21 Rock slope failure occurred during deglaciation

22

23 **Abstract**

24 Rock slope failures in the English Lake District have been associated with deglacial processes
25 after the Last Glacial Maximum, but controls and timing of failures remain poorly known. A
26 cirque headwall failure was investigated to determine failure mechanisms and timing. The
27 translated wedge of rock is thin and lies on a steep failure plane, yet the friable strata were
28 not disrupted by downslope movement. Fault lines and a failure surface, defining the
29 wedge, were used as input to a numerical model of rock wedge stability. Various failure
30 scenarios indicated that the slope was unstable and would have failed catastrophically, if not
31 supported by glacial ice in the base of the cirque. The amount of ice required to buttress the
32 slope is insubstantial, indicating likely failure during thinning of the cirque glacier. We
33 propose that, as the ice thinned, the wedge was lowered slowly down the cirque headwall
34 gradually exposing the failure plane. A cosmogenic ^{10}Be surface exposure age of 18.0 ± 1.2
35 ka from the outer surface of the wedge indicates Late Devensian de-icing of the back wall of
36 the cirque, with a second exposure age from the upper portion of the failure plane yielding
37 12.0 ± 0.8 ka. The 18.0 ± 1.2 ka date is consistent with a small buttressing ice mass being
38 present in the cirque at the time of regional deglaciation. The exposure age of 12.0 ± 0.8 ka
39 represents a minimum age, as the highly-fractured surface of the failure plane has
40 experienced post-failure mass-wasting. Considering the chronology, it appears unlikely that
41 the cirque was re-occupied by a substantial ice mass during the Younger Dryas Stadial.

46

47 **1 Introduction**

48 There are at least 84 known or suspected rock slope failures (RSFs) in the Lake District of NW
49 England that have been associated with the Late Devensian glaciation (Marine Isotope Stage
50 2: Wilson *et al.*, 2004; Jarman and Wilson, 2015a; Wilson & Jarman, 2022). Such RSFs often
51 are termed ‘paraglacial’ as they “are part of, or influenced by, the transition from glacial
52 conditions to non-glacial conditions” (Ballantyne, 2002; McColl, 2012). However, the
53 relationship between glaciation, deglaciation, and the occurrence of RSFs remains far from
54 resolved. This paper provides a contribution to further understanding of the topic. While a

55 few highly modified landforms have been identified tentatively as RSFs and related to time
56 periods before the Last Glacial Maximum (LGM; c., 26.5 ka BP to 19 ka BP, Clark et al., 2009)
57 (Jarman and Wilson, 2015b), the majority of Lake District RSFs have been associated with the
58 end of the Dimlington Stadial (see 'Glacial Context') and the final down-wasting of the Late
59 Devensian ice sheet within NW England. At that time, potential RSFs could have been fully
60 supported or partially supported by residual ice masses in topographic lows. Alternatively,
61 some RSFs could have occurred (Wilson, 2005) following the Scottish Readvance (c., 19.3 –
62 18.2 ka; Chiverrell *et al.*, 2018) and the Younger Dryas Stadial (12.9 – 11.2 ka; Rasmussen *et*
63 *al.*, 2006). However, only one disintegrated RSF has been dated. In contrast, those that
64 represent steep-slope deformation, or arrested slides, are of unknown age (Jarman and
65 Wilson, 2015b). An arrested hillslope failure occurs when the slipped mass is not evacuated
66 from the source area (Jarman, 2005), but is retained on the slope of the footwall. The role of
67 glacial ice in buttressing rock slopes, and thereby preventing failure (Whalley *et al.*, 1983;
68 Holm *et al.*, 2004; Cossart *et al.*, 2008; Le Roux *et al.*, 2009; Allen *et al.*, 2010; Hilger *et al.*,
69 2018), is largely speculative (Ballantyne, 2002; Jarman and Wilson, 2015b; Cody *et al.*, 2018;
70 Hartmeyer *et al.*, 2020) and controversial (McColl *et al.*, 2010), as are the mechanics of slope
71 failure in situations where ice-support progressively diminishes (McColl and Davies, 2013;
72 Klimeš *et al.*, 2021; Cave and Ballantyne, 2016). The latter two generic issues are the
73 primary focus of this paper.

74

75 Glacial erosion can steepen cirque headwalls to the extent that faulted and/or fractured-
76 rock slopes become unstable (Sass, 2005; Moore *et al.*, 2009), if not ice-supported. In
77 addition, the way slopes fail can provide insight to whether ice was present during the slope
78 failure. If ice-buttressed failures can be dated, then RSFs provide a source of information on
79 the timing of the final ice retreat. Here, an arrested (*sensu* Jarman, 2005) translational RSF is
80 described, dated, and the likely controls on the failure are defined and modelled. We test
81 the hypothesis that *a steep, faulted, and unstable rock slope has experienced buttressing by*
82 *glacial ice*. Our study area, which has not been previously identified as a RSF site, is within
83 Great Coum (54.3923° N, 2.6057° W), a small cirque within the southern Shap Fells to the
84 west of the Lune gorge (Fig. 1). A neighbouring cirque is named Little Coum. The Lune gorge
85 (south of Tebay; Fig. 2) separates the southerly extension of the Shap Fells to the west from
86 the Howgill Fells to the east. The site details and glacial context are described below.

88

89 Fig. 1: Oblique aerial view, looking southwestward, into Great Coum (Google Earth image).
90 The RSF is arrowed. The green grassy tread of the RSF (just above the arrow) is in sunlight
91 below the cliffed headwall (in shadow). The breadth of the RSF is between 125m and 180m.
92 Little Coum is just out of view to the right. Base image © Google Earth 2014. Scale bar
93 applies to the middle distance.

 99 respect to generalized Dimlington (ES1), (ST2) and (LT6) ice movements (after Livingstone *et*
 100 *al.*, 2010; 2012). Labels (1), (2) and (3) indicate the temporal sequence of ice movements.
 101 Locations referred to in the main text are also shown. Inset shows the location of the study
 102 area in the context of the British Isles. Base NEXTMap digital elevation topography has a 5 m
 103 resolution.

104

105 2 Glacial Context

106 The last period of extensive glaciation in northern Britain occurred during the Dimlington
 107 Stadial of the Late Devensian substage of the Pleistocene (~28-15 ka; Rose, 1985; Scourse *et*
 108 *al.*, 2009; Chiverrell and Thomas, 2010; Davies *et al.*, 2019), equivalent to Stadials 3 and 2 of
 109 the North Greenland Ice Core Project (NGRIP) chronology (Lowe *et al.*, 2008) and the Marine
 110 Isotope Stage 2 (Ehlers and Gibbard, 2013). During the LGM, the Lune gorge and surrounds
 111 were covered by several hundred metres of ice. The Lune gorge is ice-sculpted, having a

112 parabolic bedrock cross-section with truncated valley-side spurs along both the west and the
113 east margins. Great Coum and Little Coum, on the western side of the gorge, are the only
114 recognized cirques in the Lune gorge. These two Lunedale cirques should not be confused
115 with two cirques with the same names in Dentdale (Barr *et al.*, 2017). The two conjoined
116 embayments were considered by Marr and Fearnside (1909) to be a single cirque, but
117 recently have been recorded as separate cirques (Barr *et al.*, 2017; Clark *et al.*, 2018).
118 Devensian till banks and moraine (entrenched by the River Lune) fill much of the Lune gorge
119 floor and till also occurs in most tributary valleys (Aveline *et al.*, 1888; Marr and Fearnside,
120 1909; BGS, undated; 2008 a and b).

121

122 **2.1 Complexity of Devensian glaciation around Great Coum**

123

124 The context in which the RSF occurred is relevant to the interpretation of the importance of
125 potential ice buttressing and is referred to within the Discussion. Here we provide the
126 setting. Little is known of the glacial history of the Lune gorge area (Carling *et al.*, 2023).
127 Nevertheless, prior findings, in the main, have been incorporated in the BRITICE maps of the
128 area (Stokes *et al.*, 2018). A complex interplay occurred in the vicinity of the Lune gorge
129 between several upland ice dispersal centres, primarily: the Scottish, Lake District and
130 Howgill ice masses, during the period of maximum ice cover ~ 26–22 ka. All three ice masses
131 interacted in the north whilst the latter two ice masses dominated to the south. After the
132 LGM, as the ice sheets down-wasted and ice flows became increasingly valley-confined, ice
133 emanating from the two cirques would have flowed northwards (Carling *et al.*, 2023).

134

135 The complexity of regional ice flow was simplified by Livingstone *et al.* (2010; 2012) by using
136 codes to refer to different ice streams (Fig. 2) that occurred in various locations and at
137 differing times; the relevant codes are as follows. In the ES1 phase, early LGM, northern ice
138 penetrated a short distance into the Lune gorge (Harkness, 1870; Goodchild, 1875; 1889;
139 Marr and Fearnside, 1909; Hollingworth, 1931; Moulson, 1966; Letzer, 1978) as far as
140 Carlingill and Great Coum (Fig. 2) but no further. However, Davies *et al.* (2019)
141 demonstrated that, close to the LGM, (ST2 phase; *sensu* Livingstone *et al.*, 2010) and during
142 the LT6 phase (Chiverrell *et al.*, 2018), ice flowed northwards from the Lune gorge (Fig. 2).
143 On the northern flank of the Howgill Fells, any ST2/LT6 ice flow would have been to the

144 north and east from the Howgill ice dome (Fig. 2) such that the higher summits of the
145 Howgill Fells were not overrun by ice from further north (Gunson, 1966; Stone *et al.*, 2010).
146 Rather, the Howgill Fells hosted its own local ice dispersal centre. Prior work failed to
147 determine whether northern ice entered the two Lunedale cirques. Consistent northerly
148 down-wasting ice-flow was established (Hollinsworth, 1931; Rose and Letzer, 1977) from 19
149 ka (Davies *et al.*, 2019) with surrounding areas north and south of the Lune gorge being ice
150 free by ~ 19.2 to 16.6 ka (see Carling *et al.*, 2023, for a review of regional dates). These dates
151 are broadly consistent with other dates for deglaciation of the central Lake District more
152 widely (Wilson and Lord, 2014) and are indicative of a general ~ 2–3 kyr window for the
153 timing of final Dimlington ice down-wasting within the Lune gorge when the back wall of the
154 Great Coum cirque could have become ice-free. We return to this point in sections 3 and
155 6.2.

156

157 Given that ice may have reoccupied upland terrain in Lake District during the Younger Dryas
158 (Brown *et al.*, 2013; Bickerdike *et al.*, 2018), in principle, an ice mass may also have occurred
159 in the general vicinity of the Lunedale cirques at this time. However, no evidence for
160 Younger Dryas ice in the Lune gorge has been reported.

161

162 **3 Geological Setting of the cirques**

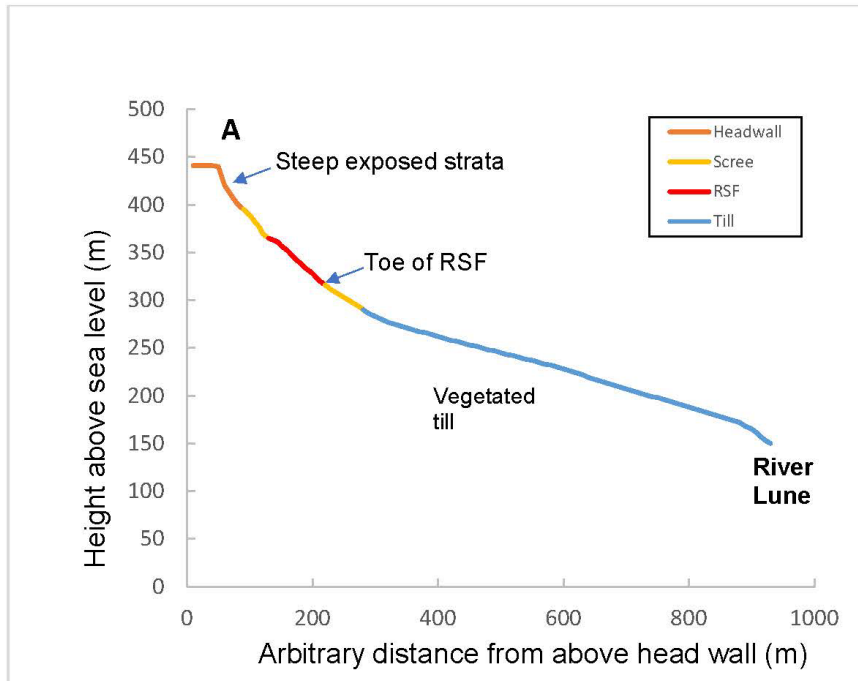

163

164 The bedrock in the cirques comprises the marine Silurian Coniston Group (Soper, 1999;
165 Soper, 2006), which here consists of fine-grained, blue-grey, sandy siltstone (greywacke) and
166 sandstones in beds from < 1 m to ~ 3 m thick. Most of the thicker beds crop-out within the
167 headwalls of the cirques. The thicker sandstone beds are more competent with fewer
168 fractures, whilst thinner fissile siltstone beds exhibit cleavage and are heavily fractured.
169 Vertical joints are frequent with spacings of a few metres, together with evidence of small-
170 scale bedding deformation and small-scale faulting. Moseley (1968; 1972) considered the
171 considerable complexity of the regional structure and noted folding, steep discontinuous
172 local faulting, joint patterns and the presence of slickenside surfaces in the southern Shap
173 Fells. In the Methods and the Results, this complexity is not considered, as the detail is not
174 pertinent to our study. None-the-less, reference is made to local steep faults, slickenside
175 surfaces and friability where these are relevant, as the rock structure in the vicinity of the

176 RSF is critical in assessment of slope stability (Bonilla-Sierra *et al.*, 2015; Stead and Wolter,
177 2015). The apparent dips of the local beds range from 0° to 30°, SW into the headwall of
178 Great Coum. However, the apparent 8° plunge of the stratal sequence is towards the NW,
179 such that the true dip is to the WSW with a NW strike (BGS, 2008 a and b). Infrequent, but
180 distinctive 10– 40 mm-thick pale bands of siltstone occur (*e.g.*, Taylor *et al.*, 1971, p. 26) in
181 some of the thicker beds, which extend discontinuously over distances of several
182 decametres parallel to the primary bedding. These siltstone bands are significant in that
183 examples (here termed marker horizons) occur in the headwall strata which correlate with
184 similar siltstone bands in the strata of the RSF.

185
186 Great Coum is orientated NE, Little Coum is orientated NNE. The orientations of the cirques
187 are influenced by the strike of local paired anticlines (Marr and Fearnside, 1909; BGS,
188 2008a), and the low-insolation aspects of both sites would have encouraged Devensian snow
189 and ice accumulation and preservation. Great Coum exhibits no distinct lip (*i.e.*, no
190 overdeepening), the ground falls steadily from around 237 m (height above mean sea level,
191 m asl) to the River Lune below (Fig. 3A). Above 300 m the ground rises more steeply to
192 rocky head walls locally near 80° at 360–440 m, giving a height range of around 225 m. Little
193 Coum exhibits a slight lip at around 262 m altitude. Above 400 m the ground rises more
194 steeply to near 80° rocky head walls at 400–440 m, and the ridge crest at 480 m gives a
195 height range of around 220 m (Fig. 3B). First to second-order minor streamlets occupy the
196 lower parts of Great Coum, and Little Coum is drained by the third-order stream, Burnes Gill.

197
198
199
200

201

202 Figure 3: Long profiles along centre of cirque: (A) Great Coum; transect from 54.389978 N;
 203 2.606625 W to 54.396675 N; 2.598278 W; (B) Little Coum; transect from 54.393789 N;
 204 2.615992 W to 54.400117 N; 2.602208 W. Exposed bedrock is indicated in the headwall and
 205 in the RSF. Data extracted from Google Earth.

206

207 The British Geological Survey (BGS,2008b) map identifies till on the lower slopes of Great
208 Coum and the BGS borehole database contains the records of 24 shallow boreholes ranged
209 along the axis of the Lune gorge over 1.25 km immediately below Great Coum. These
210 borehole logs show that the slopes just below the cirque consist of a thin soil above a 2.5 m
211 thickness of Devensian diamicton, overlying the Silurian Coniston Grit. In Little Coum,
212 hummocky till infills the cirque below 400 m (BGS, 2008b); at lower altitudes, a flatter thin
213 diamicton drapes much of the basin, including a poorly defined curvilinear moraine that
214 terminates at the lip (Fig. 3B). It is not possible to calculate an equilibrium line altitude (ELA)
215 with any certainty based on the upper limit to highest lateral limits to the curvilinear
216 moraine (Porter, 2001), but 300 m asl is a reasonable estimate. Bedrock exposures along
217 Burnes Gill and augering during the current project indicate that this moraine is no more
218 than 6 m thick. The curvilinear moraine has a distinctive, sharp, outer margin along the
219 rocky rounded ridge that separates the two cirques. Within Little Coum, three faint
220 diamicton-covered (possibly ice-recessional) benches occur on the northern slope of the
221 cirque. Thus, although Great Coum lacks any preserved indication of ice retreat, such
222 indicators may exist within Little Coum.

223
224 All the deposits described above are significant. In the first instance, substantial till in the
225 Lune gorge below Great Coum has been related to northern ice penetrating the gorge
226 around the LGM (Carling, *et al.*, 2023). At that time, the whole region was covered by a thick
227 ice sheet (Merritt *et al.*, 2019). However, as down-wasting led to increasing topographic
228 control and valley glaciers predominated, there was likely to be ice flow out of the cirques
229 prior to the near-complete ice retreat that left the diamicton-covered benches. We envisage
230 that around the LGM, thick overriding ice in the vicinity of Great Coum was dictated by
231 regional ice gradients largely independent of the local topography (Carling *et al.*, 2023).
232 Post-LGM, ice-discharge from the cirque initially would have remained high but any
233 buttressing effect on the headwall would decline as the ice thinned.

234
235 The RSF occurred in Great Coum. The most southerly backwall section of the cirque consists
236 of a steep rocky headwall facing N, whilst to the west a further steep rocky headwall faces
237 NE; a steep grassy slope occurs between these two outcrops. The RSF caused headwall
238 retreat in the vicinity of the present grassy slope, leaving the intact steep rocky sections of

239 the backwall to either side, but the failure also extends below the north-facing headwall (Fig.
240 1). Indistinct, small RSFs also occur to the east and west, which are not considered further.
241 Little Coum also contains a steep rocky headwall, but with no evidence of slope failures. The
242 mass of the RSF in Great Coum appears to have descended as a translational near-intact
243 block. Although a near-vertical fracture occurs in the right-hand side of the slipped mass
244 (Fig. 4), in other respects the undisturbed strata within the block readily correlate with strata
245 in the headwall above.

246

247 **4 Materials and Methods**

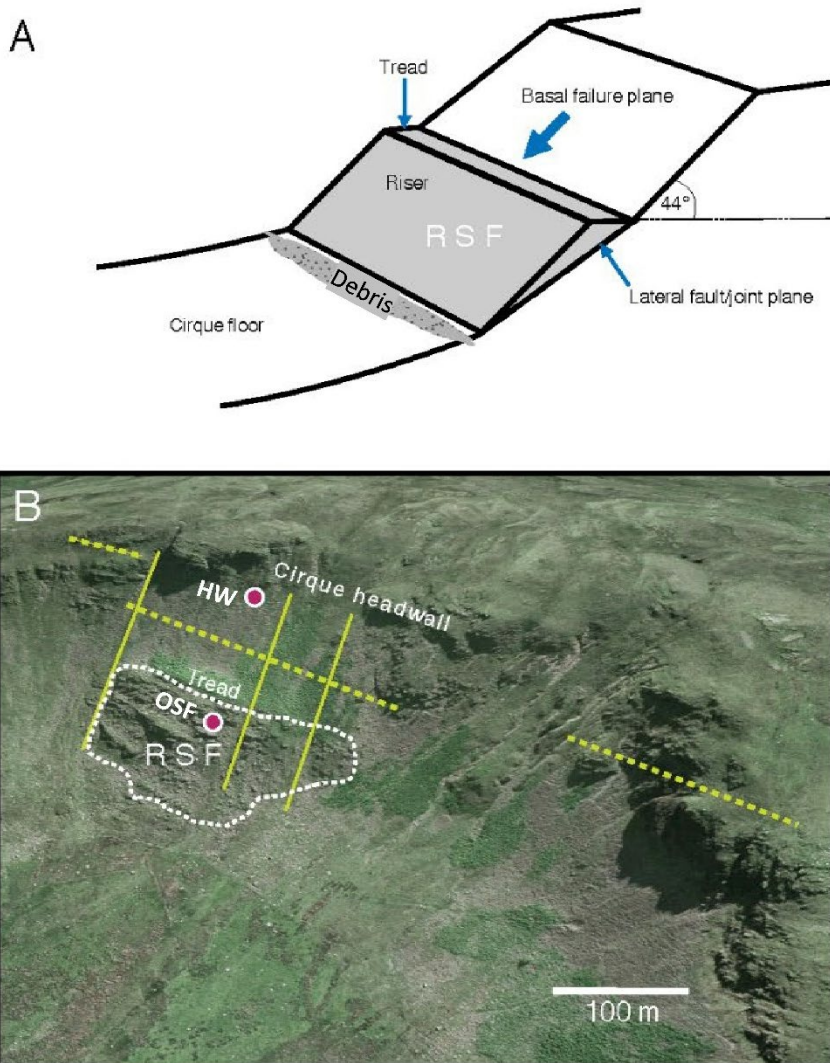

248 **4.1 Mapping landscape features**

249 The British Geological Survey (BGS, 2008a) records several lineaments in the vicinity of
250 Great Coum that represent small faults or large block joints. Google Earth satellite images
251 (2004, 2009, 2011 and 2014) were used to visually identify these linear landscape features
252 as well as others of relevance (not recorded by the BGS). Lineaments trace topographic
253 discontinuities, stratigraphic offsets, vegetation differences and slickensides, and these
254 forms were checked in the field. Smaller-scale linear features consist of the silt banding
255 marker beds, and numerous minor joints (the latter not mapped). The various points of
256 interest were recorded as single point data in the field using a hand-held Garmin global
257 positioning system (GPS). The strikes of bedding and the direction of faults were recorded
258 as compass bearings whilst the dips of bedding and faults were recorded relative to a
259 horizontal plane using a digital clinometer.

260

261 Single point data are precise in planview whereas linear features, between two or more
262 well-determined points, provide the general trend of features such as gullies and faults.
263 GPS coordinates also were used to map the extent of the slumped block. Due to the
264 inaccuracy of hand-held GPS-derived altitudes, the planview GPS coordinates were used to
265 determine the altitude of each point from Google Earth, and these were taken as definitive
266 (error < 4%) after cross-checking with Ordnance Survey 1:50,000 maps (Harley, 1975).
267 Selected topographic profiles were also developed from Google Earth imagery by reading *x*,
268 *y* and *z* coordinates at 10m horizontal spacings along selected planview lines running from
269 the top of the headwall of each cirque, across the free face and the slope below. Finally, a
270 systematic search was made within both cirques for Shap granite or limestone erratics to

271 check whether northern ice had entered the cirques. Outcrops of both these lithologies
272 occur 10km to the north.

273
274
275

276 Figure 4: A) Schematic cartoon of a simple wedge failure to indicate the terminology used
277 within the main text. B) Annotated view of Great Coum (compare Fig. 1). The fault-aligned
278 rock slope failure plane (c), above and behind the RSF, is intersected by three major steep
279 fault lines, the outer two of which (X,Y) define the RSF model. The locations of samples (HW
280 and OSF) collected for exposure dating are shown by circled symbols. Base image © Google
281 Earth 2014. Scale bar applies to the middle distance.

282

283 We refer the reader to Figure 4A for an explanation of the RSF terminology used here,
284 although the failure planes bounding the wedge are omitted for clarity. The modern

285 headwall of the cirque locally constitutes the main exposed scarp of the failure plane behind
286 the translational wedge of the RSF. The outer face of the wedge is termed the 'riser' and the
287 near-horizontal head of the wedge is termed the 'tread'.

288

289 **4.2 Rock sampling for surface exposure dating**

290 Terrestrial cosmogenic radionuclides, such as ^{10}Be , are produced and accumulate in minerals
291 within a few metres of Earth's surface due to their exposure to secondary cosmic rays and
292 are lost via erosion and radionuclide decay (Lal, 1991). In our case, two free rock surfaces
293 are recognised (Fig. 4): the riser, being the outer surface of the RSF, and the tread, which
294 forms the top surface of the slipped mass. We set out to determine when the RSF riser was
295 first exposed to cosmic rays as ice receded from the cirque. For reasons of economy, we
296 collected one sample from the riser to compare the exposure age with the timing of
297 regional deglaciation. A ~15 kg intact block of bedrock (sample OSF) was collected from the
298 outer 10 cm-thick surface of the riser (Fig. 4B); a prominent thick undisturbed stratum close
299 to the top of the RSF mass, which was ice?-smoothed (Fig. S3). Our sampling strategy was
300 restricted by the ease of access and by the nature of the bedrock surfaces. The smooth
301 bedrock surface of the riser we sampled suggests minimal loss of rock mass due to surface
302 fragmentation or spalling since the RSF occurred. A second 15 kg bedrock block (sample
303 HW) was collected from the failure plane of the transverse fault line (Fig. S3) just below the
304 cirque headwall (Fig. 4B) with an aim to determine the timing of the failure. The sampled
305 bedrock failure plane was observed to be densely fractured, suggesting some loss of
306 material from the surface since its exposure. Surface erosion affects the abundance of
307 cosmogenic nuclides and the estimated exposure age; an issue we address in the Discussion
308 (and Supplementary Materials). Samples were cut from *in situ* bedrock surfaces using a
309 powered rock saw, their altitude, bearing, tilt, and topographic shielding were recorded.
310 Topographic shielding is significant for both samples; details are given in Fig. S1
311 (Supplementary Materials).

312

313 Our approach entails three important assumptions about the last glaciation. First, we
314 assume that the cirque headwall experienced at least 2 m of bedrock glacial erosion, which
315 removed the nuclide inventory produced during preceding ice-free periods; and second, that
316 ice burial depth at the position of the OSF sample was at least 20 m and therefore sufficient

317 to effectively halt nuclide production and third, that this cover persisted until failure. These
 318 assumptions mean that sample OSF began accumulating ^{10}Be only from the time that the
 319 down-wasting ice exposed the surface to cosmic rays. In contrast, sample HW remained
 320 deeply shielded (> 5 m) within the cirque headwall until the RSF exposed the failure plane
 321 to cosmic rays.

322

323 4.3 Cosmogenic nuclide analysis

324 The two bedrock samples were prepared for cosmogenic ^{10}Be analysis at the Aarhus
 325 University Cosmogenic Nuclide Laboratory, Aarhus, Denmark, following standard laboratory
 326 procedures as described in Andersen *et al.* (2020). The $^{10}\text{Be}/^9\text{Be}$ ratios were analysed at the
 327 accelerator mass spectrometer at AARAMS, Aarhus, Denmark. A summary of the
 328 cosmogenic nuclide analyses is given in Table 1 and further details are found within
 329 Supplementary Materials.

330

331 **Table 1.** Summary of the cosmogenic nuclide analyses. ^{10}Be concentrations in quartz
 332 normalized to the “07KNSTD” standardization by Nishiizumi *et al.* (2007), and exposure ages
 333 calculated using LSDn scaling (Lifton *et al.*, 2014) and global calibration dataset (Borchers *et al.*,
 334 2016) via <http://hess.ess.washington.edu> v3.0.2. The analytical uncertainty includes AMS
 335 error on measured ratios incl. standard uncertainty of 1.1. %, Be carrier concentration, and
 336 processing blank propagation (<1.2 %). The total uncertainty also includes production scaling
 337 and calibration uncertainties. Rock density was assumed as 2.7 g cm^3 .

340 4.4 Rock slope failure modelling

341 The RSF was modelled using *Swedge* version 6.0 (2018), a specialised rock-slope stability
 342 software package, which can analyse a five-sided block (pentahedron) as a translational
 343 wedge-failure—whereby a rock mass slides along a persistent basal plane of failure
 344 bounded on each side by a fault or joint plane (Hoek and Bray, 1981; Rocscience Inc., 2018).
 345 Either, or both, laterally bounding faults can act as additional slide planes, depending on

346 the geometry of the problem (Fig. 4A). In our case, two surfaces are not confined by
347 neighbouring bedrock: the outer surface of the RSF, the riser, and the top surface of the
348 slipped mass, the tread (Fig. 4). As well as varying the geometry of the failure and the
349 roughness of the failure planes, *Swedge* has options to consider the influence of: (i) a
350 tension crack at the back of the failure (not shown in Fig. 4A); (ii) water in the failure planes;
351 and (iii) the effect of any restraining normal stress that may counter the propensity to slide.
352 In engineering applications, restraining normal stress is conventionally realized using steel
353 rock bolts, or stone and concrete structures applied to the face of the riser, especially near
354 the toe. In contrast, here the issue is whether an ice mass in the cirque can buttress a slope
355 that is otherwise unstable, as is explored below. In glaciated mountain environments,
356 permafrost (and ice segregation) can penetrate bedrock to a depth of several metres
357 (Andersen *et al.*, 2015). Ice-filled fissures tend to be stable at temperatures below -2°C ,
358 which gives rise to the concept of 'ice-cemented' fractures (Ballantyne, 2018).
359 Consequently, the possibility that permafrost stabilized the RSF failure planes is considered
360 in section 5.3.

361
362 *Swedge* was implemented adopting the Mohr-Coulomb failure criterion (*e.g.*, Jaeger and
363 Cook, 1979) pertaining to the limit equilibrium stability of a three-dimensional rock mass
364 using field data (Table 2). Further details are provided in the Supplementary Materials and
365 within the Results. Stability is defined in terms of a factor of safety (F) where $F > 1$ indicates
366 a stable slope and $F < 1$, a failed slope. $F = 1$ represents a critical state. In general terms,
367 the factor of safety is defined as the ratio of the forces resisting motion to the driving forces.
368 Driving forces include the mass of the wedge accelerated through gravity and water
369 pressure; the latter applied normal to each wetted plane. Resisting forces arise from the
370 shear strength of the wedge sliding planes. Any ice load on the wedge is considered only as
371 a weight force contribution to the normal stress. Thus, active support due to the load of any
372 glacial ice (or firn) on the riser is included in the analysis as in Equation 1; where T_n is the
373 normal component and T_s is the shear component of the force applied to the riser. Active
374 support is assumed to act in such a manner as to decrease the driving force in the factor of
375 safety calculation:

376

377
$$F = \frac{\text{resisting force} + T_n \tan \phi}{\text{driving force} - T_s} \quad (1)$$

378

379 Unless parameter values are known exactly, a single deterministic RSF model cannot be
 380 resolved using Equation 1. In view of the uncertainty, in our field case, related to the exact
 381 relationship between fault plane alignments and dips, a variety of potential failure

382

Table 2. Parameter values for RSF as determined in the field and as explored within the three model scenarios.

383

384 scenarios must be considered. To narrow the number of models, we used preliminary trials
 385 of our field-derived parameter values as input, varying both strength and slope and
 386 geometry parameters. Then, consideration of a range of fault plane dips allowed us to
 387 exclude geometrically impossible configurations and those geometries that did not
 388 resemble the geometry of the RSF. In this manner, we devised three model scenarios that
 389 represent the RSF in terms of shape and mass. More than 10,000 simulations were
 390 performed for each scenario, varying parameter values systematically (typically ± 10%) to
 391 isolate the most probable model for each case. The uncertainty and probability analyses
 392 were conducted using the dedicated approaches built into the *Swedge* platform, selecting
 393 normal distributions to describe the possible range of parameter values; for example, ± 10°
 394 of dips measured in the field. Finally, the buttressing effect of any glacial ice against the
 395 potential RSF is considered by applying an external load evenly across the area of the riser
 396 to counter any propensity for failure.

397

398 **5.0 Results**

399 **5.1 The rock slope failure**

400 The positions of the pale silt marker beds, located in the headwall and within the RSF,
 401 indicate the RSF has moved downslope by about 110 m (*H*) vertically and up to 192m (*L*)

402 horizontally. The width of the tread is about 15 m; the breadth of the slide is between 125
403 and 180 m and the vertical extent of the main slipped intact mass along the outer face (the
404 riser) is about 70 m. Assuming the displaced block is a triangular wedge thinning towards
405 the toe (Fig. 4), the volume of the intact slip is $\sim 68,250 \text{ m}^3$. Below the main slip there is an
406 area of disintegrated rubble which could increase the length of the riser, potentially adding \sim
407 3 % ($\sim 2300 \text{ m}^3$) to our volume estimate (Table S1 Supplementary Materials). The value of
408 H/L is sometimes considered a mobility ratio, whereby large values of L for relatively small
409 vertical displacement (H) can indicate unimpeded rapid descent and a long runout. Given
410 the volume of the RSF, values of $H/L > 0.6$, as here, indicate no excessive runout (Whittall *et*
411 *al.*, 2017; Table S1 Supplementary Materials).

412
413 The slope of the riser of the RSF mass is currently $\sim 30^\circ$, that is, is similar to the static angle
414 of repose. This angle may suggest slow downslope movement rather than rapid failure,
415 which tends to produce slope angles much less than the angle of repose. In addition, there
416 was no evidence of hard-rock end-point control at the toe of the slumping block to impede
417 its descent although the toe has rotated outwards (Fig. 4A). The slope of the riser today is
418 less than the slope of the failure plane (44°), which suggests a portion of the intact wedge
419 may be lying above debris derived by over-running some of the disintegrated thin toe of the
420 wedge (Fig. 4A). It is significant that the stratigraphic layers within the main RSF wedge
421 remain intact, with no evident down-slope dilation and little deformation or fracture across
422 the face of the slipped mass. The apparent plunge of the strata (8 to 10° towards the north),
423 *i.e.*, across the face of the RSF, indicates that the western margin of the slip may have
424 descended slightly further downslope than the eastern margin, as the headwall strata plunge
425 6° to 8° in the same direction. The outer face (Fig. 4B) of the RSF has undergone no evident
426 modification.

427
428
429 As shown in Figure 4B, a distinct fault (BGS, 2008b), normal to the cliff face occurs to the
430 east of the RSF at location X, with undisturbed stratigraphy in the headwall either side.
431 Slickenside structures occur along the basal failure plane (c) that continues across the cliff to
432 the north-west. The fault X is aligned with the south-eastern margin of the RSF (as seen in
433 Fig. 4B), whilst a further fault is evident as a distinct fissure in the RSF, with another fault to

434 the north-west (Y). The easterly dip of these three faults could not be determined accurately
435 although they are steep, consistent with the findings of Moseley (1968; 1972) for the
436 Coniston group in the region (see section 5.3). The basal failure plane defined the back of
437 the RSF, whilst the lateral limits to the RSF model were defined by the two marginal fault
438 lines (X,Y).

439

440 **5.2 Estimation of original angle of the outer slope of the rock surface before failure**

441 To apply the *Swedge* model it is necessary to know the angle of the outer slope of the rock
442 face before failure. From the geometry of the residual RSF mass, with respect to the
443 observed failure plane (Fig. 4B), the RSF can be considered as a translational, plane failure of
444 a pentahedron wedge. Taking a side view, the geometry is triangular (Fig. 4B), so it is
445 possible to calculate the minimum slope of the outer rock face prior to slope failure by
446 repositioning the failed block further up the failure plane. The angle of the failure plane is
447 taken as equal to that of the minimum angle of the slickenside surfaces, 44° , with a bearing
448 of between 6 and 11° . The riser (outer face) of the RSF is 70 m in length and the tread width
449 is 15 m; both lengths could have been slightly larger before fracturing occurred along the
450 basal failure plane and at the toe of the RSF (Fig. 4A). Given the small degree of uncertainty
451 with regard to the configuration of the slope before failure, the length of the failure plane
452 (necessarily longer than the riser of the RSF) was varied systematically at the same time as
453 varying the length of the riser between the measured length of 70 m and 90 m; the latter
454 value includes the small area of disintegrated toe (Fig. 4A). The tread width also is varied
455 between the measured breadth of 15 m and a 'limit' of 20 m to allow for potential
456 disintegration along the failure plane at the back of the tread. Repositioning the RSF upslope
457 in this manner, the slope of the outer face could have been no lower than 53° and if the
458 angle of the failure plane is increased beyond $\sim 54^\circ$, the resulting lengths of the failure plane
459 and outer face become incompatible with field observations.

460

461 **5.3 The Swedge model of the rock slope failure without ice buttressing**

462 Initial application of the Swedge Model used the field data shown in Table 2. We did not
463 model the stability of the wedge in its present position because the basal friction properties
464 are unknown; whether the toe of the RSF rests on rubble derived from the failure plane, or a

465 bedrock surface cannot be determined. Given that the present angle of the riser is 30° and
466 the basal failure plane is at an angle of 44° it is assumed that the wedge is now stable ($F \gg 1$).

467

468 The slope of the riser utilized is that applicable to the rock mass before failure, as
469 determined in the preceding section. The width of the tread and the lateral extent (breadth)
470 of the failed mass are determined from the field data. The summit of the cirque is fairly flat
471 so an outward slope of 1° below horizontal is used for the tread; the model is not sensitive
472 to this parameter. The angle of the failure plane is the minimum value for the slickensides to
473 the south-east of the RSF (which were not disturbed by the slope failure). The model allows
474 for defining the additional effective roughness angle (r) on the failure planes by applying a
475 'waviness' parameter (w) that was determined from the range of recorded slickenside
476 values, following Miller (1988). Other parameters were defined from the field data. It was
477 noted above that the dip of the two lateral delimiting faults could not be determined in the
478 field. However, as local faults tend to be steep (Moseley, 1968; 1972) the model was
479 implemented with the values shown in Table 2 and then varied systematically as reported
480 below. Given the geometry of the problem only three modelling scenarios are necessary to
481 explore the uncertainty in a controlled setting:

482

483 *Model 1: the RSF slides over the basal plane and against Fault Y.* The model aligns
484 the compass orientation of the basal failure plane with the orientation of the riser
485 outer face, which assumes a simple downslope slide. The orientation of Faults X and
486 Y with respect to north are as determined from field data. The X and Y fault dips are
487 steep and both dip to the west. Dips and riser length were varied slightly to optimize
488 the failed volume of the RSF to match the field estimate. In this manner, the model is
489 not consistent with the eastern side of the slip having progressed less far down the
490 failure surface than the western side. Factor of Safety: 0.83.

491

492 *Model 2: the RSF slides along the basal plane and against Fault X.* The model aligns
493 the bearing of the failure plane with the bearing of the slickensides to the east of the
494 RSF, as these define the bearing of the basal failure plane that differs from the
495 bearing of the riser face by 13° . The bearings of Faults X and Y are as determined
496 from field data. The fault dips are steep and both dip to the east. Dips and riser

497 length were varied slightly to optimize the failed volume of the RSF to match the field
498 estimate. In this manner the model is consistent with the eastern side of the slip
499 having progressed less far down the failure surface than the western side. Factor of
500 Safety: 0.86.

501
502 *Model 3: explores the addition of a tension crack to the back of the RSF.* It is not
503 known if a tension crack developed in the actual rock mass before failure, and the
504 properties of the tension crack are determined by the other model attribute values.
505 Including a tension crack, the western side of the RSF extends further down slope
506 than the eastern side, with the lower edge of the model block having a plunge of ~
507 10°, equal to the plunge of the RSF strata in the field. The bearing of the basal failure
508 plane is varied between 6° and 14°. Fault dips are steep, 90° and 62° to the east.
509 Dips and riser length were varied slightly to optimize the failed volume of the RSF to
510 match the field estimate. Given this scenario the RSF slides over the basal plane and
511 against Fault Y. Factor of Safety: 0.52 to 0.83 depending on basal plane bearing.

512
513 Given that there is unavoidable parameter uncertainty, none of the above models is an exact
514 representation of the RSF, although Model 3 is the closest match (Fig. 5). Yet, it is evident
515 that preserving the dip of the basal plane and solving to retain the mass of the failure, any
516 reasonable combination of data leads to a model of the failed block that resembles that seen
517 in nature and, in each case, the Factor of Safety is less than unity. A sensitivity analysis
518 showed that, for reasonable ranges of parameter values (typically $\pm 10^\circ$; outwith those listed
519 in Table 2), usually the geometry of the potential failure did not match that observed and so
520 could be dismissed. Specifically, in the 10,000 simulations of each model, model parameters
521 could be varied (*e.g.*, by $\pm 5^\circ$ in the case of angles), retaining a probability of slope failure of
522 96 %. In most cases the factor of safety was between 0.74 and 0.94, and higher factors of
523 safety could not be produced without significant distortion the geometry of the RSF. In a
524 very few cases of parameter combinations (4 %), a marginal factor of safety of between 1.07
525 and 1.22 is achieved. In the latter cases, wetting between 20 and 30 % of the fault planes
526 surface areas, due to percolation of meltwater affecting the water pressure, caused the
527 slope to fail.

528

529

530 Figure 5: Illustration of Swedge 6.0 Model 3: (A) before failure, and (B) during failure. The
 531 basal failure plane orientation is 14° such that the base of the RSF is plunging 10° to the
 532 north (right).
 533

534 As a final consideration it should be noted that in deglaciating mountain regions, RSFs have
 535 been related to permafrost degradation and consequent destabilization of ice-filled fractures
 536 within the rock mass (Gruber *et al.*, 2004; Gruber and Haeberli, 2007). In the RSF failure
 537 model described above, freezing of the failure planes can be considered by simply increasing
 538 the friction factors, which can result in the block remaining intact despite the absence of
 539 glacial ice buttressing. However, we expect that frozen failure planes did not persist long
 540 after glacial down-wasting. Hydrostatic pressure in the failure planes would have been high,
 541 and percolation more generally lubricates failure planes (Hasler *et al.*, 2011). In addition,
 542 permafrost support for the RSF does not explain the intact stratification of the RSF, as
 543 permafrost degradation would have resulted in a rapid RSF. Consequently, permafrost was
 544 not considered in any quantitative sense.

545

546 **5.4 The Swedge model of the rock slope failure with ice buttressing**

547 For the range of simulations reported in the previous section, $F < 1$ in all the 94 % of
 548 physically plausible cases and wetting failure planes resulted in a 100 % failure in all 30,000
 549 cases. Hence, the role of ice buttressing of the riser must be considered, as this is the most
 550 likely explanation for slope stabilization. There is no information on the dynamic behaviour

551 of ice within the cirque. Consequently, selecting Model 3 above, three contrasting scenarios
552 can be envisaged that might stabilize the slope: (a) ice can be a static load variably
553 distributed around the centroid (Fig. 6A) of the riser; (b) ice can be dynamic, moving towards
554 the riser such that the stress is variably distributed around the centroid of the riser (Fig. 6B);
555 (c) ice can be dynamic, moving away from the riser such that a bergschrund opens between
556 the ice and the slope and the stress is distributed below the centroid of the riser. Broadly
557 consistent results also are found considering Models 1 and 2 (not reported herein).

558

559 Firstly, considering scenario (a), the weight of an ice load is calculated, and the stress is
560 applied evenly across the area of the riser normal (*i.e.*, 90°) to the slope until it is stabilized
561 (for which condition: $F = 1.0065$; Fig. 6A). Subsequently, considering scenario (ii), the
562 analysis is repeated to ascertain the optimal direction to apply force that minimizes the ice
563 load. In scenario ii, the ice load can be reduced from that in (a) if the force is directed into
564 the slope and slightly upwards by 13° above the horizontal such that for $F = 1.0485$ (Fig. 6B).
565 In scenario (a), application of 40,659 tonnes of ice is required for a stable slope, which is
566 equivalent to $48,987 \text{ m}^3$, based on a debris-free low ice-density of 830 kg m^{-3} (Colgan and
567 Arenson, 2013). In scenario (b), application of 24,325 tonnes of ice ($29,307 \text{ m}^3$) is required
568 for a stable slope. For scenario (c), with a tension crack, the slope will remain stable as long
569 as the total stress applied to the slope is the same as for scenarios (a) or (b). In this study we
570 do not explore in detail how the ice mass and force direction might be distributed across the
571 riser to maintain slope stability as there are multiple permutations. Nonetheless, if the
572 cirque had been filled with ice to the top of the riser, around $166,000 \text{ m}^3$ of ice would be
573 required to fill the volume immediately adjacent to the potential RSF (Fig. 7), which is not
574 compatible with the small ice masses in scenarios (a) and (b) that are required to maintain
575 slope stability. Considering Fig. 7, it is important to recognize that, in any permutation of
576 potential RSF geometry (Table 2), the ice cover required to maintain slope stability is
577 typically less than 29 % (and possible as low as 17 %) of the volume to the top of the riser.
578 This result indicates that the slope would have remained stable as long as there was a
579 sufficiently small degree of ice buttressing due to ice in the cirque contributing a stress
580 normal to the face of the riser—which further implies failure occurred during final
581 deglaciation of the cirque. Note that, although the presence of sufficient ice on the riser
582 alone maintains rock mass stability, it is unlikely that this condition would pertain without

583 ice present immediately adjacent to the rock wedge. So, Figure 7 shows cirque ice beyond
584 the unstable slope, but only conceptually.

585

586

587

588 Figure 6: Illustration of the force application required to stabilize the potential RSF: (A) With
589 the force (point and arrow) applied 90° to the slope, the ice load required to stabilize the
590 slope (i.e., $F = 1.0055$) is 40,967 tonnes; (B) With the force (point and arrow) applied at the
591 optimum angle (13° above horizontal) the ice load required to stabilize the slope (i.e., $F =$
592 1.0485) is 28,253 tonnes.

593

594 Figure 7: Cartoon depicting the concept of ice buttressing of the potential RSF. The RSF
 595 wedge defines the unstable portion of the slope before the rock slope failure. Points A, B, C
 596 and D define a potential pentahedral volume that, if filled by ice, would cover the complete
 597 face of the riser. A smaller 'pentahedral' volume (purple), with the upper ice surface
 598 outlined by a heavy black line, shows that only a small percentage of the potential
 599 pentahedral ice volume is required to be ice-filled to provide buttressing sufficient to
 600 prevent slope failure. The inner edge of this pentahedral is show as irregular to indicate
 601 potential variable ice loading across the riser. Percentages were obtained from the ice
 602 volumes required to buttress the slope. Additional ice might be present in the cirque
 603 outside of the defined volume, but this ice does not contribute to the stabilizing load
 604 directly applied to the riser.

605

606 5.5 Exposure ages from the rock slope failure

607 In both cirques, tills are composed of local lithologies exclusively, and a search for northern-
 608 derived erratics confirmed their absence. The absence of erratic lithologies indicates that
 609 the cirques were probably finally eroded by locally generated ice masses after the LGM. At
 610 the time of the LGM, it is thought that the locations of the cirques were overridden by an ice
 611 sheet from the north moving into the northern end of the Lune gorge (Carling *et al.*, 2023).
 612 Under such thick ice conditions, the back wall of the cirque would have been stable as the
 613 volume of ice was much greater than that required for slope stability—shown by either ice-
 614 loading Model 3 scenario a or b. After the LGM, the ice volume in the cirque would
 615 decrease such that ice-loading also decreased such that the RSF slowly descended as the

616 loading fell below a critical F-value to sustain the slope. It is this lowering of the RSF that we
617 have attempted to date with cosmogenic nuclides.

618
619 The surface exposure age of 18.0 ± 1.2 ka (sample OSF) postdates the timing of maximum ice
620 cover and is consistent with the timing of deglaciation within the broader region (Carling *et*
621 *al.*, 2023) as is considered in the Discussion. As was noted in section 4.2, the outer face of
622 the RSF (the riser) constitutes a smooth surface of intact, undeformed strata, so
623 concordance of the surface exposure age and regional dates is to be expected. Exposure of
624 the RSF riser (sample OSF) predates significantly the exposure age of 12.0 ± 0.8 ka (sample
625 HW) calculated for the RSF basal plane, suggesting a relationship between debuttressing of
626 the riser face and the gradual downward slip of the RSF. The younger age for sample HW is
627 expected, due to the basal failure plane being progressively exposed after the upper portion
628 of the RSF (where sample OSF occurs) was clear of ice cover and the RSF began to move
629 downslope. Also of significance is the fact that the basal failure plane was disrupted by the
630 failure and is friable, as was noted in section 4.2. The loss of only one or two small blocks
631 from the location sampled on the failure plane at any time after failure should result in an
632 age younger than that of the outer face of the RSF (see Supplementary material). Results of
633 the cosmogenic nuclide analyses are summarised in Table 1.

634

635

636 **6.0 Discussion**

637 **6.1 Modelling the RSF dynamics**

638 The *Swedge* model was applied to the RSF assuming the original slope of the rock face was
639 53° , with a slide plane angle of 44° and no ice buttressing. The steeper slickenside surfaces
640 observed in the field directly above the RSF could indicate a steeper failure plane than that
641 used in the model, but these values were not used as they may represent strata disturbed by
642 the RSF. In any case, an increase in the failure plane angle, or the initial angle of the rock
643 face, both increase the propensity for failure. The waviness number calculated from field
644 data and applied in the model is low, which increases the propensity for failure. Preliminary
645 trials showed that to stabilize unstable model slopes would require the use of unrealistically
646 large waviness numbers (Miller, 1988) and so the waviness number was not varied in
647 sensitivity analyses. Thus, our results obtained with the *Swedge* model are conservative but

648 show that the rock face was consistently unstable before failure. The sensitivity analyses
649 accounted for parameter uncertainty and demonstrated that, in most cases, failure would
650 have occurred due to gravity alone. In those few cases where the slope was modelled as
651 marginally stable, moderate water lubrication of the failure surfaces (typically 30% of
652 surfaces) induced slope failure, but the addition of a modest amount of buttressing ice
653 ensured the slope remained stable. As there is no rock obstacle at the toe of the RSF to
654 impede descent, it is reasonable to assume that the slip occurred slowly as the ice decayed.
655 The need for buttressing of the slope to prevent rapid failure indicates that ice support was
656 important (Hilger *et al.*, 2018). Thus, our hypothesis '*a steep, faulted, and unstable rock*
657 *slope has experienced buttressing by glacial ice*' as proposed in the Introduction is
658 corroborated here.

659
660 As the amount of Model 3 scenario (a) ice (static load normal to the face) in the cirque
661 decreases, the level of the ice against the riser will fall towards the toe. Thus, the focal point
662 of the force applied to the slope by the ice cover migrates down the riser. As long as the
663 stabilizing load and the direction of the applied force remain sufficient as ice retreats, the
664 detached block will remain stable. However, the load within the cirque is unlikely to be
665 maintained as the ice elevation falls. The applied force also is variable through time and
666 across the riser as ice primarily deforms by internal flow (Hutter, 1983) such that, if any
667 additional pressure were exerted by residual ice adjacent within the Lune gorge, then the ice
668 mass within the cirque would respond accordingly. In particular, the uniaxial compressive
669 strength of ice is low and decreases as ice temperature increases, as will be the case during
670 deglaciation. Although in our model we do not consider the shear stresses associated with
671 the ice in a quantitative sense, brittle fracture of the thin, buttressing ice mass might
672 ultimately occur owing to the constant pressure associated with the mass of the RSF (Bovis,
673 1982; McColl and Davies, 2013). The presence of a tension crack will redistribute ice load
674 and induce ice segregation (frost-cracking) in the rock (Sanders *et al.*, 2012) close to the toe
675 of the rock mass, further reducing the competency. So as the factor of safety falls to close to
676 $F = 1$, the detached block will slowly move downwards. In the final stages of deglaciation,
677 low-density firn ($\sim 400\text{--}830 \text{ kg m}^{-3}$) will replace glacier ice ($\sim 830\text{--}917 \text{ kg m}^{-3}$) offering less
678 support to the RSF.

679

680 The RSF failure probably was controlled by distinct intersecting small-scale faults, as has
681 been modelled herein. Within the general area of Great Coum there appears to be two sets
682 of frequent lineaments, one trending to N to NW and the other NE, that intersect to define
683 bedrock blocks. Despite this propensity, the other steep headwalls in these two cirques
684 show no evidence of large-scale instability, although the basal fault plane of the RSF extends
685 (Fig. 4) behind the more western steep buttress in Great Coum, indicating that this slope is
686 also potentially unstable. One fault (BGS, 2008b) and several other lineaments occur roughly
687 normal to this alignment which, in conjunction, might delimit a potential wedge failure on
688 this western buttress. In the specific case modelled, slope failure is highly site-specific
689 depending, in the main, on fault alignments. Steepening of the cirque headwall via glacial
690 erosion may have altered the disposition of the rock mass load, increasing tensile stresses
691 along the fault planes, and promoting the RSF (Ballantyne, 2002). In this respect, the failed
692 slope was pre-conditioned (*sensu* McColl and Davies, 2013) to fail. However, the modelling
693 suggests that unloading likely played a role in controlling the timing of failure and the rate of
694 landslide displacement once initiated. Unloading may simply allow the unsupported
695 preconditioned block to fail, but the stress release accompanying unloading usually is
696 propagated along the fault network resulting in a reduction of internal locking stresses (*i.e.*,
697 the waviness number; Wyrwoll, 1977; Ballantyne, 2002). Other preparatory factors also
698 come into play as the ice load was removed, such as lubrication of the failure planes by
699 meltwater and weathering of the fault planes in general, moving the block closer to $F = 1$.

700

701 **6.2 Timing of the RSF**

702 Although there is only one terrestrial cosmogenic date for the riser of the RSF, the surface
703 exposure dating of 18ka (sample OSF) is compatible with the RSF movement during final
704 deglaciation around 19.2 to 16.6 ka (see Carling *et al.*, 2023, for a review of regional dates).
705 We interpret the much younger exposure age (~ 12 ka) on the fault plane (sample HW) as
706 the result of postglacial weathering and erosion of the fractured failure plane. In contrast,
707 much of the surface of the riser is relatively intact. Exposure dating necessarily only yields a
708 minimum-limiting age of exposure, except in cases where primary structures (*e.g.*, glacial
709 striations or slickensides) testify to negligible surface erosion. We observed some
710 slickensides locally preserved on the fault plane, but some degree of surface erosion is also
711 indicated by a scattering of talus and a shattered basal failure plane. We provide an estimate

712 of the magnitude of surface erosion assuming a range of plausible erosion rates in Fig. S2,
713 Supplementary Materials wherein the limitations of having only two cosmogenic samples is
714 addressed.

715
716 We note that the locally derived till and absence of northern derived erratics in the cirques
717 suggests that northern ES1 ice did not enter the cirques, despite the presence of abundant
718 (northern) Shap granite erratics in Borrowdale, Roundthwaite valley and Bretherdale just to
719 the north (Carling *et al.*, 2023). Thus, buttressing of the slope by ice moving into the cirque
720 from the north can be ruled out. We suggest that the two cirques probably fed valley
721 glaciers associated with diminishing plateau icefields after the LGM (Carling *et al.*, 2023), and
722 their final form evolved during deglaciation. The Devensian termination is thought to be a
723 4–5 kyr period of ice decay just prior to the Last Glacial-Interglacial Transition at ~ 14.7–11.5
724 ka (Stone *et al.*, 2010). During deglaciation, there was unlikely to be sufficient ice in the
725 adjacent Lune gorge to bolster the cirque ice mass.

726
727 Regarding slope failures in cirques, Cave and Ballantyne (2016) and Klimeš *et al.* (2021)
728 noted that the role of glacial ice support in cirque back wall stability is conditioned by the
729 associated time scales considered. For example, Klimeš *et al.* (2021) reported high factors of
730 safety (> 1.95) for potential RSFs beneath glacial ice during the LGM, which is assumed to be
731 the case during full glacial conditions. Ballantyne *et al.* (2014) demonstrated that, following
732 the LGM, the timing of several dated RSFs is not consistent with the probable timing of
733 glacial debuttressing, reporting ages that correspond to deglaciation and well after. In
734 contrast, at Great Coum, the surface exposure age of 18.0 ± 1.2 ka is consistent with regional
735 estimates of the timing of deglaciation (see Carling *et al.*, 2023), as was noted above.
736 However, the apparent delay in final exposure of the fault plane, sometime before 12.0 ± 0.8
737 ka, indicates that a range of exposure ages might be associated with arrested RSFs; indeed,
738 some post-glacial dates may be associated with isostatic controls on slope failure (Ballantyne
739 *et al.*, 2014).

740

741 **6.3 An ice advance during the Younger Dryas?**

742 An important remaining issue is whether Great Coum could have supported a glacier during
743 the Younger Dryas Stadial. Although the Lake District was essentially ice-free by ~ 14.7 ka,

744 Younger Dryas cooling led to a subset of cirques in northern Britain refilling briefly (Evans,
745 1997). Sissons (1980) argued that many central Lake District cirques were re-occupied by ice
746 during the Younger Dryas, and subsequent studies (reviewed by Brown *et al.*, 2011) indicate
747 the presence of cirque glaciers in the central Lake District. However, the lowest Lake District
748 cirque floors are around 320 m asl (Temple, 1965), whereas the basal lip of Little Coum lies
749 at 262 m asl. In this context, Manley (1961) argued that cirques in the Howgill Fells lack
750 evidence for reoccupation during the Younger Dryas because they are too low. Norris and
751 Evans (2017) suggested the ELA in the western Pennines was 580 m asl during the Younger
752 Dryas with the lowest estimate placing the altitude at 445 m asl (Wilson and Clark, 1995).
753 Similarly, in the eastern Lake District, immediately to the north-west of Great Coum, the ELA
754 has been estimated at 400–600 m with 400 m being regarded as distinctly marginal (Wilson
755 and Clark, 1998). Glacial ice only descended to altitudes below 400 m asl where small outlet
756 glaciers were fed from plateau icefields (McDougall, 2013), the extents of which remain
757 controversial (Bickerdike *et al.*, 2018). In this respect, Harvey (1997) noted that there was
758 no evidence of ice readvance in the west facing Carlingill, neighbouring Great Coum.

759
760 As the top of the headwall of Great Coum is at 468 m asl, with no extensive plateau above, it
761 seems unlikely that snow supply was sufficient to maintain a Younger Dryas cirque glacier.
762 Others have also noted that Howgill cirques are too low to support Younger Dryas ice but
763 have suggested that the ‘fresh’ appearance of moraines in some Howgill and western
764 Pennine cirques indicate that Younger Dryas ice was maintained locally by extensive snow-
765 blow (Gunson, 1966; Gunson and Mitchell, 1991; Mitchell, 1996). If correct, this would
766 reduce the ELA locally to as low as 311 m asl (Mitchell, 1996). Mitchell’s estimate of ELA is
767 similar to the best estimate for Little Coum (300 m asl), and it is noted by several authorities
768 (Manley, 1961; Temple, 1965; Mitchell, 1996) that the dominant wind direction during the
769 Younger Dryas was from the W and SW, associated with cyclonic disturbances.
770 Nevertheless, we are not convinced by this argument. The extensive SW-facing slopes of
771 Grayrigg Forest and Grayrigg Pike are below the Younger Dryas ELA, so it is unlikely that
772 sufficient blown-snow could have been supplied to support glacial ice within the Great and
773 Little Coums. Our exposure age of 18.0 ± 1.2 ka (sample OSF) denoting ice-free conditions
774 on the outer face of the RSF suggests the cessation of glacial erosion at Great Coum.

775

776 **7.0 Conclusions**

777 We have demonstrated that a RSF in the headwall of a cirque in the Lune gorge occurred as
778 a slow downslope movement of an intact rock mass due to the presence of a supporting
779 glacial ice mass buttressing the failed slope. The estimated RSF timing corresponds with
780 regional deglaciation occurring by at least 18.0 ± 1.2 ka.

781
782 Although the case study reported herein supports the role of ice buttressing as a process
783 which may explain arrested RSFs, the vagaries of rock structure from one location to
784 another, coupled with the spatially variable role of isostatic uplift and local meltwater
785 climate (Cave and Ballantyne, 2016) provide strong site-specific controls on the nature and
786 timing of RSFs. Further modelling of RSFs should elucidate the range of conditions
787 associated with incipient failure whilst additional exposure ages for rock surfaces should
788 assist in constraining the timing during which processes such as glacial debuttressing
789 applied.

790

791 **Code availability**

792 *Swedge 6.0* is available from Rocscience Inc., Toronto (www.rocscience.com) for purchase or
793 as a licenced educational package upon application.

794 **Supplement Link**

795 *Note to reviewer: A supplement accompanies this manuscript*

796 **Author Contribution**

797 PAC devised the project and conducted the fieldwork and the *Swedge 6.0* simulations. TS
798 assisted in fieldwork. PAC and JDJ wrote the manuscript. JLA and MFK conducted the
799 cosmogenic nuclide analysis. All authors contributed to the final presentation.

800 **Competing interests**

801 The authors declare that they have no conflict of interest.

802 **Acknowledgements**

803 Teng Su was supported by the State Scholarship Fund of the China Scholarship Council,
804 including a study visit hosted by the Lancaster Environment Centre, Lancaster University.
805 Rocscience Inc., Toronto is thanked for supplying *Swedge 6.0* as an educational package.
806 Wishart Mitchell kindly provided a copy of the Gunson (1966) thesis. Mike Cavanagh and
807 the Horned Beef Company are thanked for access permissions to collect rock samples in the

808 cirque. Sam McColl is thanked for commentary on an early version of the manuscript which
809 contributed to the final presentation. The reviewers, David Jarman and Tim Davies, are
810 thanked for their detailed commentaries on the submission.

811
