transforms into a highly active unconfined slope under continuous incision of older deposits and the outlet into the Jochbach river which imposes a high sediment transfer regime evidenced in the braided development of the river along an alluvial plain with a mean inclination of 14° and the presence of terraces with a height between 1 to 3 m from the current main channel.
Rockfalls on the southeastern and southwest slopes of the Hochvogel summit were documented in 1934, 1935, 2005, and 2007 (DAV, 2017). Between Saturday 9 and Monday 11 of July 2016 (Heißel and Figl, 2017), noises and a dust cloud alerted the local authorities due to a new rockfall event that affected the Weittal valley (Figure 1. a).
3. Methods

3.1 Multi-temporal quantification of surface change

We used large format aerial imagery surveyed by the Austrian and German Cartographic Survey offices (BEV & LDBV) and by 3D RealityMaps GmbH to investigate the spatial and temporal sediment production, transport, and accumulation patterns of the southwest slope of the Hochvogel in 6 intervals over ten years. All seven surveys (09.2010, 08.2012, 09.2014, 06.2015, 08.2017, 09.2018, and 08.2020) have a nominal 20 cm spatial resolution (supplementary Table 1.) for the production of the digital surface models (DSM) and true orthophotos from the photogrammetric point clouds. The produced DSMs were aligned to the reference dataset acquired on 21.09.2018 by means of a 3D-coregistration for the further application of change detection and volume calculation.

3.1.1 2.5D topographic time series

The photogrammetric workflow to generate DSM and true orthophoto from nadir view aircraft photographs consists of the initial standardization of the aerotriangulation provided by the survey agencies into the same spatial reference system using the software Inpho and Match-AT by Trimble, and followed by the generation of oriented point clouds, DSM, and orthophotos using the semi-global matching algorithm first developed by (Hirschmuller, 2008) and implemented in the software SURE from nFrames (ESRI) (Haala and Rothermel, 2012; Rothermel et al., 2012). We optimized the orthophotos and DSMs for a more precise volumetric calculation in steep terrain by the application of a 7-parameter 3D similarity transformation described by (Eq. (1)). To minimize the 3D distance between a reference surface (21.09.2018) and the interest datasets, we manually selected 30 multi-temporal well-distributed 3D corresponding points \((x, y, z)\) located in stable, non-changeable areas using the true orthophotos and the corresponding DSMs, and solved Eq. (1) using the least-squares adjustment solution in python.

\[
\begin{bmatrix}
    x_{obs} \\
    y_{obs} \\
    z_{obs}
\end{bmatrix} =
\lambda
\begin{bmatrix}
    \cos(\psi)\cos(\kappa) & \sin(\omega)\sin(\kappa)\cos(\psi) - \cos(\omega)\sin(\psi) & \cos(\omega)\sin(\psi) + \sin(\omega)\sin(\kappa) \\
    \cos(\psi)\sin(\kappa) & \sin(\omega)\sin(\psi) + \cos(\omega)\cos(\psi) & \cos(\omega)\cos(\psi) \\
    -\sin(\psi) & \sin(\omega)\cos(\psi) & \cos(\omega)\cos(\psi)
\end{bmatrix}
\begin{bmatrix}
    x_{ref} - x_0 \\
    y_{ref} - y_0 \\
    z_{ref} - z_0
\end{bmatrix}
\]

where \([x_{obs}, y_{obs}, z_{obs}]^T\) and \([x_{ref}, y_{ref}, z_{ref}]^T\) are the vectors of coordinates of the corresponding points at the search surface \(s(x, y, z)\) and reference surface \(r(x, y, z)\) with size \((1, 3 \cdot n_{corresponding\ points})\) respectively : \(\lambda\) is the uniform scale factor; \([x_0, y_0, z_0]^T\) is the vector of approximate values of the parameters; and \(\omega, \phi, \kappa\) represent the rotation Euler Angles used to calculate the orthogonal rotation matrix \(M_{ij} = M(\omega, \phi, \kappa)\). Parameters \(\lambda\) and \(M(\omega, \phi, \kappa)\) are initially approximated to 0 and \(M(\omega, \phi, \kappa)\) to \(\frac{\pi}{180}\). The evaluation of the estimated parameters \(M(\omega, \phi, \kappa)\) and \([x_0, y_0, z_0]^T\) after the convergence of the model (5 iterations) results in the elimination of outliers and the warranty of randomness in the residual values defined as the difference between the \(r(x, y, z)\) and \(s_{trans}(x, y, z)\), being \(s_{trans}\) the new coordinates of the corresponding points at the search surface after the application of the transformation parameters (Figure 2).
Figure 2. a) True orthophoto of the reference surface acquired on 21.09.2018. Blue dots indicated the corresponding points with the search surface acquired on 07.08.2017. Similar spatial distribution is followed for the remaining datasets according to the extent of the acquisition. b) Residuals calculated as the difference between the $r(x, y, z)$ and $s_{\text{trans}}(x, y, z)$, being $s_{\text{trans}}$ the new coordinates of the corresponding points at the search surface after the application of the transformation parameters for each spatial axis x, y, and z. c) Spatial distribution of the corresponding points at each spatial axis x, y, and z.

Repetitive topographic surveys, in our case DSMs, allow the identification and quantification of geomorphic changes such as erosion and deposition (James et al., 2012; Wheaton et al., 2010). We estimated the area and volume of change based on 2.5 data., i.e., rasterized topography following Eq. (2):

$$\text{DoD} = Z_{\text{new}} - Z_{\text{old}} \quad (1)$$

where DoD is the difference of elevation between consecutive DSMs ($Z_{\text{new}}$ and $Z_{\text{old}}$). Despite the limited depiction of vertical walls and possible artifacts for overhanging walls, gridded datasets, i.e., DEM, support the fast and straightforward calculation of 2.5 D volumes by Eq. (3):

$$V = a \sum_{i=1}^{n} \text{DoD}_i \quad (3)$$

where $a = n \times a_{\text{pixel}} \quad (4)$

and $n$ is the number of pixels conceding with a change, $a_{\text{pixel}}$ corresponds to 0.4 m$^2$, and $\text{DoD}_i$ is the elevation difference between time periods.

We used the non-interpolated DSMs to minimize the change to noise ratio (Wheaton et al., 2010; Anderson, 2019). Elevation uncertainty of photogrammetric surveys is roughly assessed as three times the spatial resolution, however, lighting conditions, surface roughness, and camera configuration among others, imprint an inhomogeneous spatially distributed uncertainty which estimation remains challenging. We evaluated the elevation uncertainty after the 3D-coregistration using 30 independent well-distributed points on stable areas with complex topography (supplementary Table 2). The elevation uncertainty, measured as the RMSE of the elevation difference in stable areas with complex topography, ranges between 30 to 40 cm (supplementary Table 3). We segmented the study area into four regions based on morphometric characteristics, to acknowledge the role of topography on elevation uncertainty. Hereby slope angle and slope aspect, influence the minimum detectable
change through time but also imprint morphodynamic characteristics (Sect. 2.). Conservative critical thresholds above the measured coregistration error and elevation uncertainty for each region were determined by best practice between 0.2 to 1 m (supplementary Table 4 and 5).

We filter the different sources of topographic changes by semi-automatic filtering, and final manual inspection using 3D visualization. The filtering processes are based on the segmentation of the DoD using a 3x3 circular kernel on a binary mask of change (1)-no change (0) defined by the critical thresholds. The size of the kernel was selected to segment an approximate connected change of a minimum of 1 m². We used descriptive statistical information from each polygon: minimum and maximum elevation change, area of change, volume of change, and mean slope before the change, to filter the polygons using the criteria described in Table 1. The slopes at the Hochvogel are mostly highly-fractured and horizontally layer, thus, rock falls preferentially follow a pseudo-cubic form. Hence, the filtering approach focuses on the identification of changes that are over-elongated in the z component in relation to their horizontal area (area/maximum elevation change <1). These types of changes are identified as “false” rockfalls. A 3D visualization supports the final visual inspection.

The 3D-coregistration process suggest a neglectable horizontal error at the pixel level, thus, the total volume uncertainty ($\delta V$) from Eq (3) is the sum of the uncertainty of each cell of volume ($\delta v$) calculated such Eq (5):

$$v = a_{pixel} DoD_{pixel} \quad (5)$$

To propagate the errors of each cell of volume, the partial derivative of Eq (5) with respect to the elevation change, which is the variable that has uncertainty, is calculated:

$$\delta v = |v'(DoD)| \delta DoD \quad (6)$$

where $\delta DoD = RMSE_{time period}$

Finally, the volume uncertainty over area A is given by Eq. (7):

$$\delta V = A \delta v \quad (7)$$
3.1.2 Frequency-magnitude curves

A frequency-magnitude curve relates the magnitude of a variable to the frequency of occurrence (Riggs, 1968). The curve is an estimate of the incremental yearly cumulative frequencies from the largest magnitude event to the smallest (Hungr et al., 2008). We included both primary and secondary rockfalls in our analysis. We acknowledge the occurrence of coalescence events, given the (multi-) yearly temporal resolution of the datasets. The frequency analysis aims to compare the activity and relative size distribution (Dussauge-Peisser et al., 2002; Benjamin et al., 2020; Hantz et al., 2021) of the different rock faces slopes that constitute the Hochvogel summit.

3.1.3 Cascading geomorphic sediment budgets

A sediment budget describes the input, transport, storage, and export of sediment in a geomorphic system. This concept provides an effective basis for representing the key components of the sediment delivery system within a catchment and for assembling the necessary data to elucidate, understand and predict catchment sediment delivery (Walling and Collins, 2008) and estimate related natural hazards. The geomorphic sediment budget (Wheaton et al., 2010) is calculated as the sum of the masked DoD values of erosion (negative change) and deposition (positive change).

We calculate the proportion of net erosion and net deposition per year (m$^3$ y$^{-1}$) based on the number of days between acquisitions, comparable to previous studies. Conversion to mass (t) is based on reported densities of limestone 2.6 t m$^{-3}$ and limestone deposits 2 t m$^{-3}$ according to (Krautblatter et al., 2012). Spatially averaged short-term wall retreat rates were calculated by dividing the total rockfall volume per year (m$^3$ y$^{-1}$) by the area over which the volumes were calculated, i.e., northern slope (253,643 m$^3$), western slope (115,098 m$^3$), southwestern slope (254,686 m$^3$), southeaster slope (165,037 m$^3$), rockface (234,329 m$^3$), upper channelized erosive debris flow channel (53,072 m$^3$), widened dispersive debris flow channel (91,241 m$^3$) and outlet (34,004 m$^3$).

3.2. Volume estimation of the 2016 multi-event

3.2.1. 3D cumulative volume

The 2016 rockfall dramatically changed the morphology of the southwestern slope of the Hochvogel. A visual comparison of images taken by Land Tirol during a helicopter flight inspection to the summit on 03.07.2015 and the UAV images acquired by the landslide group (Andreas Dietrich) at the Technical University of Munich (TUM) using a UAV DGI Phantom 4 during a monitoring survey as part of the AlpSenseBench project on 28.09.2017, revealed the pre-event topography of the southwestern slope (Figure 3). Recent developments in dense matching algorithms in combination with structure from motion (SfM) retrieve dense point clouds (Eltner and Sofia, 2020). For a more precise reconstruction of 3D geometry of the cliff fall, particularly on the vertical slopes, we calculated the volume of change using the most complete photogrammetric point clouds from an acquisition before the event, 23.09.2014, and after the event, 07.08.2017. We manually delimited the extent of the 2016 rockfall event based on the cloud-to-cloud distance algorithm in CloudCompare v2.0. The volume calculation was performed over a grid of 0.2 cm and an average height cell in CloudCompare v2.0. For visualization purposes, we reconstructed the detached surface by creating a mesh using the Poisson Surface Reconstruction plugin (Kazhdan et al., 2020) and
the two-point clouds. The approximate orientation of fractures was extracted from the photogrammetric point cloud 23.09.2014 using the CloudCompare plugin Compass (Thiele et al., 2017).

3.2.2. Multi-stage detachment analysis

For the time interval in which the 2016 failure occurred (July 9 to 11), we downloaded all available seismic data from seven surrounding broadband stations (distance to Hochvogel: 12-55 km) (supplementary table 7). By analyzing the local seismic amplitude and the corresponding spectrograms at each station, we identified all seismic events with the strongest impact at the closest station in Oberstdorf. Rock falls produce a seismic impact over all frequencies between 5 and 50 Hz (Dietze et al., 2017; Le Roy et al., 2019); in our case, we expect a clear decrease in seismic intensity with increasing distance of the stations from the Hochvogel and significant arrival time differences of up to 20 s (supplementary Fig. 3). On the contrary, earthquakes often show distinct arrivals of P and S waves, a lower frequency content, and smaller arrival time differences. Local anthropogenic noise is characterized by higher frequency contents and missing coincidence of the signal between different stations. Following these criteria, we identified all potential seismic signals originating from the rock fall series at the Hochvogel.

Despite significant variability in the scaling of $E_p$ to $E_S$ (cf. Hibert et al., 2011), Le Roy et al., 2019 determined a relation between generated seismic energy $E_S$ and the potential energy of a rock fall $E_p$ such:

$$E_s = 10^{-8} \times E_p^{1.55} \quad (11)$$

The initially failed volume can then be derived from the potential energy if we determine the fall height of the block that generated the seismic signal. We estimated the fall height of the rock fall event from the photogrammetric point cloud differences and 3D models. A simple toppling of the center of gravity towards the slope corresponds to a fall height of 50-60 m while a sliding of the failed block suggests a probable fall height of 75 to 100 m. The calculation of the seismic energy and the determination of all needed parameters mainly follows the methodology in Le Roy et al., 2019 (supplementary Sec. 2). We estimated the error of the calculations based on Monte Carlo simulations with 1000 iterations and the variability of the different stations.

4. Results

4.1 Multi-stage occurrence of the 2016 cliff fall event

The cliff fall that occurred during the summer of 2016 resulted in the detachment of 1.31 (±0.01) *10^5 m$^3$ of dolomite following a multi-stage development. The extent of the cliff detachment is indicated by the clearer color tone on the rock surface (Fig 3b.), and the detachment area was measured to be 4,777 m$^2$ using a combination of photogrammetric derived point clouds before and after the cliff fall. Prior to the cliff fall, the area was characterized by a vertical rock tower surrounded by pervasive fractures with orientation NW and pseudo-vertical dip angles that may have contributed to the multi-stage detachment by widening preexisting rock discontinuities (Figure 3a). The rock tower had a height exceeding 60 meters and was a prominent feature in the landscape. Currently, partially disconnected blocks are limited by penetrative fractures and represent areas of potential detachments. The cliff fall resulted in a significant change in the morphology of the southwest slope increasing the mean slope by 1° from 45.6° to 46.6°.
Figure 3. Picture taken by Land Tyrol before the cliff fall (03.07.2015). The yellow line indicates the cliff fall detachment area in the summer of 2016. The fracture orientations (in white) intend to exemplify approximate structure orientation and must be taken with caution due to the low point density in the exposed fracture surfaces. b) Picture taken by TUM Landslides group (Andreas Dietrich) after the cliff fall (28.09.2017). The red arrows indicates the cliff fall detachment area in the summer of 2016. c) Photogrammetric point clouds from the surveys on 23.09.2014 in black and 07.08.2017 in white. d) Mesh reconstruction of the cliff fall.

The seismic signal analysis indicates a progressive failure of the total mass in at least three to six portions within 3 days (Table 2). The biggest parts of the rock mass failed on the last day (2016.07.11) at 20:48, 21:05, and 21:07 local time. The volume estimation from the seismic energy at the closest station in Oberstdorf (OBER) results in a median volume of $1.02 \pm 0.09 \times 10^5$ m$^3$ for a fall height of 60 m. The estimated volume excludes smaller rockfalls, since the limited energy released by these events may not been recorded by the seismic stations. As a result, the seismically estimated volume may underestimate the total amount of material detached.

4.2 Summit slope erosion

Over the last decade, the Hochvogel summit has produced 1.713 (±0.04) *10⁵ m³ of sediment, corresponding to an annual production rate of 43,990 (± 1 069) t y⁻¹ when assuming a rock density of 2 600 kg m⁻³ (Krautblatter et al., 2012). Notably, 97% of this sediment can be attributed to the 2016 cliff fall at the Southwestern slope. A total of 667 erosional events, including primary and secondary rockfalls, were detected at the Hochvogel summit, with a median volume ranging between 4.6 to 9.3 m³. The minimum detectable rockfall volume ranged between 1.4 to 2.1 m³, depending on the slope orientation. The sediment production on the four slopes of the summit showed a significant disproportion. The western and southeastern slopes had the lowest rockfall frequency, while the northern slope experienced the highest rockfall activity per year (Figure 5). However, when considering the
contribution of rockfall magnitudes, debris falls dominate the northern and western slopes, while the southeaster
take proportion of boulder fall, accounting for 55% of the total contribution (Table 3).

4.3. Geomorphic sediment budget

The short-term denudation rates in the catchment prior to the cliff fall were 45 to 52 mm y⁻¹, resulting in a negative catchment sediment budget ranging -1.72 (±0.01) *10³ m³ y⁻¹ and -1.97 (±0.01) *10³ m³ y⁻¹. Following the cliff fall, the catchment’s denudation rates increased abruptly by ten times, reaching 257 mm y⁻¹. Despite the erosion of 9.74 (±0.01) *10⁴ m³ y⁻¹, the sediment delivery to the outlet was significantly reduced, resulting in a positive
The catchment sediment budget of $1.306 \pm 0.06 \times 10^4$ m$^3$ y$^{-1}$ (Figure 6). However, two years after the event, within the catchment sediment waves dominated the sediment flow to the outlet leading to a negative sediment budget of $-1.033 \pm 0.08 \times 10^4$ m$^3$ y$^{-1}$. Subsequently, a slightly positive sediment budget of $6.12 \pm 2 \times 10^2$ m$^3$ y$^{-1}$ evidenced the ongoing sediment redistribution within the catchment four years after the cliff fall, even though, the catchment denudation rates returned to pre-event levels of 44 mm y$^{-1}$. Catchment scale erosion and deposition volumes at each time interval are listed in Table 4.

4.4. Geomorphic sediment budgets across the sediment cascade

The time series of spatial distribution of differences of DSMs (Figure 7) and differentiated geomorphic sediment budgets (Figure 8) reveals the fast system response to the cliff fall. The concept of sediment continuity refers to the transfer or exchange of sediment across various parts of the hillslope system, which involves the conservation of mass among sediment inputs, stores and output (Joyce et al., 2018). Sediment storages and sinks (marked as (1), (2), (3), and (4) in Figure 7) define the boundaries between different morphodynamic components, which are characterized by slight changes in mean slope that imprints morphological controls on transport processes. Regardless of the existence of depositional landforms, sediment continuity dominates from 2010 until 2014 evidenced in negative net change at all the geomorphic system components.

An initial disruption in the sediment continuity is observed between 2014 and 2015. At the rockface, boulder and block falls occur, which detach from the sub-vertical wall and deposit at its base. Additionally, in the upper channelized erosive debris flow channel, less than $10^3\,\text{m}^3$ of recently deposited material (less than two years of residence time) are internally redistributed. However, even during this period of localized disruption, sediment redistribution continues to take place at the widened debris flow channel, which ensures sediment delivery to the outlet into the braided sediment-supercharged Jochbach river.

Following the cliff fall event, there was an immediate disruption of sediment transfer among the different regions of the system, with about 75% of the produced sediment being deposited at the upper channelized erosive debris flow channel. A total of $1.356 \pm 0.003 \times 10^5\,\text{m}^3$ of sediment were deposited over the 1.5 km length of the upper channelized erosive debris flow channel (Figure 8). Despite the positive sediment budget at the widened disperse debris flow channel, massive deposition occurred at the outlet. The formation of a terrace of almost 3 m evidence the positive net change of $2.60 \pm 0.03 \times 10^4\,\text{m}^3$. Although the stream power was strong enough to incise the terrace and prevent the formation of a dam, the outlet flood plain was filled with new debris that impacted the dynamics of the riverbed.

A dramatic inversion from deposition to erosion occurs two years after the cliff fall. Sediment waves or slugs deposited $8.14 \pm 0.04 \times 10^4\,\text{m}^3$ at the apex of the widened dispersive debris flow channel infilling the valley with 3 m of transported material which increased to almost 10 m four years after the cliff fall (supplementary Fig. 2, profile C-C'). Despite the increased sediment input due to the cliff fall, there were reversed net changes between the widened dispersive debris flow channel and outlet four years after the cliff fall (Figure 7). This suggest that the sediment transport processes had not fully recovered to pre-disturbance levels, even though, the sediment continuity within the catchment was restored one year after the initiation of the disturbance, i.e., increased sediment due to the cliff fall.
Figure 7. Time-series of spatial distribution of erosional (red) and depositional (blue) areas with black arrows as an indication of sediment continuity based on the net changes. (A) rockface (B) upper channelized debris flow channel, (C) widened dispersed debris flow channel, and (D) outlet to the Jochbach river. (1), (2), (3), and (4) mark the position of morphological blockages that promotes deposition thus attenuation in the sediment flux.

The braided sediment-supercharged Jochbach river incised the 3m terrace formed after the cliff fall by developing a single fluvial channel confined towards the north side of the alluvial plain, opposite to the pre-event river channel, located at the south of the alluvial plain. However, a braided channel characterizes the lower outlet sink.
suggesting an ongoing adjustment to the depleted sediment delivery ratio as a consequence of the cliff fall event.

Figure 8. Segregate sediment budget. a) Left axis: Bar plot for net yearly erosion and deposition volumes. Right axis: Sediment delivery ratio. b) net change as an indicator of sediment continuity. Dark grey polygons highlight the temporal stamp at which the cliffs fall took place. Lighter grey indicates the system response two and four years after the event.

5. Discussion

The scarcity of high-magnitude rockfalls limits the understanding of the physical response of mountain catchment to a sudden increased of sediment input. Digital photogrammetry and image-matching algorithms revolutionized the usage of optical sensors to study topographic changes. The recently available high-resolution temporal and spatial datasets provide a fresh look for geomorphic responses and the time lag between disturbance (increased sediment input due to cliff fall) and reaction (geomorphic response: increased sediment transport by means of debris flows) times from which typically short-term responses become a societal concern (Owens et al., 2010).

Even though the proposed 3D-coregistration workflow optimizes the DSMs extracted from consecutive nadir view large format aerial surveys for volumetric calculations in steep terrain, there are still limitations on the representation of complex topography. Thus, it requires careful thought about the validity of the measurements. Despite this, the presented results are paramount to identifying and better understanding coupling mechanisms of high-magnitude slope events at a high temporal-spatial resolution to a wide extent. The analysis of within hillslope morphodynamics and its coupling with the fluvial system exemplify the alpine catchment response to future climatic changes and landscape dynamics.

5.1. Validity of measurements

Considering the inhomogeneity of the aerial imagery, the quantitative data described above are comparable to other published results obtained by digital photogrammetry (e.g. (Kaufmann and Ladstädter, 2003; Schiefer and Gilbert, 2007; Marzolf and Poesen, 2009; Fabris and Pesci, 2009; Micheletti et al., 2015; Hilger and Beylich, 2018; Geissler et al., 2021). The authors acknowledge the limitations of aerial imagery to depict vertical surfaces and in particular negative vertical surfaces. Nevertheless, the proposed workflow resulted in consistent landscape
representations through time evidenced by topographic profiles extracted from the DSM and volume calculation of the 2016 cliff fall using all possible DSM combinations (supplementary Table 6). Additionally, the back calculation of the failed volumes from the seismic signals of regional stations (Sec. 4.1.) is in the range of the photogrammetrically determined volumes, thus supporting the results via a second methodological approach.

Even though we followed a very conservative approach, possible overestimations of the volumes are expected, particularly for the rockface where complex topography predominates. When visualizing the point clouds, it is possible to perceive the dense point cloud on the horizontal surfaces, but little to no points on vertical and pseudo-vertical surfaces for some of the datasets (e.g., 2015 dataset). Additionally, even if the vertical sides are completely depicted, the gridded component of the analysis poorly represents the vertical topography. On the other hand, the results on the northern slope (Figure 5a), often acquired under poorer illumination conditions, are prone to higher uncertainty.

The 3D-coregistration successfully mitigates spatial discrepancies between surveys and evaluate the relative correspondence of x, y and z in the range of the spatial resolution. A remaining challenge lies in the assessment of the ratio to noise. The segmentation approach was designed to filter topographic changes at each landscape compartment having into account the stated data limitations. Lower uncertainty is achieved at the widened disperse debris flow channel and outlet due to the smoother surfaces favorable for the photogrammetric reconstruction. In spite of the discussed drawbacks, the presented workflow aims for an efficient and fast calculation of volumetric changes foreseen by the usage of aerial imagery for the early detection of future hazardous areas over wide extents or multiple basins in the context of a fast-changing climate and landscape.

The complementary analysis of seismic datasets elucidates the multi-stage detachment of possibly 6 events with exact timing (3 block falls followed by 3 cliff falls). The latest three seismic events show clear evidence of a source located close to the Hochvogel rock failure, while the first three events are harder to constrain due to their smaller amplitude. Nevertheless, these also show the same intensity-distance decay and signal arrival time patterns and can therefore be considered. Additionally, the respective sub-event’s percentage of the total volume is very similar for the stations OBER, RETA, DAVA, MOTA and A307A (supplementary Fig 6, Table 13). The stations PART and ZUGS must be excluded due to their bad signal-to-noise ratio in the relevant frequency band. For a fall height of 60 m, the volume estimated from the seismic signal at OBER is 20 % lower than that estimated photogrammetrically, but the seismic method neglects detachments that are too small to be recorded by the distant broadband sensor, detachments from the same source area but not belonging to the 3-day event, and energy that gets lost due to fragmentation of the failed mass. The other stations further away underestimate the volume due to stronger signal damping, distortion and worse coupling compared to the closest station OBER.

5.2. Rockfall activity as landscape re-shaping mechanism

Bi-annual rockwall retreat rates for the five years prior to the cliff fall, which averaged 6.5 mm y⁻¹, slightly exceed short-term (< 10 years) rock wall retreats for limestones (Draebing et al., 2022) with a maximum retreat of 9.5 mm y⁻¹ between 2012 and 2014. However, they are consistent with previous funding of enhanced rockfall activity for carbonate cliffs (Krautblatter et al., 2012). The (multi-)annual temporal intervals used in this study are unlikely
to be sensible to precursory deformations, however, patterns of erosion across the rockface slope in the years prior to the cliff fall might reveal signs of alert. Close-up observations of the area of the cliff failure evidence block fall and boulder fall at the base of the failure with volumes of $1.71 \pm 0.005 \times 10^3$ m$^3$ and $1.05 \pm 0.003 \times 10^3$ m$^3$ in 2012-2014 and $2.91 \pm 0.01 \times 10^2$ m$^3$ in 2014-2015 reflecting a main deformation area (Kromer et al., 2018). The cliff fall resulted in the rockwall retreat of 390 mm y$^{-1}$ between 2015 and 2017 increasing the mean steepness of the rockface by 1%. The consecutive detachment of at least 6 block falls over 3 days follows an increase in magnitude from $10^3$ m$^3$ to $10^4$ m$^3$ previously suggested by other studies (e.g., (Kromer et al., 2017; Rosser et al., 2007; Abellán et al., 2009; Benjamin et al., 2020), and paramount for the understanding of cascading risk in alpine regions.

The triggering mechanism for this multi-stage event is hard to constrain and needs further research. Among common triggering factors are precipitation and cyclic thermal stressing (Dietze et al., 2017b). The multi-stage event is preceded by a phase of several dry and hot summer days. In the night before the first block fall, minor amounts of rain have been recorded, but the three final cliff falls on July 11th are preceded by more intense rainfall of up to 1.4 mm/10 min with a time lag of less than 1 h (Figure 4). Also, all recorded events happened during the morning and evening hours where a strong thermal gradient might have an influence on the stressing of the rock mass (Dietze et al., 2017b, 2021).

5.3. Mechanism of sediment delivery continuity.

The fast system reaction time of 1 to 2 years is evidenced by the massive inversion from a depositional regimen (2015-2017) to an erosive regime (2017-2018) which mobilizes sediment through the system with short temporal residence times in the sediment cascading. The material detached by the cliff fall entrained older deposits at the upper channelized erosive debris channel, which we traced back to 1945 by the visual inspection of historical aerial imagery, increasing the amount of transported sediment downslope. Despite the remobilization of older deposits, more than 10 m of recently deposited sediment remains at the upper channelized debris channel which serves as a source for future debris flows and possibly extends the system relaxation times according to recent numerical simulations (Heckmann and Schwanghart, 2013) as the main mechanism of sediment transport in the studied catchment is debris flows.

Observations in the Swiss Alps suggest increased debris flow activity after a sudden sediment input from a rock avalanche or large landslides (Baer et al., 2017; Frank et al., 2019). Debris flows are a common process in the studied catchment before the cliff fall event, but spatially confined to the widened dispersed debris flow channel where sediment availability is high. On the contrary, increased sediment remobilization is clearly triggered at the upper channelized erosive debris flow channel shortly after the cliff fall, acting as an efficient process to restore sediment continuity. A systematic study of six catchments in Switzerland affected by landslides that generated new sediment deposits suggests a considerable increase in debris-flow frequency for one to eight years following the landslide with no clear rain-fall-related apparent trigger (Frank et al., 2019). For the studied catchment, relaxation times exceed the observation time thus we plan to continue with the monitoring.
Debris flows are normally triggered by short-duration and high-intensity rainstorms. A study in the Zermatt Valley (Swiss Alps) concluded that the occurrence of debris flows would depend on short-term changes in triggering rainfall rather than on long-term climatic changes (Bollschweiler and Stoffel, 2010), thus high-resolution temporal and spatial analysis are paramount to better assess the cascading natural hazard of rock slope failures. A review of nine debris flow monitored sites around the world suggests that hourly rainfall intensities between 5 and 15 mm/h are sufficient to trigger debris flows (Hürlimann et al., 2019). Particularly, at Illgraben basin, Switzerland, sediment transport was reported at rainfall intensity of 2.2 mm/10 min while debris flows were initiated in a range between 3.8 to 9.6 mm/10 min. Precipitation stations at the vicinity of the Hochvogel (Hinterhornbach/AUS - Station ID:6290) display increased mean seasonal (April-November) rainfall intensity over the last decade for events with a duration less than 4 hours (Figure 9). The frequency of rainstorms exceeding 10mm/h, 3.8 mm/10min, and 9.6mm/10min are higher for the time interval when the cliff fall occurred (2015-2017: T4). The marked depositional regimen obscures the possible within slope impact of rainstorm increased frequency on debris flow activity, nonetheless, it might be reflected in the Jochbach stream power to erode the almost 3-meter terrace that incipiently blocked the outlet, preventing the blockade of the river system. Even though the massive erosive regimen subsequent to the cliff fall is characterized by rainfall frequencies similar to those pre-cliff falls (6 to 7 days with more than 10mm/h), the increased mean rainstorm intensity might play a role in the fast response times of the system.

Debris flow inferred trajectories evidence short travel distances (<500 m) promoting the sediment transfer within the slope morphodynamic components but rarely reaching the outlet. Empirical relationships express the runout distance of debris flows in terms of topography and volume of mass (Rickenmann, 2005; Hürlimann et al., 2008). Sediment storages and sinks (marked as (1), (2), (3), and (4) in Figure 7) spatially correspond to slope changes that decrease flow energy thus debris flow travel distances. Regardless of the temporal lumping, multiple debris flow events were visually identified on the orthophotos based on differences in color and granulometry, but a complete separation remains challenging.
The formation of at least three levels of terraces with predominance course sediment after the cliff fall evidence the fluvial response to the decreased sediment flux at the outlet. The channelization of the river channel increases the stream erosion power thus possible lateral erosion downstream. Hence, the effects of the cliff fall event are seen not only in the higher erosive regimen at the hillslope but also in the morphodynamic adjustment of the Jochbach river. A remaining key question deals with the conditions, mechanism, and timing required to reestablish the pre-event morphodynamics. Currently, sediment storages resulting from geomorphic processes such as high magnitude slope instability and paraglacial and glacier sediment storages, are often landforms decoupled from the present-day geomorphic process. In the context of increased rainfall activity, the couple/reconnection of those systems and their magnitude and persistence will become key parameters for the management and development of alpine communities.

6. Conclusions

The combination of seismic information and temporal series of high-resolution wide-extent true-orthophotos and DSMs provide an accurate assessment of the temporal and special evolution of rockfalls and the subsequent massive sediment redistribution. A multi-stage detachment of more than 150,000 m$^3$ in the Hochvogel summit, northern calcareous alps (DE/AT), was responsible for the production of 97% of the total sediment eroded between 2010 and 2020. We identified a significant disproportion in the contribution of rockfall magnitudes for the four slopes that constitute the summit with predominance of debris falls for the northern and western slopes, while the southeastern slope has a large proportion of boulder fall, thus, increased hazard. The seismic analysis revealed consecutive blockfalls with increased magnitude from $10^3$ to $10^4$ m$^3$ in a time period of 3 days during the summer of 2016, strongly increasing the rockfall risk in the area. Therefore, these results enhance the need of monitoring alpine slopes to better assess possible increased rockfall activity that leads to safety concerns. We suggest the integration of wide-extent photogrammetric datasets in future alpine early warning system.

Conclusively, the time series of spatial distribution of differences of DSM and differentiated geomorphic sediment budgets contributes to a better understanding of the complex nature and feedback of cascading processes. The alpine catchment quickly responded to the cliff fall within 0 to 4 years, resulting in massive sediment redistribution within the catchment and reduction in sediment delivery to the outlet. This, in turn, modified the fluvial response at the catchment outlet. Sediment continuity/transfer within the hillslope was rapidly recovered two years following the cliff fall. The recovered sediment flux mobilizes sediment along the geomorphic subsystems; however, the sediment waves were inefficient in delivering sediment to the catchment outlet. Relaxation times are expected beyond 10 years given that the latest observations (2020) still revealed perturbation in the system and the deposition of up to 10 m of sediment at the upper channelized debris flow which serves as a sediment input for future debris flows.

The results present the first step towards a better understanding, prediction, and early warning of alpine natural hazards under expected extreme climatic conditions. The ongoing interdisciplinary AlpSenseRely project aims to integrate high-resolution multi-scale, multi-temporal remote sensing data (Large format digital aerial...
photogrammetry and UAV) for an accurate quantification of temporal and spatial changes in alpine geomorphic systems.

Data Availability

The original aerial imagery is available at Landesamt für Digitalisierung, Breitband und Vermessung (LDBV), Bundesamt für Eich- und Vermessungswesen (BEV), and 3D RealityMaps GmbH upon request. Precipitation data is freely available at the Geoportal from the Deutscher Wetterdienst (https://dwd-geoportal.de/). Seismic data is freely available at reported sources in the supplementary material.

Author contributions

N.B. wrote the manuscript with contributions from J.L.
N.B. developed the topographic time series workflow, analyzed the data and compiled results
J.L. calculated seismic volumes
J.J. created DSM and orthophotos from digital aerial imagery
M.D. verified and advised on the implementation of the seismic volume’s calculation
U.M, F.S and M.K provided guidance and funding
All authors checked and revised the text and the figures of the manuscript and contributed to the ideas developed in this study.

Competing interests

An author is a member of the editorial board of the journal Earth Surface Dynamics. The peer-review process was guided by an independent editor, and the authors have also no other competing interest to declare.

Acknowledgments

We thank the Land Tyrol and particularly Mag. Thomas Figl for the open sharing of the pictures taken during the aerial inspection of the Hochvogel before the cliff fall which helped us to better picture the magnitude of the detachment, the Landslide research group at TUM for the fieldwork support during the UAV acquisitions, particularly to Andreas Dietrich for the UAV acquisition on 2017. We are indebted to Peter Mederer for his contribution to the early developments of the 3D-coregistration python workflow during his internship at 3D RealityMaps GmbH, and the colleagues at 3D RealityMaps GmbH, Munich for the outstanding support with the implementation of the 3D models used for visualization, visual interpretation, and figures.

Financial support

This research was funded by the Bavarian Ministry of Environment and Consumer Protection in the framework of the project “AlpSenseRely” Alpine remote sensing of climate-induced natural hazards: Reliability of multi-method hazard prediction in a changing climate (Teilprojekt TUSO1UFS-77318). Initial datasets were acquired during the project ‘AlpSenseBench’ Alpine remote sensing of climate-induced natural hazards funded by the Bavarian Ministry of Economic Affairs, Regional Development and Energy (grant no. 45-6723a/15/2).
